**ABSTRACT**—Cyclotosaurus naraserluki, sp. nov., is a new Late Triassic capitosaurid amphibian from lacustrine deposits in the Fleming Fjord Formation of the Jameson Land Basin in Greenland. It is based on a fairly complete and well-preserved skull associated with two vertebral intercentra. Previously reported as Cyclotosaurus cf. posthumus, C. naraserluki is unique among cyclotosaurs for having the postorbitals embaying the supratemporals posteromedially. The anterior palatal vacuity presents an autapomorphic complete subdivision by a wide medial premaxillary-vomerine bony connection. The paraphosphenoid projects between the pterygoids and the exoccipitals, preventing a suture between the two, a primitive condition shared with Rhinesuchidae, Eryosuchus, and Kupferzella. Within Cyclotosaurus, the Greenlandic skull has a distinctive combination of circular choanae (shared with C. ebrachensis, C. posthumus, and C. robustus) and a convex posteromedical margin of the tabulars (also present in C. ebrachensis and C. intermedius). A phylogenetic analysis indicates that C. naraserluki is the sister taxon of the middle Norian C. mordax from southern Germany, with which it shares a pair of premaxillary foramina. Cyclotosaurus is one of the most successful and diverse genera of Late Triassic temnospondyls, with at least eight species reported from middle Carnian to late Norian. Cyclotosaurus naraserluki is the largest amphibian ever reported from Greenland and one of the Late Triassic vertebrates with the highest northern paleolatitude currently known.

**INTRODUCTION**

Late Triassic lake deposits of Norian–early Rhaetian age of the Fleming Fjord Formation are very well exposed along the margin of the Jameson Land Basin in East Greenland (Clemmensen, 1980a, 1980b) (Fig. 1A-B). These lacustrine deposits have yielded a rich and diverse vertebrate fauna, including most of the main vertebrate groups known from the Late Triassic (Jenkins et al., 1994, 1997, 2001; Clemmensen et al., 1998, 2016; Gatesy et al., 1999; Milà, 2012; Mateus et al., 2014; Sulej et al., 2014; Hansen et al., 2016; Marzola et al., 2016). The amphibian fauna reported from the Jameson Land Basin includes the plagiosaurid Gerrothorax pulcherrimus Fraas, 1913 (Jenkins et al., 2008), and remains tentatively associated with the capitosaurid Cyclotosaurus Fraas, 1889 (Jenkins et al., 1994; Sulej et al., 2014). Cyclotosaurus belongs to a family of Late Triassic temnospondyl amphibians, the Cyclotosauridae, sensu Damiani (2001) and Schoch (2008), characterized by a dorsoventrally flat, elongated, parabolic skull, with eye sockets placed in the posterior half of the head, a long, laterally compressed tail, and relatively short limbs (Milner, 1994; Rinehart and Lucas, 2016). Moreover, at least four synapomorphies are known to identify cyclotosaurids: infraorbital canals curving over the lacrimals with a ‘Z’ shape, vomerine tusks positioned lateral to the palatal vacuity, a wide parabolic snout, and a vomerine palate as long as wide (Damiani, 2001; Schoch, 2008). Among the largest amphibians to have ever lived (total body length up to 3 m), cyclotosaurids were mostly piscivorous, semi-aquatic predators, colonizing freshwater niches, such as rivers and lakes, as well as coastal brackish to marine areas (Milner, 1994; Fortuny et al., 2016; Witzmann et al., 2016). In this study, we provide the first complete anatomical description and phylogenetic analysis of the capitosaurid skull reported in Jenkins et al. (1994) and associated vertebral intercentra. We support the original assignment of the Greenlandic specimen to the genus Cyclotosaurus based on the undoubted presence of seven of the eight synapomorphies given for this genus in Witzmann et al. (2016). Cyclotosaurus naraserluki is erected as a new species, based on a combination of autapomorphies and associated characters unique among known cyclotosaurids.

MATERIALS AND METHODS

Cyclotosaurus naraserluki: holotype MGUH.VP 9522 (Figs. 2–5), a nearly complete skull on exhibit at the GeoCenter of Mons Klint, Denmark. Associated with the skull are two intercentra, MGUH.VP 9523 and MGUH.VP 9524 (Fig. 6). Locality: Macknight Bjerg Quarry, Jameson Land, Greenland (see Jenkins et al., 1994). Horizon and age: Late Triassic (late Norian) of the Fleming Fjord Formation (see Jenkins et al., 1994) (Fig. 1).

