End-of-service wood chips and crumb rubber were repurposed for this study. Additionally, fly ash and ground granulated blast furnace slag (GGBS), both industrial by-products were used as the base materials for the geopolymer binder. The overall appearance and particle size distribution of the wood chips and crumb rubber are shown in Figs. 1 and 2.

(a) (b) (c)

Fig. 1 General ppearance: (**a**) wood chips, (**b**) powder rubber, (**c**) 1–3 mm rubber granules

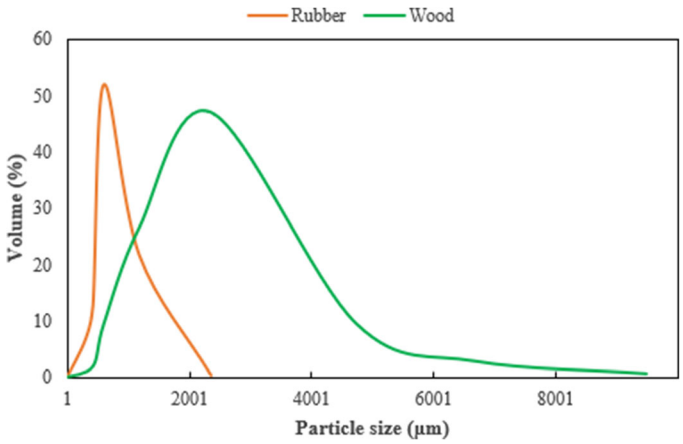

Fig. 2 Particle size distribution

The wood chips used in this study were chipped from recycled untreated pine pallets. These wood chips exhibit an apparent density of 443 kg/m^3 and a moisture content of 11%. The water absorption, determined following the method outlined in [14–16], was found to be approximately 154%. The rubber for this study was supplied by Tyrecycle and comprised a mixture from two different grades, as illustrated in Fig. 1. The rubber used in all mixes was an equal combination of powder rubber and 1–3 mm crumb rubber granules.

Geopolymer cement was used as a binderto further promote sustainability. It was produced by incorporating fly ash and GGBS as the primary constituents. The chemical compositions of these materials were assessed through XRFT (X-ray fluorescence spectroscopy), and the results are presented in Table 1.

A combination of sodium hydroxide and sodium silicate was used as an alkaline solution to activate the base materials. The concentration of the sodium hydroxide was 12M and was prepared from 98% pure flakes. A laboratory grade D sodium silicate solution with a solid ratio in weight % of 44.6 was used. The sodium silicate solution had a SiO_2: Na_2O ratio of 2.05.

Table 1 Chemical composition of binders

3 Experimental Program

The study involved the production and testing of cube samples to establish an optimal mix design by examining various proportions of wood and rubber content through a partial-factorial experimental design. The objective was to develop a wood–rubber–geopolymer composite mix design that not only delivered the required workability and compressive strength but also maximized the utilization of waste aggregates (Wood and crumb rubber). This involved testing of various mix designs through 50 mm × 50 mm × 50 mm cubes to identify the most suitable composition for constructing masonry units. While structural requirements took precedence, factors such as material workability and appearance were also integral considerations. To achieve this, the mix design by Gigar et al. [15, 16], developed for wood-geopolymer composite, served as the foundation, with adaptations made to modify the workability and incorporate rubber. The overarching goal was to devise a mix design for wood–geopolymer composite and wood–rubber–geopolymer composites that could potentially be used in the production of masonry units.

The optimal mix for the wood-geopolymer composite was first established through the examination of seven distinct wood-to-binder ratios (0.1, 0.15, 0.2, 0.25, 0.3, 0.4, and 0.5), designated as Set-A. Following this, the impact of partially replacing wood with rubber was explored at wood chips to binder (WC/B) ratios of 0.25 and 0.4, categorized as Set-B and Set-C, respectively. To assess the effect of partially replacing wood chips with rubber, a 5 × 2 factorial design was implemented, creating 10 different mixes with varying WC/B ratios (2 levels) and five levels of partial replacement. The partial replacements of the wood with rubber were examined at replacement levels of 0%, 25%, 50%, 75%, and 100% by volume. The complete experimental design, encompassing Sets A to C, is outlined in Table 2.

The slag-to-binder ratio and alkaline solid-to-binder ratio were consistently maintained at 0.4 and 0.18, respectively, across all mixes. The water utilized in this investigation was classified into geopolymer water and compensating water, following the methodology proposed by [14–16]. The total water quantity, designated as TW, was calculated using the formula $TW = 0.29GPS + 0.5WC$, where geopolymer solid (GPS) represents the combined weight of the binder and the solid portion of the alkaline solution, and WC corresponds to the weight of the wood chips.

The samples were created in a controlled laboratory setting using a pan-type concrete mixer. The mixing process involved two steps to produce a consistent mix. Solid components such as binders, dry wood chips, and rubber were mixed for the first 3 min. The alkaline solution and water were then added and mixed well for

another 5 min. Following the mixing process, the freshly mixed material was placed into the mold and subjected to vibration for 30 s to ensure adequate compaction. Following compaction, each sample was moved to the environmental control room, where the relative humidity was kept at 50% and the temperature was kept at 20 ± 3 °C until the testing day. This controlled environment guaranteed uniform conditions for precise evaluation and permitted the composites to cure as intended.

4 Results and Discussion

The compressive strength of the cube samples was tested according to the ASTM D3501 standard [17], and the results are presented in Table 3.

4.1 Wood–Geopolymer Composites

The results of the cube tests for WGC shown in Table 3 are plotted in Fig. 3. for comparison. The graph also shows the targeted 5 MPa and 10 MPa strengths for non-load-bearing and load-bearing masonry units, respectively. The compressive strength of the WGC was in the range of 4–25 MPa, while the corresponding density

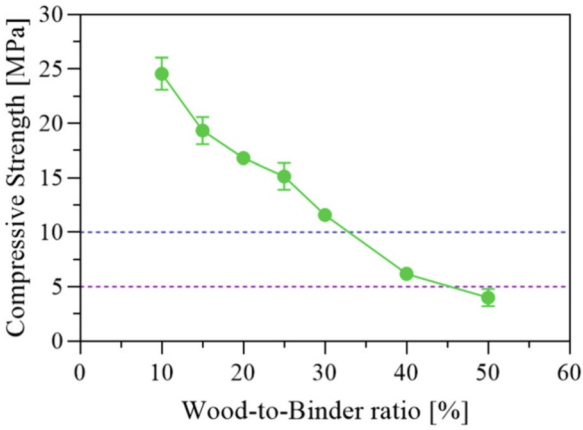

Fig. 3 Compressive strength of WGC with vffig4arying wood content

was in the range of 0.807–1.52 g/cm^3. The graph highlights that the compressive strength of the WGC decreased as the wood content increased. This is mainly attributed to the increase in porosity and weak interface between the wood aggregate and the geopolymer matrix [15]. A similar trend was also observed for the density.

The WGC with WS/B ratios of 0.1–0.3, with compressive strength higher than 10 MPa, can potentially be used to produce load-bearing masonry units, while WGC with WS/B ratio 0.4, with compressive strength just above 5 MPa could potentially

be used for the manufacturing of non-load-bearing masonry units. WGC with the maximum wood content of WS/B ratio of 0.5 fails just short of the minimum compressive strength to produce masonry units. The following stages explored the effect of partial replacement of the wood with rubber. WS/B ratios of 0.25 and 0.4 were selected for this (Fig. 3).

4.2 Wood–Rubber–Geopolymer Composite

The effect of incorporating rubber in the wood-geopolymer mix can be seen in Fig. 4. As can be observed, the strength of the composites is inversely proportional to the total volume of waste aggregate. The 25% waste aggregate cubes achieved between 12 and 15 MPa, while the 40% cubes achieved between 6 and 10 MPa strengths.

The graph also shows that the compressive strength of the wood–rubber–geopolymer composite (WRGC) generally increased with the relative rubber content. The relationship between wood and rubber also impacts the workability of the mix, with an increase in wood causing a drier and stiffer mix, while an increased proportion of rubber caused a much wetter mix. This is mainly attributed to the relatively small water absorption capacity of the crumb rubber.

Since the target is developing sustainable material with a minimum compressive strength of 10 MPa while maximizing the recycling of wood and rubber aggregates, a ratio of half wood to half crumb rubber was selected to provide an appropriate consistency for cinderblock manufacture. Given that the 25% samples exceeded the desired 10 MPa by an average of 4 MPa and the 40% samples were 3.5 MPa lower on average, the ideal waste aggregate content of 30% aggregate mix with half rubber and half wood can potentially be used to produce load-bearing masonry units.

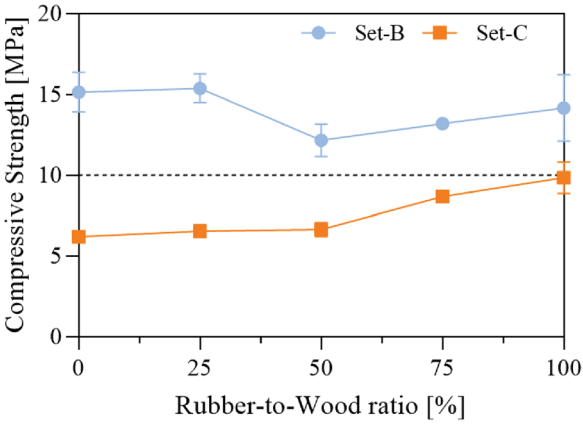

Fig. 4 Compressive strength of WRGC with varying wood and rubber content

5 Conclusion

In summary, this experimental program aimed at formulating an environmentally sustainable construction material through the incorporation of end-of-service materials, such as wood and rubber. It focused on optimizing mix designs with considerations for workability, strength, and the goal of maximizing waste recycling. The key findings of the study are summarized below:

- The compressive strength of the composites decreased with an increase in the wood content.
- The incorporation of rubber affected the appearance, workability, and compressive strength of the composite.
- The wood-binder ratio of 0.2–0.4 showed promising results for the production of load-bearing and non-load-bearing non-traditional masonry units. In addition to their sustainability, these composites are characterized by their lightweight nature and enhanced energy-absorbing capacity, distinguishing them from conventional composites.