Other taxa used for comparison from personal observation and the literature

The following specimens were analyzed by personal observation of original material: Cyclotosaurus intermedius Sulej and Majer, 2005: ZPAL Ab III 1173 (holotype); C. mordax Fraas, 1913: SMNS 13014 (holotype), 50008, 50059, 50063, and 51102; C. posthumus Fraas, 1913: SMNS 12988 (holotype); C. robustus von Meyer and Plieninger, 1844: SMNS 5775 (holotype), 4139, and 4935; Eocyclotosaurus wellesi Schoch, 2000: UCMP 42841 (holotype), 41343, 41645, 41646, 55466, 123590, 123595, and 125364; E. appetitulous Rinehart et al., 2015: NMMNH P-64166 (holotype), 43126, 63328, 64360, 66832, and 67401; Kupferzella wildi Schoch, 1997: SMNS 54670 (holotype); and Quasicyclotosaurus campi Schoch, 2000: UCMP 57754 (holotype), 41635, 132022, 172489, 172490, 172491, 172492, and 172493. Photos of C. ebrachensis Kuhn, 1932, BSGP 1931 X 1 (holotype), were kindly provided by Dr. Oliver Rauhut.

From the literature, the following species were analyzed: C. buechneri (Witzmann et al., 2016:85, 87, figs. 2–3); C. hemprichi (Kuhn, 1942:tables I–III); Mastodonsaurus cappelensis (Wepfer, 1923); M. giganteus (Schoch, 1999:150, fig. 54); Paracyclotosaurus davidi (Watson, 1956:255, fig. 14); and Procyclotosaurus stantoniensis (Paton, 1974:256, fig. 1).

Phylogenetic Analysis

Cyclotosaurus naraserluki MGUH.VP 9522 was coded in the data set by Witzmann et al. (2016) for a total of 17 taxa and 69 characters (Appendix 1). Character 7 of Witzmann et al. (2016) was reformulated for the present analysis as character 7: Lateral line sulci: weakly impressed and discontinuous (0); discontinuous and well impressed (1); well impressed laterally and weakly impressed or discontinuous medially (2). State 2 for character 7 was coded for C. ebrachensis, C. hemprichi, C. mordax, C. naraserluki, C. posthumus, and C. robustus. We used TNT 1.5-beta, available at www.lillo.org.ar/phylogeny/tnt (Goloboff and Catalano, 2016). We performed an heuristic search, with 1000 replications using Wagner trees as starting trees, followed by tree-bisection-reconnection (TBR), retaining 10 trees per replication.

GEOPHICAL SETTING

The Fleming Fjord Formation is exposed in East Greenland at the Jameson Land Basin, between 70° and 73°N (Clemmensen, 1980a, 1980b; Clemmensen et al., 1998, 2016) (Fig. 1). During the Late Triassic, the Jameson Land Basin lay farther to the south, at around 40°N (Kent and Clemmensen, 1996; Kent and Tauxe, 2005). The basin was located in a climatic transition zone of the Pangaea continent, between a relatively dry inland of the supercontinent and a more humid peripheral part (Clemmensen et al., 1998, 2016; Kent et al., 2014).

Three members of cyclically bedded lacustrine deposits from the Late Triassic Fleming Fjord Formation, with a thickness of 300–400 m are: the lowermost Edderfugledal Member, the middle Malmros Klint Member, and the uppermost Ørsted Dal Member (Clemmensen, 1980a, 1980b; Clemmensen et al., 1998). The Ørsted Dal Member lies towards the eastern margin of the basin and is composed of a lowermost unit of red mudstones, the Carlsberg Fjord beds, and an uppermost unit of variegated mudstones and light gray dolomitic mudstones, the Tait Bjerg Beds (Jenkins et al., 1994; Clemmensen et al., 2016).

Temnospondyl amphibian remains have been reported from the easternmost part of the basin at the Macknight Bjerg Quarry (71°22'N, 22°33'W) in the lowermost part of the Carlsberg Fjord beds (Sulej et al., 2014; Clemmensen et al., 2016). The Cyclotosaurus specimen described here originates from this quarry (Jenkins et al., 1994).

The Carlsberg Fjord beds are composed of siliciclastic sediments of mudflat and lake origin. The most common facies are red-brown to purple mudstones, light greenish-gray mud-peloid siltstones with wave ripples, intraformational conglomerate, and light grayish, fine- to medium-grained sandstones with current-formed cross-stratification. Numerous Grallator and cf. Brachychirotherium tracks are seen on upper bedding planes of the wave-rippled siltstones, the former attributed to theropod dinosaurs and the latter to stem crocodylians (Clemmensen et al., 2016; Klein et al., 2016).

According to Kent and Clemmensen (1996) and Clemmensen et al. (1998), the Macknight Bjerg Quarry at the base of the Carlsberg Fjord beds of the Ørsted Dal Member has an age of approximately 209 Ma. However, using the stratigraphy of Andrews et al. (2014), the site would be dated around 217 Ma. The age and duration of the Norian has seen considerable work (e.g., Kent and Olsen, 1999; Lucas et al., 2012). According to the International Chronostratigraphic Chart (Cohen et al., 2013; latest version available at www.stratigraphy.org/ICSchart/chronostratChart2016-04.pdf), the Norian ranges from ~227 to ~208.5 Ma. However, U-Pb dating, biostratigraphy, magnetostratigraphy, and chemoostratigraphy analyses place the Norian-Rhaetian boundary at about 205.70 ± 0.15 Ma (Wotzlaw et al., 2014; Bertellini et al., 2016). Thus, an age estimate of the quarry site of 209 Ma (Clemmensen et al., 1998) would place it in the late Norian, whereas an age estimate of 217 Ma (Andrews et al., 2014) would give a mid-Norian age.

CYCLOTOSAURUS Fraas, 1889
CYCLOTOSAURUS NARASERLUKI, sp. nov. (Figs. 2–6)
**Cyclotosaurus** cf. *posthumus* Fraas, 1913: Jenkins et al., 1994:7–8, figs. 4–5 (original report); Schoch, 2008:202.

**Cyclotosaurus**, sp. nov.: Schoch and Milner, 2000:156.

**Cyclotosaurus posthumus** Fraas, 1913: Damiani, 2001:404.

**Holotype**—MGUH.VP 9522 (previously V-2012-146a, as on the label on the specimen), a mostly complete skull, 56.8 cm in length along the midline from the tip of the snout to the posterior end of postparietals and with a maximum width of 42.4 cm (Figs. 2–5; Supplementary Data 1, 2).

**Associated Material**—MGUH.VP 9523 and MGUH.VP 9524 (previously V-2012-268 and V-2012-269, respectively, as on the labels on the specimens), two vertebral intercentra (Fig. 6).

**Type Locality**—The type specimens were collected during the 1989 expedition to Macknight Bjerg Quarry (71°22.30′N, 22°33.14′W), at Jameson Land, East Greenland (Fig. 1).
FIGURE 2. The holotype specimen of Cyclotosaurus naraverluki, MGUH.VP 9522. A, C, photograph and interpretative drawing of dorsal view; B, D, photograph and interpretative drawing of ventral view. Scale bar equals 20 cm.
Type Horizon—Late Triassic Carlsberg Fjord beds (Ørsted Dal Member) of the Fleming Fjord Formation (Fig. 1).

Etymology—The specific name is after ‘naraserluk,’ Greenlandic for ‘amphibian, salamander.’

Diagnosis—Cyclotosaurus naserluki has the following autapomorphies among other Cyclotosaurus species: (1) the postorbitals notching posteromedially in the supratemporals; (2) the parasphenoid projecting between the pterygoids and the exoccipitals, thereby preventing a pterygoid-exoccipital suture; and (3) the anterior palatal vacuity is subdivided by a wide medial connection of the premaxillae and the vomers. Moreover, C. naserluki has the following unique combination of characters among Cyclotosaurus: (1) a pair of premaxillary foramina for accommodating mandibular tusks (shared with C. mordax, see Fig. 4); (2) a posteromedial convex margin of the tabulars (shared with C. ebrachensis and C. intermedius, doubtfully with C. mordax); and (3) a circular choanal outline (shared with C. ebrachensis, C. posthumus, and C. robustus).

DESCRIPTION

General Aspect and Dermal Bone Ornaments—The entire skull MGUH.VP 9522 (Figs. 2–5; Supplementary Data 1, 2) is very well preserved. The skull outline is parabolic, with a widely parabolic snout and convex lateral margin of the postotic region. The only appreciable missing part is the posterior contact of the right tabular and squamosal, which leaves the right otic fenestra open posteriorly. Some sutures and contacts between bones,
especially from the posterior part of the skull, are not visible due to lack of preparation and sediment still present on the specimen. A slight deformation seems to affect the entire left half of the skull. The bone sutures are more evident in the posterior half of the skull, fading almost to complete fusion anteriorly. Skull length is 56.8 cm, as measured along the midline suture, from the tip of the snout to the posterior end of the postparietals. The maximum width is 42.4 cm, measured at the maximum distance between the lateral margins of the quadratojugals.

*Cyclotosaurus naraserluki* presents the typical dorsal ornamentation of temnospondyl skulls. Subcircular to subpentagonal pits and a reticular pattern of ridges cover most of the skull roof, especially evident on the tip of the snout, as well as all over the parietals and the postparietals. Ridges and anteroposteriorly elongated ornamentation are evident in the posteromedial region of the snout, covering most of the frontals and part of the nasals and prefrontals. This elongated ornamentation is associated with intensive growth of the skull (Bystrow, 1935). The same kind of ridge-elongated sculpture is evident in the postorbital regions, covering most of the squamosals and part of the postorbitals, the jugals, and the quadratojugals.

**FIGURE 4.** Close-up views of the premaxillary foramina (highlighted by white arrows) in cyclotosaurids. **A, B,** dorsal and ventral views of the holotype of *Cyclotosaurus naraserluki*, MGUH.VP 9522; **C,** holotype of *Cyclotosaurus mordax*, SMNS 13014. Scale bar equals 5 cm.
FIGURE 5. The holotype specimen of Cyclotosaurus naraserluki, MGUH.VP 9522. A, B, photograph and interpretative drawing of right lateral view; C, D, photograph and interpretative drawing of left lateral view; E, F, photograph and interpretative drawing of occipital view. Scale bar equals 20 cm.
Lateral Line Sulci

The lateral line sulci in *C. naraserluki* are present as pairs of supraorbital, infraorbital, and postorbital sulci. They are more evident laterally, especially in the posterior part of the skull, and weakly impressed medially, especially across the snout.