Preliminary results showed significant promise in the viability and performance of these innovative composites for the production of masonry units manufactured from recyclable materials. The findings of this study will contribute to the ongoing efforts within the construction industry to adopt sustainable practices and materials, aligning with the imperative to mitigate environmental impacts. Future works will explore the production of masonry units using wood and rubber as base materials, evaluating their physical, mechanical, and durability properties. The performance of this units will be compared with conventional msonry units and assessed against international standards. Additionally, future research will explore the feasibility of integrating other recyclable materials, such as cenosphere, into the manufacturing process.

1 Introduction

The construction sector is facing heightened scrutiny in response to the urgent need to combat climate change and reduce greenhouse gas emissions [1]. Governments and institutions are implementing immediate measures to achieve a 70% decrease in carbon emissions by 2030, which is a pivotal step towards the overarching objective of achieving net-zero emissions by 2050 [2]. Over recent decades, there has been increasing interest in reducing the negative environmental impacts of buildings to address global challenges and fulfil governmental obligations. On one hand, researchers are exploring ways to reduce the carbon footprint associated with material production and construction processes by investigating alternative materials with lower embodied carbon and refining construction methods to minimize waste and energy use [3–5]. On the other hand, there is a focus on designing buildings and infrastructure with energy efficiency and sustainability at the forefront, incorporating

passive design strategies and renewable energy systems [6–8]. Furthermore, advancements in digital technologies like Building Information Modelling (BIM) are facilitating more precise simulation and optimization of building performance over its lifecycle, aiding in identifying areas for improvement and reducing energy consumption [9–10]. However, the structural optimization of reinforced concrete foundations has been widely disregarded [11], even though foundations contribute significantly to the structural embodied carbon in various structures like high-rise buildings, fences, lightweight structures and wind turbines [12–13]. This lack of attention is largely attributed to a scarcity of prior data and uncertainties regarding the measured properties of the soil [14]. This chapter aims to determine the optimal pile designs made of three different materials concrete, timber and steel and compare their embodied carbon emissions. The authors have previously introduced a detailed study on optimizing the embodied carbon of reinforced concrete deep foundations [15]; however, the carbon emissions associated with steel and timber piles construction are still not covered in the literature. A genetic algorithm tool is proposed and used to compare the values of the resultant embodied carbon for the different pile materials at different load capacities to assess their environmental impact. Finally, a case study for an existing pile design in London clay is presented, and the proposed algorithm is then used to compare the different piling scenarios and compare their environmental impact to the as-built design to assess the potential carbon savings for future designs.

2 Methodology

A safe pile design should satisfy at least the following three design criteria:

- Structural capacity (N): The applied load should be less than the capacity of the pile as a short concrete column.
- Geotechnical capacity (Q_t): The applied load is less than the factored sum of the base bearing capacity and the pile's skin friction.
- Serviceability: The pile's settlement under the working load is within an acceptable range given the structure's type and sensitivity.

Following are the details of the adopted models to assess the three design criteria for different materials.

2.1 Structural Capacity

The structural capacity of piles is assessed in accordance with Eurocodes [16–17]. The structural capacity of short concrete columns ($N_{con.}$) is calculated as shown in eq. (1). While eq. (2) calculates the structural capacity of timber piles subjected to axial loading (N_{tim}) [18]. Equation (3) is simplified to calculate the

structural capacity of stocky steel columns ($N_{stl.}$); the steel pipe's diameter-to-thickness ratio is assumed to be <80 to avoid local buckling of the structural element ($D/t < 80$) [19].

$$N_{con.} = 0.4\, f_{ck}\, A_c + 0.75\, f_y\, A_s \tag{1}$$

$$N_{tim.} = \frac{f_{ctk}}{\gamma_m}.A_t \tag{2}$$

$$N_{stl.} = \frac{f_y}{\gamma_p}.\ A_s \tag{3}$$

where

- A_c , A_t and A_s = concrete area, timber area and reinforcement steel area
- f_{ck}, f_{ctk} and f_y = compressive strength of concrete, timber and steel
- γ_m = partial factor for timber compressive strength
- γ_p = partial factor for steel compressive strength

2.2 Geotechnical Capacity

The geotechnical capacity of piles is the sum of the base bearing and the total skin friction. Steel pipes are assumed to be fully plugged when driven to the desired depths in clay [20]; therefore, the geotechnical capacity of concrete and steel pipes is calculated using eqs. (4, 5). However, timber piles are usually naturally tapered [21]; therefore, the geotechnical capacity of tapered piles is being assessed using the cavity expansion theory proposed by Khan *et al.* in 2008 [22], authors proposed adding a taper factor (k_t) to account for the effect of taper angles as shown in eqs. (6, 7 and 8).

$$Q_t = Q_b + Q_s \tag{4}$$

$$Q_b = q_{soil}.\pi.r_b^2 \tag{5}$$

$$Q_s = 2\pi \int_0^L L.r_i.\tau_s\, d(L) \tag{6}$$

$$\tau_{st} = k_s.k_t.\sigma'_v.tan\delta \tag{7}$$

$$K_t = \frac{tan\ (\alpha+\varphi).cot\delta}{1+2\xi tan\alpha.\, tan(\alpha+\varphi)} + \frac{4Gtan\alpha.\, tan(\alpha+\varphi).cot\varphi}{k_s[1+2\xi tan\alpha.\, tan(\alpha+\varphi)]}\,\frac{\Delta_r}{\sigma'_v} + \left(\frac{c.\,sec^{\,2}\alpha}{(1-tan\alpha\ tan\varphi)}/[1+2\xi tan\alpha.\, tan(\alpha+\varphi)]\ k_s\ \sigma'_v\ tan\varphi\right) \tag{8}$$

where

- Q_t, Q_i and Q_s = total capacity, base bearing capacity and shaft friction resistance
- q_{soil} = soil bearing capacity
- r_i and r_{ob} = pile radius and pile base radius
- τ_s = pile's surface friction
- α, φ and δ are the taper angle, the angle of internal friction and the concrete–soil friction angle
- σ_v' and φ' = soil effective stress at a given point and effective angle of internal friction

2.3 Settlement Calculation Model

A 2D model is coded to deploy the load–displacement (t-z) method for pile calculation as proposed by Randolph and Wroth in 1978 [23]. Equations (9, 10 and 11) show a summary of the adopted approach, the assigned settlement limit is assumed to be 10% of the pile's diameter, as recommended by Eurocodes [24]:

$$\{F\} = \left[K_p + K_s\right] \cdot \{u\} \tag{9}$$

$$\{u\} = \left[K_p + K_s\right]^{-1} \cdot \{F\} \tag{10}$$

$$k_{base} = \frac{G}{r \cdot ln\left(2.5\, L \frac{1-\nu}{r}\right)} \tag{11}$$

where

- $\{F\}$ and $\{u\}$ = vectors of axial force and vertical displacements
- $[K_p]$ and $[K_{base}]$ = stiffness matrices of pile and soil end bearing
- G and ν = shear modulus and Poisson's ratio of the soil
- L and r = length and radius of the pile

2.4 Carbon Calculation Model

According to standard and codified life cycle carbon assessment practice [25], the embodied carbon of any building is split into several stages [A1-D]. For this study, only the 'cradle-to-gate' stages [A1–A3] are considered, as calculated in eq. 12. In line with convention, biogenic carbon stored in timber is ignored in this analysis.

$$\sum TEC = (m_x)(ECF_x) \tag{12}$$

where

- $\sum TEC$ = total embodied carbon ($kgCO_2e$)
- m_x = mass of the construction material (kg)
- ECF_x = embodied carbon factor for a given material ($kgCO_2e/kg$)

2.5 The Optimization Algorithm

In this research, the primary solving method for the suggested hybrid optimization tool is the genetic algorithm. Subsequently, a local minimization function in MATLAB (minion) is employed to refine and validate the results obtained from the genetic algorithm. The tool's layout is shown in Fig. 1. The optimization tool is used for fulfilling the analysis detailed in Sect. 2.6.

2.6 Analysis Setup

The algorithm presented in Fig. 1 is run to test the following:

- The optimal pile design corresponding to the lowest embodied carbon for solid and hollow concrete piles constructed in clayey soil with properties summarized in Table 1 at different load capacities. The algorithm is capable of determining the optimal pile geometry; length and diameter (L and D) as well as the optimal concrete grade (f_{ck}). Analysis results are shown in Fig. 2.
- The optimal Douglas fir pile designs for square and circular piles constructed in the same soil at different load capacities; the results are compared in Fig. 3.
- The optimal pile design for steel pipes, including optimal pile diameter, length, and thickness (L, D and t) for different load capacities. Results are presented in Fig. 4.

The input material properties are shown in Table 2, the chosen geometry dimensions ranges are based on recommendations from three different major contractors.

3 Results and Discussion

3.1 Concrete Piles Optimization Results

Figure 2 shows the optimal concrete grades f_{ckc} and slenderness ratios $(L/D)_c$ at different load capacities for both solid and hollow concrete piles. The results show that

- For high-capacity piles, optimal hollow concrete piles provide a significant cut of up to 75% less embodied carbon compared to conventional solid piles despite the construction complexities associated with hollow pile construction.