**Supraorbital Sulci**—The supraorbital sulci originate on the anterior part of the snout, medially to the nares. They meander anteroposteriorly from the nasals to the prefrontals, reaching the posterior part of the frontals, and weakly ending on the postfrontals, at around the midline of the orbits. Regardless of the weak preservation of both lacrimals, the left supraorbital sulcus seems to run along the suture between the prefrontal and the lacrimal, like in other cyclostaurids and temnospondyls (see Schoch, 2008; Rinehart et al., 2015; Rinehart and Lucas, 2016; Witzmann et al., 2016).

**Infraorbital Sulci**—The infraorbital sulci originate lateral to the nares, first meandering anteroposteriorly on the maxillae, then curving with an acute flexure onto the lacrimals, ending atop or parallel to the jugal-maxilla sutures.

**Postorbital Sulci**—The postorbital sulci originate from the postorbital rim of the orbits. They run with a 'S'-shaped curvature onto the jugals and the quadratojugals at first, then along the squamosal-quadratojugal sutures, ending at the posterior margin of the skull.

Skull Roof

**Teeth**—Complete and incomplete labyrinthodont teeth are visible ventrally, protruding both from the vomers and the palatines as tusks, anteriorly to the palatal vacuities. These tusks have a conical shape and a circular cross-section. The vomers also bear six small teeth medially located posterior to the anterior palatal vacuity. Tooth alveoli are seen along the maxillae, the palatines, and the ectopterygoids, organized in rows.

**Premaxillae**—The premaxillae form the anterior-most rim of the snout and contact medially. In dorsal view, they contact the nasals posteriorly, the maxillae laterally, and form part of the nares rims. In ventral view, the premaxillae contact the maxillae laterally, the vomers posteriorly, and form the anterior half of the rim of the anterior palatal vacuity. The premaxillae bear the two premaxillary foramina for the accommodation of the mandibular tasks.

**Maxillae**—The maxillae form the major part of the lateral skull margin, extending from the anterior part of the nares to the midlength of the skull, up to the anterior margin of the orbits. Dorsally, they contribute to the lateral rim of the nares. The maxillae are bordered anteriorly by the premaxillae and medially by the nasals, the lacrimals, and the jugals. Ventrally, they contact the premaxillae anteromedially, the vomers and the palatines medially. They contribute to the anterolateral rim of the choanae.

**Nasals**—The nasals form most of the anterior part of the snout. Subrectangular in shape, they pair medially and contact the premaxillae anteriorly. Posteriorly, they taper to a triple point with the frontals postero-medially and the prefrontals posterolaterally. Laterally, the nasals contact first the maxillae behind the nares, then the lacrimals. Anterolaterally, they contribute to the narial rims.

**Lacrimals**—The lacrimal sutures are very faint. The right lacrimal seems to have a drop shape, with a wider parabolic posterior suture, where it contacts the prefrontal medially and the jugal laterally, and a more tapered anterior suture, where it is bordered by the nasal medially and the maxilla laterally. Ventrally, there are no visible sutures between the lacrimals and the bordering bones.

**Jugals**—The jugals form most of the cheek regions. Their total contribution to the length of the snout cannot be clearly delineated due to the weak preservation of the anterior sutures. Anteriorly, they taper at the contact with the lacrimal-maxilla suture, although this suture is faintly visible only on the right jugal. Medially, the jugal-maxilla suture runs anteroposteriorly. Laterally, the jugals are bordered by the prefrontals anterior to the orbits and by the postorbitals posterior to the orbits. The postorbital-jugal suture runs with a 'Z'-shaped outline until reaching a triple point, where the jugals are bordered by the squamosals medially and the quadratojugals laterally. The jugals contribute to form a small part of the orbital rim.

**Prefrontals**—The prefrontals are two elongated bones that narrow anteriorly to a three-point suture with the nasals anteromedially and the lacrimals anterolaterally. Almost as long as the nasals and the frontals, they contact the former medioanteriorly and the latter medioposteriorly. Laterally, the jugals contact anteriorly the lacrimals and laterally the jugals; posteriorly, they form the anteriormost rim of the orbits.

**Frontals**—The frontals contact along the midline from the medial part of the snout until reaching the posterior level of the orbits. With a subtriangular anterior outline, they are bounded by the nasals anteriorly, forming a straight suture. The frontal-prefrontal sutures run laterally, first with a straight course, then with a sigmoid curvature. Posteriorly, the frontals present a 'W'-shaped suture, defined by the parietales postero-medially and by the postfrontals postero-laterally. The frontals contribute to a narrow portion of the orbital rim, projecting between the prefrontals and the postorbitals.

**Postfrontals**—The postfrontals have a subcircular shape and contribute to the postero-medial rim of the orbits. Anteriorly, they contact the frontals and are bordered by the parietales postero-medially, the supratemporals posteriorly, and the postorbitals laterally.

**Postorbitals**—The postorbitals have a subtrapezoidal shape and contribute to the posterolateral rim of the orbits. Medially, they contact the postfrontals and embay into the supratemporals postero-medially, projecting more laterally than the orbits. The postorbitals contact the jugals and the squamosals laterally.

**Quadratojugals**—The quadratojugals form the posterior-most side of the cheeks and the lateral-most part of the skull. In dorsal view, they have a subrectangular shape and contact the jugals anteriorly and the squamosals medially, along a sigmoidal suture. In ventral view, they contact the insulae jugalis anteriorly and the quadrates medially. They form a big part of the lateral and posterior rims of the adductor fossae. In occipital view, the quadratojugals contact the quadrates medially and the squamosals dorsally. In posterior view, the general aspect of the *C. naraserluki* skull appears to be rounded, with a slight deformation to the right side, probably due to taphonomy.

**Parietales**—The parietals contact medially, and they form a heart-shaped outline, with the tip facing anteriorly. They enclose the parietal foramen posteriorly to the midlength of their medial suture. They contact the frontals anteriorly, the postfrontals and the supratemporals laterally, and the postparietals posteriorly.

**Supratemporals**—The supratemporals present an arcuate shape, with the concavity projecting postero-medially. Anteriorly, the supratemporals embay the postorbitals and slightly contact with the postfrontals. The supratemporals contact the parietals medio-anteriorly, by a straight suture, and the postparietals medio-posteriorly, by an anterolaterally concave suture. The postero-medial supratemporal suture is a gentle curve contacting the squamosals and the tabulares.

**Squamosals**—The squamosals form a small part of the posterior rim of the skull, projecting between the quadratojugals and the tabulares. They contact the postorbitals and the jugals anteriorly, the supratemporals and the tabulares medially, and the quadratojugals laterally. The tabular-squamosal suture is fully visible in the left side of the skull, where it runs postero-laterally. The squamosals contribute to form about half of the otic fenestrae rims.
**Postparietals**—The postparietals contact along the posteriormost part of the midline and form the posterior concavity of the dorsal rim of the skull. Different from the rest of the midline, the contact between the two postparietals is not straight but follows a zig-zag course. The postparietal-parietal sutures extend mediolaterally, whereas the lateral contact with the supratemporals and the tabulars curves with a lateral concavity.

**Tabulars**—The polygonal shape of the tabulars broadens anteriorly and ends along the posterior, slightly convex margin of the skull. They contact the supratemporals anteriorly, the postparietals medially, and the squamosals laterally along a suture that embays the otic fenestra. The suture between the tabular and the squamosal is only appreciable posteriorly to the left otic fenestra. In dorsal view, the tabular horns project laterally. Also, they are the posterior-most projecting bones of the skull.

**Endocranium**

**Quadrates**—Ventrally, the quadrates present a polygonal shape that contacts the pterygoids medially and the quadrant jugals laterally. The sutures of the quadrates are not clearly exposed or preserved. Anteriorly, the quadrates form part of the posterior rim of the adductor fossae, whereas posteriorly they contribute to the posterior margin of the skull.

**Exoccipitals**—The exoccipitals contact ventromedially and suture with the parapsphenoid anteriorly. They project posteriorly to form the articulation with the atlas and diverge dorsally to enclose the ventral part of the foramen magnum. The posterior projection of the exoccipitals falls at the same level as the posterior-most projection of the quadrates. The posterior contact surfaces of the exoccipitals with the atlas are suboval in shape and flat.

**Palate**

**Vomers**—Anteriorly, the vomers form the posterior rim of the anterior palatal vacuity. Immediately behind this opening, six teeth are borne by the vomers, two by the left vomer and four by the right one, all set in a transverse row. The vomers also bear the first couple of palatal tusks. Anterolaterally, the vomers contact the premaxillae and the maxillae. Laterally, the vomers only contact the palatines and contribute to part of the choanae and to most of the medial rim of the palatal vacuities. The left vomer has a small posterolateral projection into the palatine. In ventral view, the vomers contact anteriorly, forming the posterior rim of the anterior palatal vacuity and the posterior part of the premaxillary-vomerine subdivision. Along the midline, the vomers contact one another except for the enclosure of the cultriform process of the parapsphenoid. At their contact along the palatal vacuities, the vomers form a ‘V’-shaped ridge that projects ventrally. The posterior contact between the vomers and the parapsphenoid is weak.

**Palatines**—The palatines have a subrectangular shape and bear the second pair of palatal tusks. The right palatine also bears the third palatal tusk, which is not preserved on the left counterpart. Anteriorly, the palatines form the posterior rim of the choanae and contact the maxillae. The palatine-maxilla sutures run posterolaterally from the choanae to the ectopterygoid. Medially, the palatines contribute to the rim of the palatal vacuities. The posterior contact between the palatines and both the pterygoids and the ectopterygoids are indistinct.