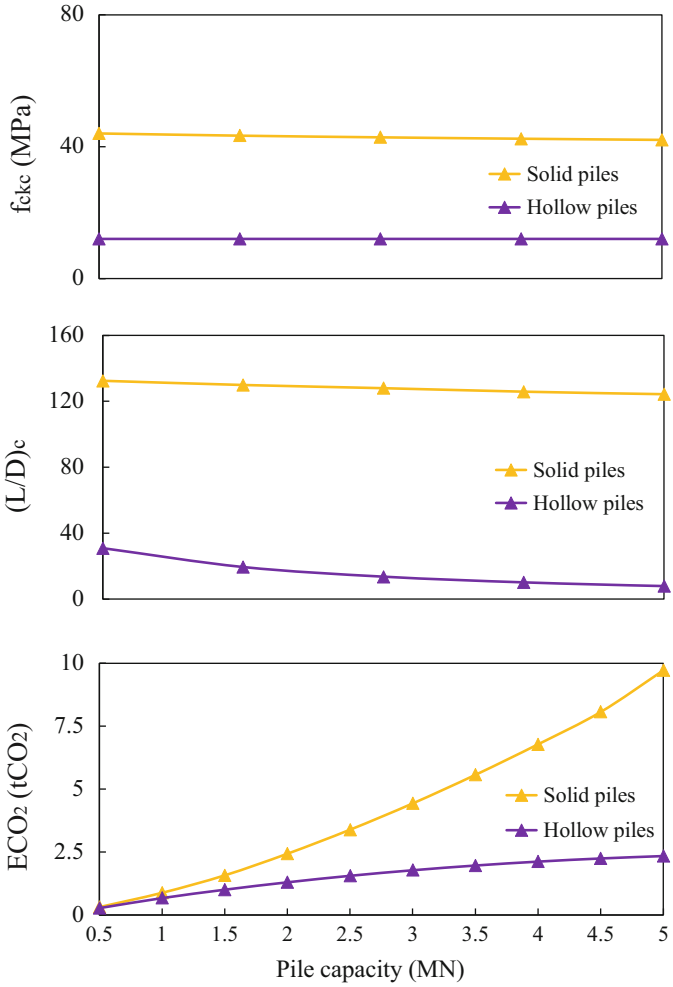

Fig. 2 Optimization results for solid and hollow concrete piles

- Optimal solid piles are very slender (high $(L/D)_c$) and this raises concerns regarding the practicality of constructing optimal solid piles [27], particularly augering.
- Optimal solid piles are usually corresponding to optimal concrete grades of (f_{ckc}) $\geq$ 40 MPa; however, hollow concrete piles make use of low concrete grades to get wider piles at lower embodied carbon.

3.2 *Timber Piles Optimization Results*

Figure 3 shows the optimization results for circular and square timber piles with material properties summarized in Table 2; the following are the main observed points:

- Timber pile designs produce significantly lower embodied carbon values compared to concrete piles; however, timber piles failed to provide pile capacities higher than 2.5 MN as the geometric limitations are met.
- Square piles produced slightly lower values of embodied carbon compared to circular piles; however, optimal square timber piles are more slender than optimal circular timber piles. It should also be noted that square piles are created through sawing of an initially cylindrical log and that the excess timber is not included in this study.

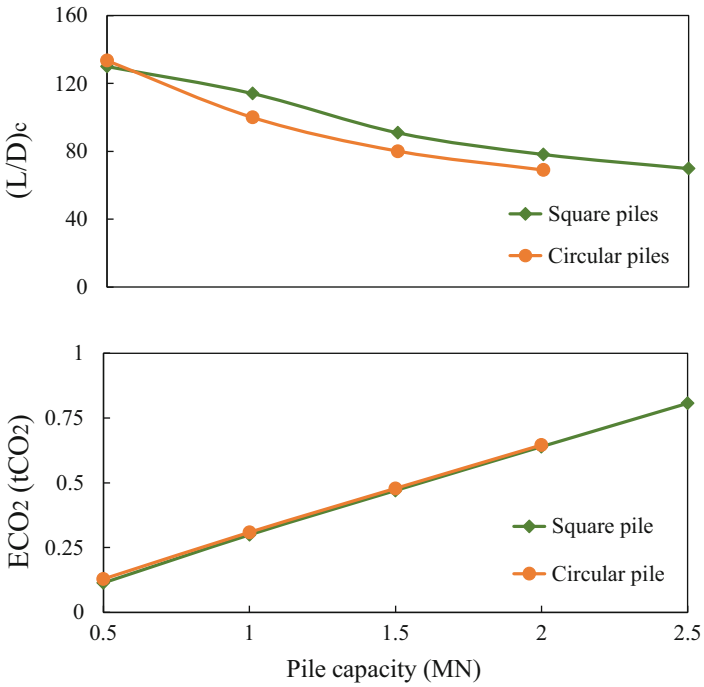

Fig. 3 Optimization results for circular and square Douglas fir timber piles

Table 2 Material properties and dimensions input for the optimization algorithm

Group	Input	Symbol	Value/range
Material strength (MPa)	Concrete grade range [16]	f_{ck}	[12–90]
	Timber compressive strength [18]	f_{ctk}	21
	Steel yield stress [16]	f_y	360
Geometry dimensions (m)	Concrete pile length	l_c	[1–200]
	Concrete pile diameter	D_c	[0–5]
	Minimum concrete cover	t_c	0.05
	Timber pile length	l_t	[1–30]
	Timber pile diameter	D_t	[0–0.45]
	Steel pipe length	L_s	[1–40]
	Steel pipe diameter	D_s	[0–2]
	Inner-to-outer diameter ratio for hollow concrete piles	D_i/D_o	[0.2–0.8]
Partial factors	Partial factor for timber [26]	γ_m	1.3
	Partial factor for steel [17]	γ_p	1.3
ECF (kg of CO_2e/kg)	Embodied carbon factor for concrete, 25% GGBS [15]	$ECF_{conc.}$	$0.082 + f_{ck} \cdot 0.002$
	Embodied carbon factor of reinforcement steel, worldwide steel	$ECF_{str.}$	1.99
	Embodied carbon factor of timber [25]	$ECF_{tim.}$	0.263
	Embodied carbon factor of steel sections, worldwide steel [25]	$ECF_{ste.}$	1.55

3.3 Steel Piles Optimization Results

Figure 4 shows the optimization results for steel piles; the following are the main observed points:

- Steel piles are the most emitting amongst all the different tested materials and designs, this is believed to be due to geometric limitations and local buckling of pipes. However, a significant cut in the embodied carbon can be achieved if stiffeners are used and piles are designed to avoid local buckling effects.
- The optimal values of slenderness ratios $(L/D)_c$ for steel pipes are between 85 and 90 as these values are corresponding to the lowest carbon emissions.

4 Case Study

This section applies the proposed algorithm to an existing case study to test the potential for emission savings.

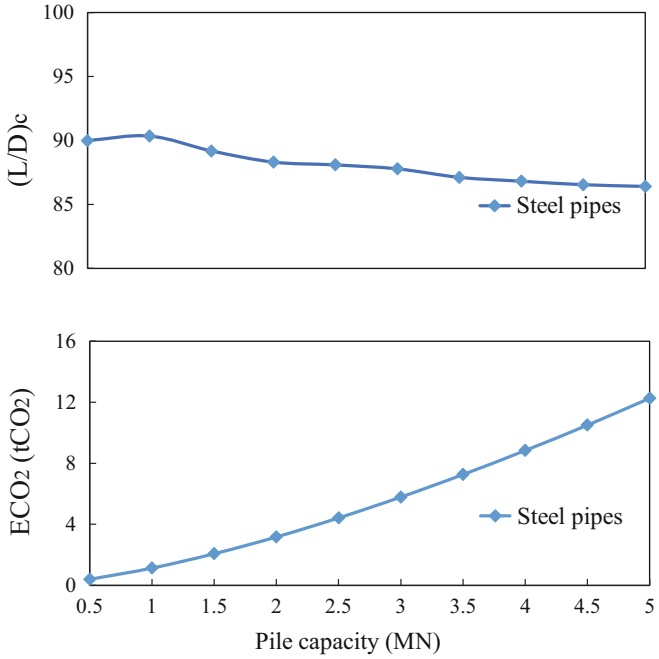

Fig. 4 Optimization results for tubular steel piles

4.1 Definition and Soil Properties

The case study is the design of the foundation system for the Hyde Park Cavalry Barracks, a 31-storey residential tower block located in central London and constructed in 1970 [28]. The main foundation system used is bored concrete piles with various diameters to support a piled raft. The soil encountered is typical of London, with 7 m of terrace sand and gravel [29] over a deep layer of undrained clay soil of unit weight $\gamma = 18$ kN/m^3 and a soil cohesion c_u (kPa) profile defined as shown in eq. 13, where z is the depth.

$$c_u = 6.1z + 60 \tag{13}$$

The soil properties were input to the optimization algorithm and was run to compare the embodied carbon of the different pile designs and materials at different load capacities. Concrete, timber and steel piles were compared given the described soil properties. Moreover, the as-built designs are compared to the different optimal designs to assess potential carbon savings for future projects.