**Pterygoids**—The pterygoids have a sinusoidal shape, extending between the palatal vacuities and the adductor fenestrae and forming part of their respective rims. Anteriorly, the pterygoids contact the palatines. Medially, the sutures that separate the pterygoids from the ectopterygoids and the insulae jugales are poorly preserved to indistinguishable, except for the left pterygoid-insula jugalis suture. Posteriorly to the adductor fossae, the pterygoids contact the quadrates and form part of the posterior margin of the skull. The medial contact between the pterygoids and the parapsphenoid is weakly noticeable. The right pterygoid bears a weak ornamentation anterior to the adductor fossa rim.

**Parapsphenoid**—The parapsphenoid is an unpaired, midline bone. Anteriorly, the cultriform process of the parapsphenoid extends beyond the anterior margin of the palatal vacuities, enclosed by the vomers. The cultriform process projects ventrally, forming a keel-like structure that narrows posteriorly. The parapsphenoid-exoccipital suture has a flat and long ‘M’ shape. The crista muscularis of the parapsphenoid is an unpaired structure running transversely. Laterally, the parapsphenoid contacts the pterygoids, although the sutures are barely visible. Nonetheless, it looks like the parapsphenoid-pterygoid sutures are as long as the width of the parapsphenoid basal plate. The left parapsphenoid-pterygoid suture is the best preserved and ends at the posterior embayment of the skull margin, avoiding the contact between the pterygoids and the exoccipitals, a primitive condition shared with Rhinesuchidae, Eryosuchus Ochev, 1966, and Kupferzellia. The parapsphenoid contributes to the postero-medial rim of the palatal vacuities and presents a left anterior protuberance, probably due to taphonomic deformation.

**Ectopterygoids**—The ectopterygoids are not easily observed in the palate of C. naraserluki because they are not completely preserved. Nonetheless, the left ectopterygoid preserves a somewhat distinct medial suture with the pterygoid and a posterior suture with the insula jugalis. The right ectopterygoid bears at least three distinct alveoli organized in a row, whereas the left ectopterygoid bears at least 12 distinct alveoli organized in an anteroposteriorly oriented row.

**Insulae Jugales**—The insulae jugales are weakly preserved. The right insula jugalis is nearly indistinguishable, whereas the left insula jugalis presents a trapezoid shape. It bounds the ectopterygoid anteriorly, the pterygoid medially, the quadrant jugal laterally, and posteriorly it forms the anterior-most margin of the adductor fossa.

**Skull Openings**

**Nares**—The nares are two oval dorsal openings in the anterior part of the snout, with a maximum width of 3.5 cm. They are bounded by the premaxillae, the maxillae, and the nasals.

**Premaxillary Foramina**—The C. naraserluki skull bears two premaxillary foramina for the reception of the mandibular tusks (Fig. 4). These two circular openings are filled with grayish sediment and noticeable on the dorsal surface of the skull, where they are enclosed completely by the premaxillae. Dorsally, the premaxillary foramina are evident in the anterior palatal vacuity.

**Orbits**—The orbits are the major openings of the dorsal side of the skull, with a maximum width of 5.5 cm and a subcircular outline. They are rimmed by the prefrontals, the frontals, the postfrontals, the jugals, and the postorbitals. The dorsal margin of the orbits is level with the rest of the skull roof.

**Parietal Foramen**—The parietal foramen is the smallest of the skull openings and the only unpaired one. Its maximum width is 1.1 cm, and it is completely enclosed by the parietals.

**Otic Fenestrae**—The otic fenestrae characterize the posterior skull roof and are bounded by the squamosals and the tabulars. The left otic fenestra is an oval cavity, elongated anteroposteriorly, with a maximum width of 4.5 cm. The right otic fenestra is posteriorly open due to the missing portion of the posterior contact between the squamosal and the tabular.

**Anterior Palatal Vacuity**—The anterior palatal vacuity is an ‘U’-shaped depression with a maximum length of 4.9 cm and width of 11.3 cm. It is enclosed by the premaxillae and the vomers. The anterior palatal vacuity presents the premaxillary foramina, two subcircular openings filled with sediment.

**Choanae**—The choanae are two circular cavities in the anterior part of the palate with a maximum width of 4.4 cm. Only the
left choana preserves its original shape, whereas the right choana is deformed.

**Palatal Vacuities**—The palatal vacuities are the biggest openings of the palate, with a 'D'-shaped outline, a maximum length of 28.9 cm, and a maximum width of 10.9 cm. The marginal rims are almost straight, whereas laterally they present a parabolic curvature with the posterior curvature more acute than the anterior one. The palatal vacuities are enclosed by the vomers, the palatines, the pterygoids, and the parasphenoid.

**Adductor Fossae**—The adductor fossae characterize the posterior-most region of the palate. The left adductor fossa is the best preserved and presents an arch shape with a gentle lateral convexity and a more acute medial concavity. The maximum length measured parallel to the midline is 16.9 cm, and the maximum width is 10.4 cm.

**Postcranial Skeleton**

**Vertebrae**—Two amphicoelic intercentra represent the only preserved postcranial elements of *C. naraserluki* (Fig. 6). They display a convex ventral surface, with a ventral thickness of 21 mm in MGUH.VP 9523 and 22 mm in MGUH.VP 9524. Dorsally, they are characterized by a central dorsoventral depression that also compresses the two intercentra anteroposteriorly down to 11 mm in thickness for MGUH.VP 9523 and down to 13 mm for MGUH.VP 9524. In MGUH.VP 9523 the maximum width is 42 mm and the maximum thickness is 25 mm, whereas MGUH.VP 9524 has a maximum width of 48 mm and height of 37 mm. Among other capitosaurs, these kinds of intercentra have so far only been reported from *Mastodonsaurus* Jaeger, 1828, and *Cyclotosaurus hemprichi* (Kuhn, 1942; Schoch, 1999). Intercentra of similar size and morphology have been further described by Milner et al. (1996) from the Norian of Luxemburg and the ?Carnian–Norian of Algarve in Portugal (Witzmann and Gassner, 2008), the latter associated to stereospondyls, such as *Mastodonsaurus* and *Cyclotosaurus*. However, the material from Portugal is questionable: new well-documented discoveries from the Algarve (Steyer et al., 2011; Brusatte et al., 2015) show the presence of *Metoposaurus algarvensis* Brusatte et al., 2015, which may suggest a need to reassess the identification of the previous fragmentary material (Witzmann and Gassner, 2008).

**PHYLOGENETIC RESULTS**

The phylogenetic analysis yielded one most parsimonious tree (Figs. 7, 8), with a tree length (TL) of 109 steps and consistency index (CI) of 0.624, retention index (RI) of 0.680, and rescaled consistency index (RCI) of 0.424. Because of the recoding of character 7 and the addition of *C. naraserluki*, our phylogeny of *Cyclotosaurus* is slightly different from the one presented in Witzmann et al. (2016). *Cyclotosaurus* loses one synapomorphy (char. 48-1, quadrate ramus of the pterygoid laterally aligned and abbreviated) and the synapomorphy based on character 7 passes from state 0, ‘lateral line sulci weakly impressed, discontinuous,’ to state 2, ‘lateral line sulci well impressed laterally but weakly impressed or discontinuous medially.’ In general, most of the groups within Capitosauroida (sensu Schoch, 2008) are poorly supported, with the exception of the genus *Mastodonsaurus* and the Heylerosauridae (sensu Schoch, 2008), which includes *Eocyclotosaurus* Ortlam, 1970, and *Quasicyclotosaurus*. Moreover, despite presenting seven synapomorphies, the genus *Cyclotosaurus* is not well supported and may easily collapse due to the numerous reversals. New data and characters may help to overturn and increase the precision of the relations between these species.

*Cyclotosaurus robustus* remains the most basal *Cyclotosaurus* taxon, a position supported by a cultriform process that forms a deltoid base (char. 52-1). The remaining *Cyclotosaurus* taxa
FIGURE 7. Most parsimonious tree of the Capitosauroida (sensu Schoch, 2008) produced by a TNT 1.5 analysis (tree length = 109 steps, consistency index = 0.624, retention index = 0.680, rescaled consistency index = 0.424). Synapomorphies are shown along the tree and numbers refer to the characters listed in the phylogeny in Witzmann et al. (2016). Thicker branches represent the genus *Cyclotosaurus* in the analysis. **Abbreviations:** *C.*, *Cyclotosaurus*; *R.*, reversal.

possess a preorbital projection of the jugals shorter than half of
the snout length (reversal for char. 13-0). Cyclotosaurus buech-
neri presents lateral line sulci weakly impressed and discontinu-
ous (reversal for char. 7-0). All post-C. buechneri cyclotosaur
have an interorbital width to width of the orbits ratio equal to or
greater than 1.8 (char. 68-1). Cyclotosaurus hemprichi and C. posthunus are sister taxa, a relationship supported by a tapered
preorbital region (char. 1-1) and an elongated parabolic snout
(reversal for char. 66-0). A straight-to-convex posteromedial
margin of the tabulars (char. 69-1) is synapomorphic for the
remaining four species of Cyclotosaurus, which branch into two
clades. The clade formed by C. naraserluki and C. mordax is sup-
ported by a snout bearing a pair of premaxillary foramina to
accommodate mandibular tusks (char. 57-1). The second clade
includes C. intermedius and C. ebrachensis. It is supported by the
presence of palatal denticle fields borne on the parasphenoid
and/or the pterygoid (char. 32-0) and straight postorbital lateral
margins of the skull (char. 67-1). Cyclotosaurus intermedius is
supported by having the quadrates projecting posteriorly to the
distal ends of the tabular horns (char. 2-0) and a weakly and dis-
continuous impression of the lateral sulci (reversal for char. 7-0).
Cyclotosaurus ebrachensis is supported by supraorbital sulci
passing over the nasals (reversal for char. 10-0) and an unpa-
paired anterior palatal vacuity (reversal for char. 20-0).