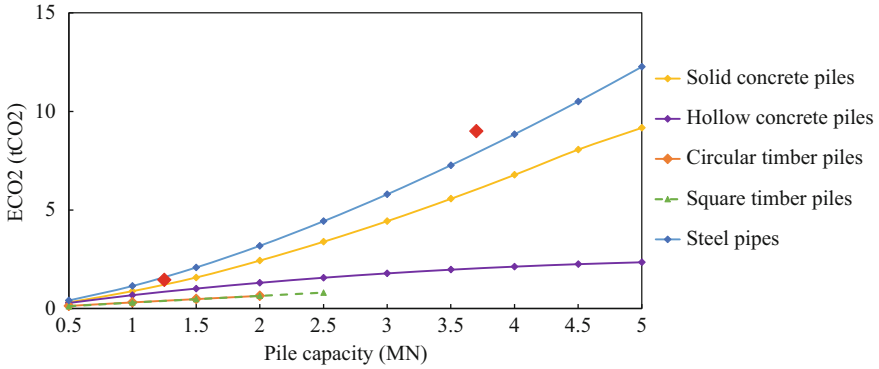

Fig. 5 The optimization results showing as-built designs as red marks

4.2 Optimization Results

Figure 5 shows the optimal embodied carbon values corresponding to the different pile designs resulting from the optimization algorithm. On the graph, the two red marks represent two as-built solid pile designs of capacities 1250 kN and 3760 kN, respectively. The analysis shows significant embodied carbon reduction possibilities if the optimal designs were utilized. For low-capacity pile, utilizing an optimized timber pile could have resulted in 68% less embodied carbon. For high-capacity pile, utilizing an optimized hollow concrete pile could have saved 76% of the embodied carbon. Therefore, the proposed optimization algorithm demonstrated an excellent carbon reduction efficiency and is highly recommended for geotechnical designers.

5 Conclusion

This paper is part of an ongoing research project that aims to optimize the design of deep foundations and build robust carbon-cost optimization models. The paper has introduced a pile optimization algorithm, which is used to compare the embodied carbon of different pile geometries and materials. The following are the main conclusions:

- Despite difficulties associated with construction, hollow concrete piles provide an excellent alternative to common solid piles as they provide the same pile capacity at significantly lower embodied carbon, with a more practical slenderness and concrete strength.
- Timber piles are excellent substitutes for concrete piles at low capacities; however, they can provide a limited threshold of pile capacities, this is mainly due to geometric limitations and the availability of adequate tree sizes.

- The embodied carbon associated with steel piles construction is significantly higher than that of concrete and timber piles.
- The algorithm is applied to a case study of London clay and showed significant potential to cut embodied carbon.
- This study emphasizes the potential for a substantial decrease in the overall embodied carbon linked to substructures. Most common pile designs are usually overdesigned, which leads to an unnecessary increase in values of embodied carbon. Moreover, there is an imminent need to introduce novel pile construction techniques to accommodate the optimal pile designs and geometries [30].
- The findings of this study are well timed, given the growing importance of assessing embodied carbon in construction, especially within the built environment.

1 Introduction

Cement production is responsible for up to 8% of global CO_2 emissions [1]; whilst a proportion of this is due to processes such as mixing and transportation, emissions affiliated with the calcination of limestone and associated decomposition make up two-thirds of emissions attributed to cement. To tackle such large emissions, cement alternatives such as ground granulated blast furnace slag (GGBS) or pulverized fuel ash (PFA) are often used as a partial, but direct replacement. However, a critical limitation lies in the finite supply of such alternatives. The search for replacement materials with similar pozzolanic properties has led to increasing utilization of calcined clay.

Clay is a globally abundant and low-cost material, however, is unreactive when raw. Therefore, dependent on application, calcination is often a necessity. Clay calcination typically takes place at 700–800 °C, approximately 600 °C lower than that needed for cement. In addition, clay calcination itself does not release CO_2. In

recent years, calcined clay has been integrated into cement mixtures, with the most prominent combination called LC3—limestone calcined clay cement–which comprises 50% of clinker being replaced by 30% calcined clay, 15% limestone powder and 5% gypsum. Earth is a traditional building material with minimal associated emissions; however, its inherent weaknesses in terms of strength and durability often require stabilization. While cement is frequently employed for this purpose, the adoption of geopolymers presents an opportunity to reduce emissions further. Although excavation waste often serves as the primary matrix in earthen construction, its potential as a stabilizer is often overlooked. Kaolinite-based geopolymers are often used due to kaolinite's pronounced reactivity; however, literature suggests that despite the prevalence of 2:1 minerals, their application and thus contribution to SCM reactivity remains insufficiently explored [2–5].

Calcined clay within the construction industry is almost exclusively targeted for use within concrete. This chapter takes a more innovative approach focusing on calcined waste excavation clay and investigates the feasibility for use as a geopolymer precursor within earthen construction materials.

1.1 Earthen Construction Stabilization

Earthen construction can take many forms. Throughout literature, compressed earth blocks (CEBs) and rammed earth are the most common. However, in the United Kingdom, earthen construction materials are often disregarded, with more durable materials such as concrete taking precedence. In 2018, 21.7% of UK excavation waste was reused as backfill; however, 50.4% (equivalent to 29.5 Mt) of total generated waste soil ended up in landfill [6]. While small quantities may be deemed hazardous and unsuitable for use, it is evident that there are ample opportunities to capitalize on soil reuse.

Soil stabilization represents a multifaceted concept aimed at enhancing engineering properties to fulfill specific performance requirements. Such criteria will often address strength, durability, shrinkage and workability. For instance, in the context of load-bearing walls, CEBs and rammed earth must have dry compressive strengths of 4 MPa and 2 MPa, respectively [7, 8]. Without stabilization, compressive strength can be significantly lower [5, 9, 10]. Central to earthen stabilization are pozzolanic reactions—a mechanism drawing upon the high reactivity of pozzolans. In the realm of earthen construction, conventional practices involve cement or lime stabilization, however high associated emissions remain [8, 11, 12]. Geopolymers offer an alternative solution, harnessing the reactivity of alkali-activated aluminosilicates to yield significant mechanical improvements, thereby enabling earthen stabilization. The realization of geopolymers as binders has led to lower carbon stabilization methods, in some cases achieving compressive strengths much higher than those obtained with ordinary Portland cement [13, 14].

Preethi and Reddy examined the effects of combining raw soil with an alkali activator, GGBS and PFA on the compressive strength of CEBs [5]. The alkali-activated samples experienced marginal improvement in comparison to

GGBS and PFA, owing to the inherent low reactivity of raw clay minerals. Consequently, significant emphasis should be placed on calcined clay. Several investigations [15–17] have explored the impact of metakaolin-based geopolymers on earthen blocks. However, similar to work by Dhanapani et al. [4], this study will be centered around waste excavation clays as geopolymer precursors, with particular focus on reactivity due to mineral composition. Subsequent investigations will explore the potential of geopolymer formation through alkali activation and its subsequent influence on the durability of earthen structures.

1.2 Reactivity Potential

Geopolymer precursors, characterized by their rich content of alumino-silicate oxides and high reactivity, often utilize pozzolanic materials like GGBS, PFA and metakaolin. Their highly amorphous nature, fine particle size and minimal inert material content render them ideal choices as precursors. Conversely, waste excavation clay can exhibit significant pozzolanic tendencies and appropriate grain sizes. However, a notable limitation lies in the presence of inert materials. The reactivity of clay is intricately linked to its mineralogy; samples with higher kaolinite content demonstrate greater reactivity, while those with high quartz proportions exhibit lower reactivity.

Various methods exist to quantify an SCM's reactivity [18–20] with the R^3 test emerging as one of the most effective options. This modern procedure is designed to emulate the reaction environment observed during cement hydration thereby facilitating a rapid assessment of reactivity [21]. Despite offering two routes for analysis—the cumulative heat release study and the bound water study—both pathways yield highly correlated results, ultimately leading to conclusions comparable to classical methods such as the modified Chapelle test [20, 22, 23].

The R^3 test homes in of the nature of geopolymers as SCMs are mixed with an alkali solution to simulate a reactive environment. Calcined clay R^3 test results, obtained from literature, are provided in Fig. 1 [20–27]. Among the findings, approximately one-third were categorized as metakaolin; however, considering the R^3 values, the majority are presumed metakaolin. Avet et al. [23] reported the lowest value of 225 J/g of SCM, utilizing a 95% kaolinite mixture. It is pertinent to note that this study employed a calcined clay-to-alkali ratio surpassing ASTM C1897 [28] standards by 13%. Given that Avet et al. [23] introduced the R^3 procedure, the recent studies reporting higher values are deemed more accurate.

Clay reactivity is heavily influenced by mineral reactivity, with kaolinite recognised as the most reactive mineral. Consequently, calcined clays containing high proportions of kaolinite demonstrate enhanced performance [23, 30]. The complexity of clay reactivity becomes more apparent when 2:1 minerals are considered, as their reactions tend to be slower and less extensive, often with the influence of individual minerals becoming blurred [4]. Weise et al. reported a result of 300 J/g of SCM [27]; this was the only example disclosed as a mixed clay, comprising 25%

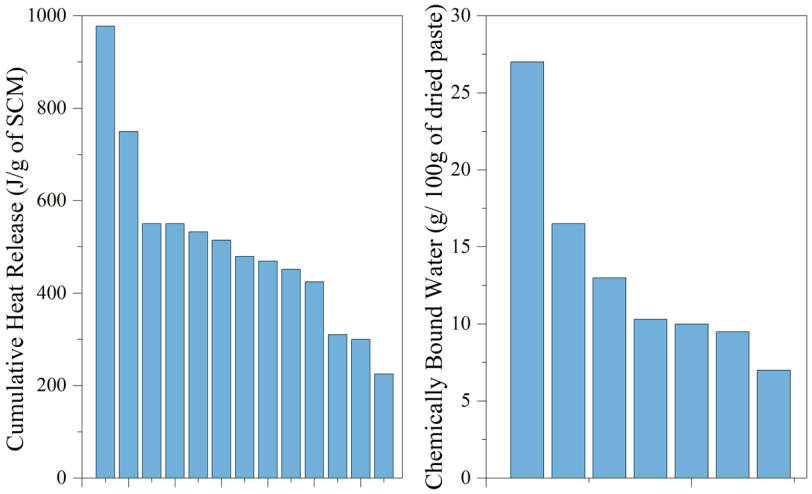

Fig. 1 Comparative analysis of calcined clay R^3 test results obtained from literature [20–27, 29]

kaolinite, 30% muscovite, 11% illite, 6% chlorite and 18% quartz. While numerous studies suggest a 40% kaolinite [3, 4, 31] threshold for SCMs, the above results indicate that comparable results can be achieved using lower grade or mixed clays. This study therefore utilizes waste excavation clay that is likely to comprise moderate to low levels of reactive minerals, to evaluate its suitability as a geopolymer precursor.

2 Methodology

2.1 Materials and Mixtures

The minerology and reactivity of four excavation waste clays will be studied, with the results compared against reagent kaolin and bentonite. The low expandability and high chemical reactivity of kaolin render it a prevalent choice as a geopolymer precursor. Conversely, bentonite is less utilized as a construction material due to its high demand within the geotechnical field. All waste clays were obtained from live UK construction projects; the site locations are illustrated below (Fig. 2).

According to the British Geological Survey [32], the A30 sample originates from the Mylor Slate Formation, the A391 from the St Austell Intrusion—a granite formation recognised as a global kaolin resource, the Copthall sample from the London Clay Formation and the RDP North sample from the lower/middle Pennine Coal Measures formations.

Fig. 2 Site locations of four excavation waste clays to be used for analysis

2.2 *Preparation of Samples*

All waste clays were air dried upon receival then ground using a mortar and pestle, sieved to a maximum grain size of 75 μm and stored in air-tight containers. Each powdered sample was calcined at 800 °C for a burning time of 1 h, in line with the work carried out by Avet et al. [23] and Abiodun et al. [33]. After calcination, all samples demonstrated significant redish discolouration, indicating the presence of iron.

2.3 *Experimental Program*

2.3.1 Characterization Using Thermogravimetric Analysis and X-Ray Diffraction

The chemical composition of both raw and calcined samples was characterized by thermogravimetric analysis (TGA) and X-ray diffraction (XRD). The thermographic analyzer used in this study is the PerkinElmer Simultaneous Thermal Analyzer. For each study, circa 15 mg of material was placed into a crucible, and the change in

mass was monitored. The TGA began at 30 °C and saw a steady heating rate of 10 °C/min until 950 °C was reached. Upon reaching 950 °C, the samples were held at temperature for 1 min. In addition, derivative thermograms were studied to demonstrate dehydration and dehydroxylation patterns within the samples.

The XRD was carried out independently using a Siemens D500/501 diffractometer. The XRD patterns were generated using Cu-Kα radiation and power parameters 40 kV and 20 mA, from a range of 2–70° 2θ, a step size of 0.02° 2θ at 2 s per step. Further to this, bulk mineralogy was determined using semi-quantitative analysis.

2.3.2 R^3 Test

The pozzolanic reactivity was determined in accordance with R^3 requirements, as advised by ASTM C1897 [28]. The R^3 pastes were prepared using proportions discussed in Table 1. R^3 mixture proportions, with the potassium solution comprising 4 g KOH and 20 g K_2SO_4 dissolved in 1 L of deionized water. The dry materials were combined using the Heidolph RZR 1 mechanical stirrer for 2 min. Thereafter, the alkaline solution was added and mixed for a further 2 min until a homogenous mixture was achieved. The paste was then poured into air-tight plastic molds for curing or isothermal calorimetry containers for immediate testing.

The cumulative heat study was conducted using a Calmetrix I-Cal 8000 HPC isothermal calorimeter set at 40 °C, whereas the bound water study was undertaken using the Carbolite CWF 1200 furnace at 350 °C and a desiccator. The chemically bound water was calculated using Eq. (1), where ω_0 is the total mass of the dried paste and crucible after stabilisation at 40 °C, ω_h is the total mass of the paste and crucible following 2 h at 350 °C and an hour in a desiccator, and ω_c is the mass of the empty crucible.

$$H_2O_{bound}\ (g/100\ g\ dried\ paste) = \frac{\omega_0 - \omega_h}{\omega_0 - \omega_c} \times 100 \tag{1}$$

The cumulative heat release is calculated using Eq. (2), where H is the cumulative heat release from 75 min until 7 days (168 h ± 10 min) after the start time of mixing by integration of the recorded heat release.

$$H_{SCM}\ (J/(g\ of\ SCM)) = \frac{H}{(m_p \times 0.101)} \tag{2}$$

Table 1 R^3 mixture proportions

	Clay-based sample	$Ca(OH)_2$	$CaCO_3$	Potassium sol^n
Mass (g)	10.00	30.00	5.00	54.00

3 Results and Discussion

3.1 Chemical Composition

The XRD patterns are given in Fig. 3. The analysis revealed significant proportions of quartz in all waste clay samples, as indicated by significant peaks at 26.6°. Given its inert characteristics, quartz can be detrimental to reactivity. Among the samples examined, A30 and A391 exhibited the highest quartz contents, with semi-quantitative analysis, i.e. the normalized reference intensity ratio (RIR) method, confirming beyond 50% content, notably higher than the average observed in the remaining waste clays. Conversely, Copthall and RDP North each comprise over 20% 1:1 minerals, thereby indicating the likelihood of increased reactivity. Following calcination, peak intensities reduced, indicating a decrease in mixture crystallinity. Similarly, the XRD analysis identified shifts in mixture composition. Despite a reduction in crystalline minerals, 2:1 minerals continued to be identified, thereby indicating an incomplete transformation into amorphous minerals. The trade-off between heightened calcination temperatures and influence on reactivity is an area for potential study.

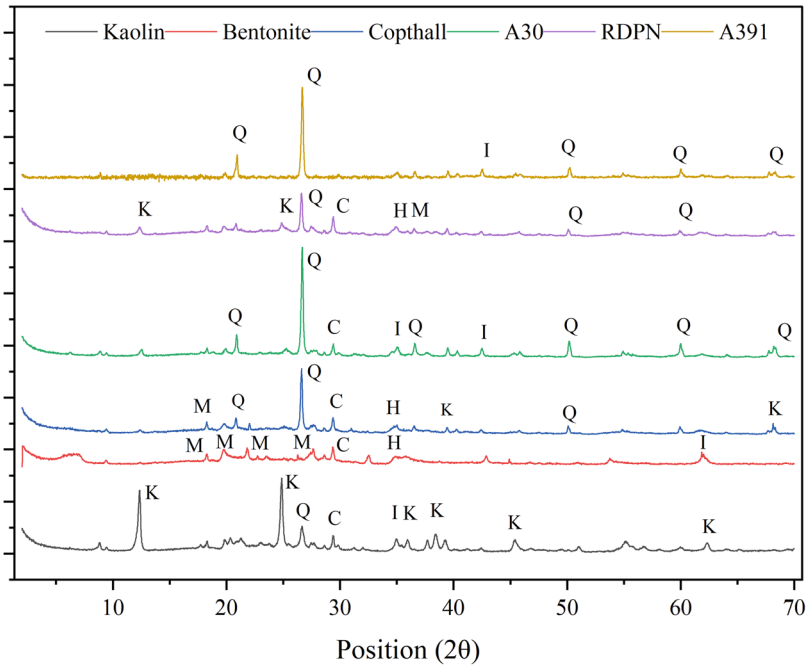

Fig. 3 XRD patterns of raw clays. C: Calcite, I: Illite, H: Halloysite, K: Kaolinite, M: Montmorillonite, Q: Quartz

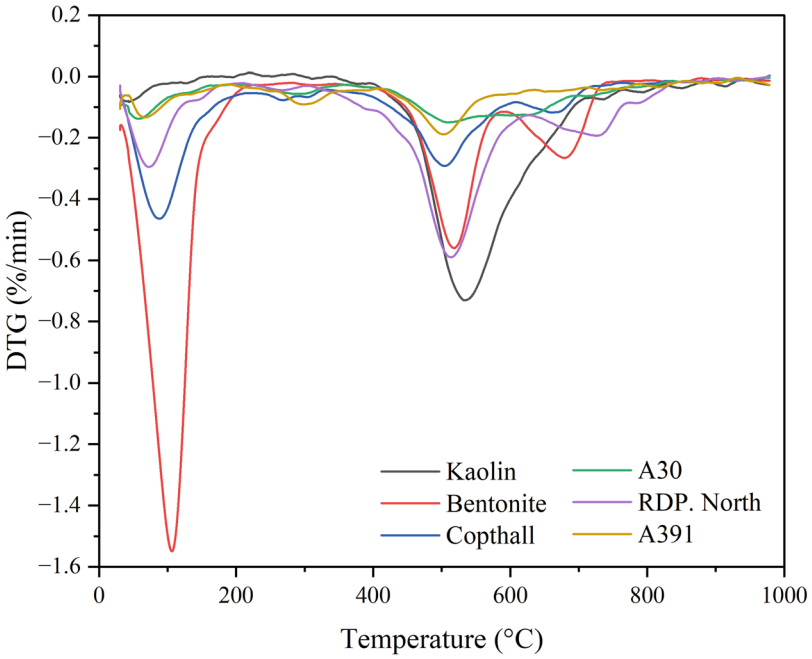

Fig. 4 Derivative thermograms of raw excavation waste clays, kaolin and bentonite

Figure 4 presents the differential thermogravimetric (DTG) curves for all samples. Owing to the mixed mineral composition of waste clays, the DTG troughs overlap. Below 200 °C, the dehydration of 2:1 minerals and evaporation of free water are observed. Above these temperatures, minerals are dehydroxylated. Kaolinite is dehydroxylated between 400 and 600 °C, whereas dehydroxylation of illite and montmorillonite will occur between 450–700 °C and 600–800 °C, respectively [2, 34]. Figure 4 reinforces the XRD findings. In terms of kaolinite content, RDP North is comparable to bentonite. Furthermore, in the analysis of 2:1 minerals, bentonite displays the largest trough owing to its substantial montmorillonite content, with Copthall following closely.