DISCUSSION

Paleoecology and Paleogeography

The remains here described belong to a new species of Cyclo-
tosaurus, namely, C. naraserluki, sp. nov., the largest amphibian
reported from Greenland heretofore (Jenkins et al., 1994, 2008).
Cyclotosaurus naraserluki shared its living habitat with other
semiaquatic amphibians and reptilian predators, such as Gerro-

horax pulcherrimus (Jenkins et al., 2008) and phytosaurs
(Mateus et al., 2014; Clemmensen et al., 2016; Marzola et al.,
2016). The co-occurrence of Cyclotosaurus with other predators
in the same area is consistent among all the known Late Triassic
faunal associations from Europe where Cyclotosaurus has been
reported (i.e., Sulej and Majer, 2005; Witzmann and Gassner,
2008). In the Greenland scenario, this may be explainable by dif-
ferent predatory habits, strategies, and physiological capacities
of different taxa over the coasts of a huge seasonal lake in the
Jameson Land Basin: large phytosaurs were actively preying on
large terrestrial vertebrates and fish, like modern crocodiles;
Cyclotosaurus and Gerrothorax were probably sharing ecological
niches, but with the former being larger in size and preying
mostly on fish, and the latter feeding on small fish, larvae, and
invertebrates.

The Late Triassic Greenland fauna shows more affinities to
European occurrences (dominated by genera such as Cyclotosau-
rus, Gerrothorax Nilsson, 1934, Mastodonsaurus, Metoposaurus
Lydekker, 1890, and Procyclotosaurus Watson, 1958) than to
North American ones. In the Late Triassic, there is a clear dis-

between the European-Greenlandic and the North
American faunas, with the unique presence in the latter of Apha-
chesaurus Hunt, 1993, Eocyclotosaurus, Koskinonodon Branson
and Mehl, 1929, Paracyclotosaurus, and Quasicyclotosaurus
(Watson, 1958; Jenkins et al., 1994, 2008; Schoch, 1999, 2000;
Sulej, 2002; Brusatte et al., 2015; Kear et al., 2016; Rinehart et
al., 2015; Rinehart and Lucas, 2016).

Greenland is, and always has been, part of the North
American continent, and despite the early opening of the
North Atlantic, the Triassic fauna and flora show more affini-
ties to the one in central Europe. This may be explained by
several factors: (1) the equivalent paleolatitude of Greenland
and central Europe promoted similar faunas, in contrast to
the subequatorial paleolatitudinal position of known North
American fossil occurrences in Texas, New Mexico, and
Arizona; (2) at that time, the geographical distance between
Greenland and central Europe was shorter than to southern
North America, which may have facilitated dispersal; and (3)
the deserts and arid regions separating Greenland and Texas,
New Mexico, and Arizona may have been a much more effi-
cient barrier to the temnospondyls than the proto-Atlantic
between Greenland and Europe. Some tolerance for salinity
may have given a dispersal advantage to captosaurus.

CONCLUSIONS

Cyclotosaurus naraserluki is the largest amphibian ever
reported from Greenland. It possesses several autapomorphies
that distinguish it from its sister taxon, C. mordax, within the
genus Cyclotosaurus.

The record of Cyclotosaurus from the Fleming Fjord Forma-
tion in East Greenland, together with Gerrothorax pulcherrimus,
shows a close correlation between the Greenlandic Late Triassic
amphibian fauna and the amphibian fauna of the coeval Euro-
pean basins, such as Germany, Poland, and Portugal.

The temnospondyl faunas of Europe and the Scandinavian
Arctic (Greenland and Svalbard archipelagos) are characterized
by taxa not found in coeval temnospondyl faunas from North
America, showing a geographical connection between East
Greenland and central Europe despite the opening of the North
Atlantic.

The geographic position of Greenland and the Jameson Land
Basin during the Late Triassic makes C. naraserluki one of the
amphibians known to have lived at the highest paleolatitude,
sharing trophic habitats with other amphibian and reptilian
predators.

ACKNOWLEDGMENTS

We thank K. M. Gregersen (MGUH) and N. Natorp (GCMK)
for access to the material. We are also thankful to M. Moreno-
Azanza (Universidade NOVA de Lisboa/Museu da Lourinhã)
for invaluable help and discussion on the phylogeny; A. Luz
(Museu da Lourinhã) for the artwork of the skull; O. Rauhut
(BSPG/Ludwig Maximilian University) for kindly providing

photos of the holotype of *Cyclostaurus ebrachensis*; and R. Schoch (SMNS) and F. Witzmann (MB) for useful discussion on cyclostaur phylogeny and character identification. Finally, we are thankful to T. Sülej (ZPAL), J. Fröbisch (MB), and an anonymous reviewer for useful reviews and for helping to significantly improve the original manuscript.

M.M. is supported by the Fundação para a Ciência e a Tecnologia doctoral fellowship SFRH/BD/99580/2014 (Ministério da Ciência, Tecnologia e Ensino superior, Portugal). M.M. was also supported in visiting museum collections by the 2015 European Association of Vertebrate Palaeontologists Research Grant (EAVP-ERG) and by the 2015 Stan Wood Award of The Palaeontological Association (PA-SW201502). Field work in Greenland by J.B.C. was supported by the Carlsberg Foundation.