3.2 R^3 Test: Cumulative Heat Release

Figure 5 illustrates the cumulative heat released during the R^3 test, with kaolin exhibiting a notably value compared to other samples, as expected given its renowned reactivity. This value falls within the range reported in the literature, reinforcing the study's accuracy. Among the excavation waste samples, RDP North exhibited promising performance as a geopolymer precursor, aligning closely with the outcome observed with bentonite. While the use of calcined bentonite as an

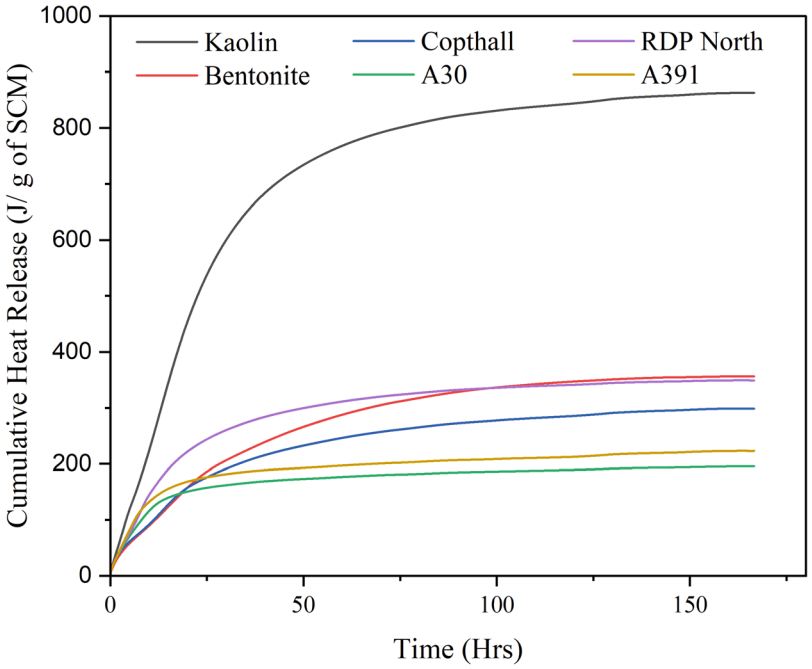

Fig. 5 Reactivity assessment of waste clays against kaolin and bentonite using R^3 cumulative heat release method

SCM is briefly discussed in literature, it acknowledges that pozzolanic activity is comparable with 30–35% kaolinite clays [29]. According to Fig. 5, kaolinite content is comparable, thus yielding similar outcomes. In addition, it has been demonstrated that low-quality kaolinitic clays and high smectitic clays can produce geopolymers with a cumulative heat release beyond 450 J/g of SCM [29]. This finding supports the notion that lesser utilized clays, such as bentonite or more readily available common clays, hold promise as viable geopolymer precursors.

According to literature [20–27], excavation clays Copthall and RDP North exhibit values within the realm of kaolin. However, this study confirms that kaolin presents a higher reactivity, with Copthall and RDP North aligning more closely with bentonite, a pure 2:1 clay. Samples A30 and A391 result in cumulative heat below the range depicted in Fig. 1. The lack of reactive minerals within A30 and A391, as confirmed through XRD and TGA, are consistent with the low R^3 test results.

An intriguing observation emerges from the near-identical heat released from bentonite and Copthall samples within the first 24 h. The identification of kaolinite and montmorillonite via XRD, coupled with similar dehydroxylation patterns at higher temperatures, indicates similar proportioning and thus could explain this similarity in reactivity. This finding corroborates Diaz's [3] and Vallina's work [29], reaffirming that montmorillonite-rich clays can be selected for use as a SCM.

3.3 R^3 Test: Bound Water

The R^3 values obtained using the chemically bound water study are presented in Fig. 6. The strong correlation observed between R^3 procedures underscores the reliability of the methodology. Notably, kaolin demonstrating significantly higher performance than the waste excavation clays, with those aligning closely with the outcomes observed in the R^3 cumulative heat study.

Consistent with the heat release study, the performance of the kaolin sample corresponds to ranges documented in the existing literature [20–27]. Notably, the excavation waste samples from RDP North and Copthall share similarities with those derived from GGBS and PFA—materials well-known for their rich silicate and aluminate compositions. On the other hand, A30 and A391 samples align more closely with values obtained from natural and blended pozzolans, such as volcanic ash and siliceous PFA. Pure quartz, however, yields values of 1–1.2 g/100 g of dried paste [24, 25]. This reaffirms that despite a reduced reactivity, hydration reactions occur in the high quartz R^3 paste samples, albeit to a lesser degree.

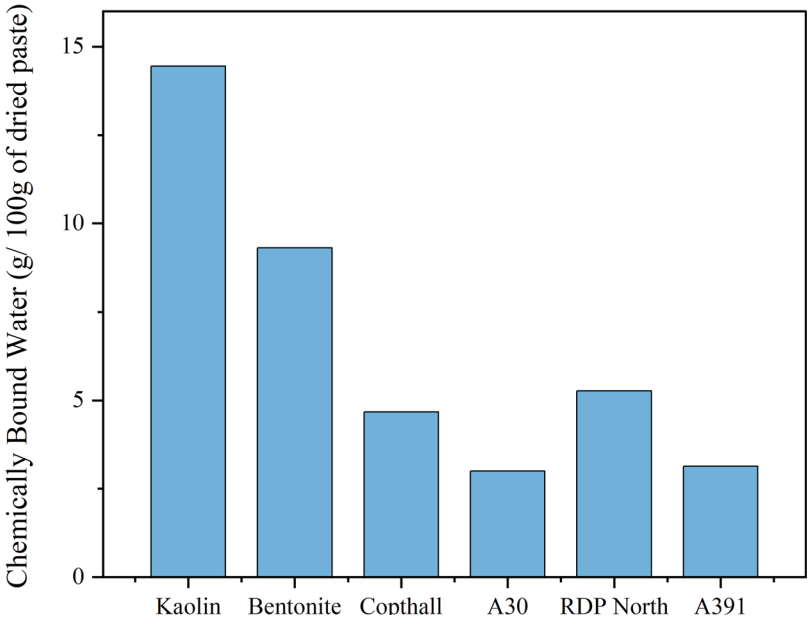

Fig. 6 Reactivity assessment of waste clays against kaolin and bentonite using R^3 bound water method

4 Conclusion and Future Work

In conclusion, this study sheds light on the reuse of excavation waste clays as SCMs. The effectiveness of R^3 tests in simulating cement hydration environments indicates the promise of common clays like Copthall and RDP North, both materials low in quartz but with sufficiently high 1:1 and 2:1 minerals, as geopolymer precursors. Achieving reactivity levels akin to high-quality kaolin proves challenging; however, attaining a reactivity comparable to pure smectitic clays indicates that common clay precursors, with appropriate mineral compositions, can yield satisfactory reactivity levels, enabling the advancement of alternative geopolymer precursors. While the presence of kaolinite significantly influences reactivity, reactivity comparable to traditional SCMs like GGBS of PFA can be achieved using waste, illite- and montmorillonite-rich clays [20, 22, 24, 29]. The advancement of common clay geopolymer precursors will not only mitigate emissions associated with earthen stabilizers but it will also alleviate demand for kaolin, PFA, GGBS while concurrently reducing the volume of waste clay directed towards landfill sites.

Particle size, though often overlooked, is a secondary factor affecting reactivity, especially in hand-processed clays where larger grain sizes may dominate. It is possible that much of the accepted material could be silt or sand-sized grains, thereby impacting pozzolanic reactions. Physical properties of the clays such as particle size distribution and fineness will therefore be studied. Furthermore, while semiquantitative analysis offers estimations, more precise techniques such as XRF and XRD Rietveld refinement are crucial for better quantification of mineralogy. This study not only highlights the potential of excavation waste clays as SCMs but also emphasizes the importance of thorough mineralogical characterization to optimize their utility in earthen applications.

Alongside compressive strength, durability is a key indicator for earthen materials. Future studies will therefore explore the implications of utilizing waste excavation clays on the mechanical and durability properties of earthen construction following their transformation into geopolymers.

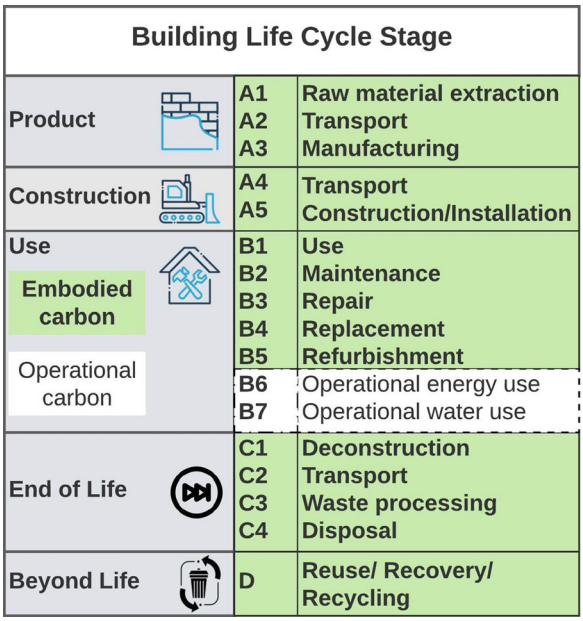

Fig. 1 Building life cycle stage and modules

is responsible for consuming half of the raw materials extracted, one-third of energy use, and more than half of global electricity, leading to 37% of greenhouse gas emissions, of which 9% is attributed to the manufacturing of building materials—termed "embodied carbon" (as illustrated in green color in Fig. 1). Projections indicate a potential doubling of embodied carbon emissions under the current trajectory and a rise of up to 49% of total carbon emissions from the building and construction sector [2]. In light of these findings, it is vital to acknowledge the pivotal role of the global building sector in advancing future sustainability goals, necessitating considerable attention to achieve sustainable development.

On the other hand, such an increase in embodied carbon highlights a critical gap in sustainability practices due to the lack of research efforts [3, 4]. The 2021 Global Status Report for Buildings and Construction by the United Nations Environment Programme underscores a glaring void in research on strategies to curtail embodied carbon [5]. Unlike operational carbon, which has been extensively studied, embodied carbon reduction strategies lack comprehensive long-term evaluation, particularly in manufacturing where small- to medium-sized enterprises struggle to both quantify and mitigate their environmental impact. This gap is not only a barrier to sustainability but also hinders progress toward the ambitious goals set by the United Nation for environmental stewardship. This challenge is particularly acute for small- to medium-sized manufacturers, which may lack the necessary knowledge, resources, and expertise to measure and monitor the environmental impact of their products.

Life Cycle Assessment (LCA) is instrumental in assessing environmental impacts and promoting sustainable practices. The efficacy of LCA depends on the integrity of Life Cycle Inventory (LCI) data, which requires high-quality data. Current LCI databases exhibit significant shortcomings, thereby undermining the precision and reliability of LCA findings [6]. As shown in Fig. 1, life cycle carbon emission comprises operational carbon (grey color) and embodied carbon (green color). Stage A encompasses the product and construction phases and includes A1–A5; they are all embodied carbon [4]. Stage B is the use stage, including substages B1 through B7. B6 and B7 generate operational carbon, and the rest are associated with embodied carbon [4]. Stage C is the end-of-life stage and includes substages C1 through C4. The beyond-life stage is the D stage [6]. Within the embodied carbon, A3 is the major contributor (45%) [7] followed by C stage (40%) and B1–B5 stage (10%) [8].

Environmental Product Declarations (EPDs) are standardized documents providing detailed and quantified information about the environmental impact of products or systems, and they are essential for gauging the environmental impact of products across their life cycle (ISO, 2010). As a result, adopting EPDs information enables stakeholders to determine embodies impacts of materials by utilizing data sources that outline environmental footprint of products or systems over their life cycle. Hence, the utilization of EPDs data offers a useful means to enhance the transparency of sustainable assessment, as well as to compare the impacts of production processes. Also, it is a crucial tool in decision-making in sustainable construction [9, 10]). Consequently, the reliability and completeness of EPDs are of paramount importance in ensuring the credibility and accuracy of environmental footprint assessment.

2 Background and Motivation

The previous work, including the authors', highlights two major barriers to obtaining reliable and precise LCI data [3, 11, 12]. First, data scarcity for life stages B–D is a significant challenge, primarily due to the changes in regulatory frameworks. Compliance with standard EN 15804 + A1 is limited to the product's initial life stages (A1–A3), leaving later stages at the manufacturer's discretion [13]. The newer EN 15804 + A2 standard, effective from July 2022, extends this requirement to include stages C1–C4 and mandates an end-of-life scenario analysis (stage D), introducing more complex regulatory expectations [14]. EPDs largely reflect the earlier standard, thus perpetuating the data gaps in stages B–D. Second, the A3 stage suffers from data inaccuracy issues [15]. Accurate A3 data, crucial to evaluating the environmental impact of a product, necessitates detailed recording of all manufacturing processes. Traditional methods for collecting this data are resource-intensive and cost-prohibitive, leading to limited LCA adoption by manufacturers and affecting the generation of EPDs.

The 2021 Federal Sustainability Plan, via Executive Order 14057, established the Buy Clean initiative to prefer low-carbon construction materials in federal projects [16]. This policy aims to reduce the carbon footprint of construction while boosting the domestic industry and job market. Federal agencies, like the General Services Administration (GSA) and the Department of Defense (DoD), encourage using sustainable materials with EPDs to inform their purchasing decisions, aligning with broader environmental and sustainability objectives [16]. Other government procurement (e.g., Department of Transportation) policies may favor or require products that have demonstrated environmental performance through EPDs or similar documentation. This is part of broader efforts to ensure government purchases support environmental and sustainability goals.

This proposed framework aims to fill the knowledge and data gaps by leveraging machine learning (ML) and collaboration with manufacturers, catalyzing a significant leap toward sustainable manufacturing practices. To this extend, this research proposal aims to leverage ML techniques to address data deficiencies in the LCI stages B through D and to integrate live manufacturing data to optimize operations during the A3 life cycle stage. The goal is to reduce the embodied carbon of construction products. Anticipated outputs include a data-driven framework and tool to help small and medium-sized manufacturers optimize their production processes, leading to more sustainable construction products. This effort is expected to contribute to developing precise and credible LCA results and EPD, thereby enhancing transparency and reliability in the construction industry's environmental assessments. The specific research objectives are:

Objective 1: Employ Machine Learning for Life Cycle Inventory Data Enhancement: Utilize ML to augment LCI data from existing EPDs, targeting life cycle stages B through D.

Objective 2: Develop screening Life Cycle Assessment Tool: Develop and pilot a plug-in tool integrated into existing open access LCA tools (e.g., OpenLCA) powered by Python scripts.

3 Proposed Methodology

Figure 2 outlines the proposed research plan comprised of (a) enhanced B through D stage data imputation, (b) A3 stage live data integration, and (c) tool development. At its core, the strategy begins with establishing a robust LCI database enriched by leveraging EPD and ML techniques. The subsequent phase leverages this data through an embodied carbon assessment, aided by an integrated screening LCA tool, to refine manufacturing processes through collaboration with manufacturers leveraging research trams' long-time collaboration with a wood manufacturer (refer to Sect. 4). In the following section, the research tasks under the two research objectives are explained.

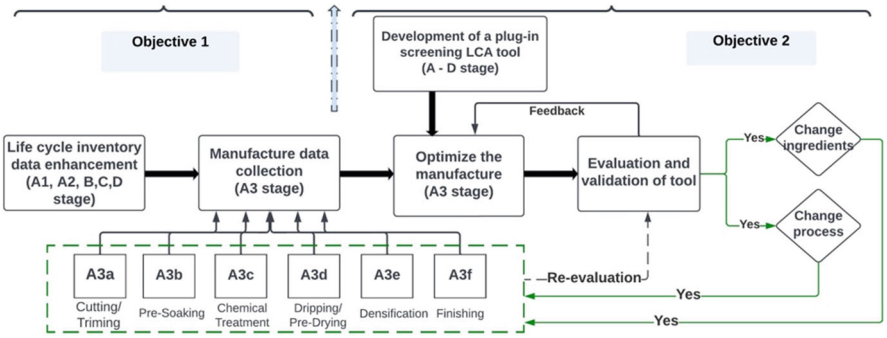

Fig. 2 Conceptual framework of proposed research plan

3.1 Employ Machine Learning for Life Cycle Inventory Data Enhancement

As of December 2023, there are over 130,000 construction product EPDs available globally. A largest number of construction product EPDs are reported to come from the United States, with over 80,000 concrete EPDs (conformed to ISO 21930) listed in the United States. Additionally, there are over 16,000 Verified EPDs (conformed to EN 15804) of construction products registered globally [10, 17]. These figures indicate a significant and growing number of EPDs for construction products, reflecting the increasing emphasis on environmental performance and transparency in the construction industry. We will acquire the existing EPD data via an automated web-scraping tool developed in Python. The available EPD data from multiple sources (e.g., EPD International Library) will be downloaded [18]. Available in an XML format, the downloaded EPDs will undergo parsing, consolidating their contents into a database for future reference. Critical information extracted from the EPDs includes all key input and output of product LCA results, such as product or service names, material classifications, the geographical context of the study, quantitative references, and the life cycle stage impact assessment results concerning specific impact categories (e.g., global warming, acidification potential, ozone depletion potential). This descriptive and categorical information will serve as inputs for the ML algorithm responsible for predicting impact assessment results in the given category.

Natural language processing (NLP) and random forest algorithms are chosen for enhancing Life Cycle Inventory (LCI) data because they provide powerful and complementary capabilities to address the specific challenges associated with LCI data.

NLP is crucial for LCI enhancement because it enables the extraction and structuring of relevant information from large volumes of unstructured text. In the context of LCA, much of the LCI data is embedded in textual product documentation, such as Environmental Product Declarations (EPDs). These documents contain detailed but unstructured data about the environmental impact of products. NLP

facilitates the interpretation, categorization, and transformation of this data into a structured format that can be further analyzed and compared. Through steps such as named entity recognition and text classification, NLP can organize and prepare LCI data for quantitative analysis, which is essential for a reliable LCA.

The random forest algorithm, an ensemble tree-based ML method, was chosen due to its robustness and accuracy in dealing with complex datasets that may have nonlinear relationships and interactions between variables. Random forests are particularly effective for prediction and classification tasks, even when datasets are imperfect or incomplete, which is often the case with LCI data. They work by constructing multiple decision trees during training and outputting the mode of the classes for classification tasks. This method is less likely to overfit than individual decision trees and is known for handling large datasets with many input variables—common in LCI datasets.

By employing these methods, the framework can process and enhance the LCI data, particularly addressing the common issues of data scarcity and inaccuracy in stages B to D of the LCI. This approach is expected to improve the quality and reliability of LCI datasets, thus leading to better-informed decisions in the context of sustainable construction and environmental stewardship.

3.1.1 Data Collection and Processing

The intention is to transform the EPD data into a structured LCI database using NLP [19], thus facilitating the analysis and comparison of products based on their environmental impacts. This structured, numeric database could then be utilized for various assessments and evaluations in the field of sustainability and environmental science. As illustrated in Fig. 3, the process comprises six steps.

The initial stage is text preprocessing, where raw text data is cleaned and formatted to ensure uniformity. This step may include converting all text to a standard case, removing special characters, and correcting typos, among other things. It will be followed by the second step, named entity recognition (NER) [20], which involves identifying and classifying key information from the text into predefined categories such as product names, and geographical locations. This is crucial for extracting specific pieces of data from unstructured text. After identifying entities, the third step is text classification, categorizing descriptions into predefined

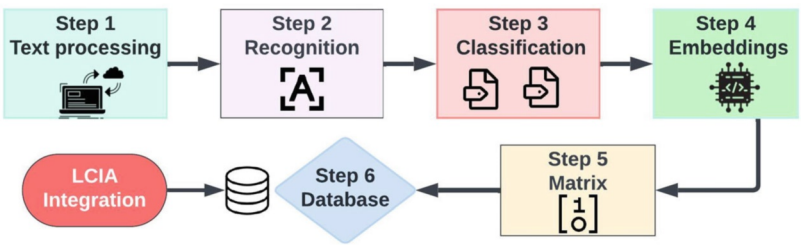

Fig. 3 Flowchart depicting the six-step process of data collection and processing

classes. For example, material descriptions from EPDs will be classified into material types or life stages of the product [21]. This categorization helps in organizing the data for subsequent analysis. Following classification, the fourth step is term frequency-inverse document frequency (TF-IDF) scores and word embeddings. These are techniques to quantify the importance of words or terms within the dataset. TF-IDF highlights words that are more relevant to a document in a corpus, while word embeddings provide a vector representation of words that captures their context and semantics. These methods help us understand the significance of terms and their associations with different categories [22]. After the processed text is classified and highlighted, the text data will then be converted into a numeric matrix in the fifth step, which is expected to be large, with thousands of rows and columns. This matrix quantifies the text data, with each row representing an item (such as an EPD) and each column representing a feature extracted from the text. In the last step, the matrices created from the above steps will be encoded and stored in a database. This structured format is essential for efficient retrieval and analysis. By integrating NLP, the EPD data can be transformed into a structured, numeric LCI database, and stored in the open-access database (repository) along with encoded information for further use in the following.

3.1.2 Quality Assessment and Data Imputation

This step involves examining data integrity, consistency, and reliability. We will employ data profiling techniques and statistical analysis to identify outliers, inconsistencies, and any discrepancies that may compromise data quality. The data profiling techniques will include but are not limited to range and frequency analysis, pattern recognition, and null/missing value analysis [23]. The statistical analysis includes a variety of techniques, such as correlation analysis and anomaly detection. Additionally, we will assess the completeness of the datasets to ensure that all necessary variables are present and properly populated. In parallel, we will evaluate the relevance of the collected datasets to the context of construction product EPDs. This evaluation is crucial to determine whether the data aligns with specific performance goals related to embodied energy and environmental impact categories. By undertaking this task, we aim to provide an informed analysis of the collected data's quality, completeness, and relevance, ensuring that only high-quality and pertinent datasets are used for further analysis.

ML models, like decision trees and clustering algorithms, will be utilized to detect missing data patterns and anomalies in the data. Clustering algorithms will help identify data points that do not conform to established patterns, while dimensionality projection can unveil latent structures and identify inconsistencies. We will also explore outlier detection methods based on ML models to flag and rectify data errors, ensuring the dataset's integrity. Additionally, we will conduct temporal analysis to understand the temporal variations in the LCI data using techniques like time series analysis to identify trends and patterns over time. By the end of this subtask, we will have a comprehensive understanding of the data deficiencies and a strategy for applying ML methods to rectify them.

3.1.3 ML-Driven Data Enhancement

In statistics, imputation refers to the process of replacing missing data with substituted values. We will develop imputation models using both traditional and advanced methods that reflect a strategic approach to address the varying complexities and nuances of missing data in datasets. The traditional methods include k-nearest neighbors (k-NN) and regression analysis. For example, the k-NN algorithm can be used for estimating continuous variables via a weighted average of the k-NN, weighted by the inverse of their distance. For regression imputation, available information for both complete and incomplete data is used to predict the missing value of a specific variable. Fitted values from the regression model are then used to impute the missing data. However, such a model does not supply uncertainty about the data. To mitigate this issue, we can leverage stochastic regression that adds the average regression variance to the regression imputations to introduce error [24]. These models will learn from LCI data patterns and relationships to impute missing values reliably.

Besides the above-mentioned traditional statistical methods, we will employ advanced imputation techniques such as autoencoders and generative adversarial networks (GANs) to enhance the imputation process. An autoencoder consists of two networks: an encoder and a decoder [25]. The encoder encodes an input data sample to a compressed representation in the latent space. The decoder decodes the latent representation back to reconstruct the data sample as close as possible. There are two kinds of autoencoders: regularized autoencoders and variational autoencoders. Variations of regularized autoencoders include sparse, denoising, and contractive autoencoders. Unlike autoencoders, GANs are explicitly set up to optimize for generative tasks [26]. A GAN has two networks: a generator (G) and a discriminator (D), which contend with each other in a zero-sum game. G learns to synthesize a generic sample from an unknown noise distribution or a fake sample with a specific condition or characteristic, while D distinguishes between instances from the true data distribution and candidates produced by G.

To deal with the problem of increased noise due to imputation, we will experiment with multiple imputation that averages the outcomes across multiple imputed datasets. In particular, multiple imputation with denoising autoencoders (MIDAS) [27] uses denoising autoencoders to learn fine-grained latent representations of the observed data, which is more accurate and efficient than traditional multiple imputation methods. Furthermore, we will investigate the use of GAN, such as the generative adversarial imputation net (GAIN) [28] for imputing missing data. GAIN uses a hint vector to ensure that D forces G to learn the desired distribution. The hint reveals partial information D about the missingness of the original sample, which is used by D to focus its attention on the imputation quality of particular components. To impute multivariate time series, we will employ a modified gate recurrent unit for imputation (GRUI) [29] in GAN to model the temporal irregularity of the temporal data by introducing a time decay vector to decrease the memory of the GRUI cell. In addition, we will apply the noised compressing and reconstructing

strategy [20, 30] to improve imputation accuracy [27, 28]. We anticipate that the diverse datasets we collect from multiple sources and across different construction products will exhibit various characteristics and distributions. This renders the same network trained on one dataset less effective for the imputation of another dataset. To cope with this issue, we will apply transfer learning where a pre-trained model on one dataset can be used as the starting point for repurposing on another dataset, allowing rapid progress or improved performance when modeling the new dataset. At the end of this task, we will have (i) a set of reliable imputation models tailored for LCI data and (ii) guidelines for the application of transfer learning in the context of LCI data imputation. Hypothesis 1a will be tested; the ML-enhanced LCI dataset will reveal previously unrecognized environmental impacts during the B through D.

3.1.4 Develop a Screening Life Cycle Assessment Tool

To develop this tool, we will use open-access LCA software to integrate real-time production stage data. We will embed the developed ML models into a plug-in interface compatible with one selected open-access LCA software tool. This will include establishing interfaces for data input, user interaction, and output visualization. We will utilize the API to design an intuitive UI/UX for the plug-in that allows users to easily input data, run the ML models, and interpret the results. This plug-in tool aims to streamline the LCA process, making it more user-friendly and actionable for small manufacturers who seek to optimize their processes and reduce their environmental footprint. Figure 4 illustrates the architecture for a plug-in software tool. It delineates the integration of an open-access LCA database with an enhanced

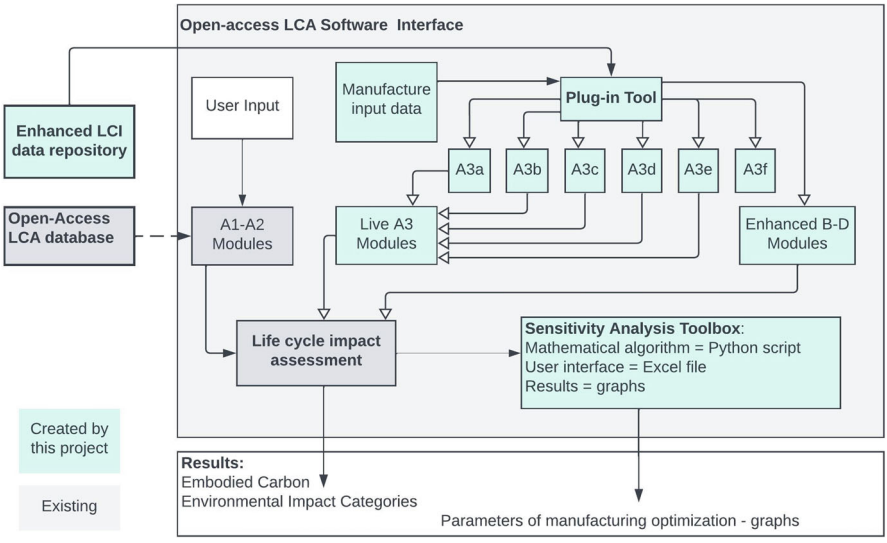

Fig. 4 Architecture of the developed plug-in tool within open-access LCA software

LCI data repository, both of which are foundational elements of the tool. The user interacts with the software through an interface that accepts user input, which informs the A1–A2 modules representing the initial stages of product life. It also interfaces with live A3 modules, which are updated in real time and reflect the manufacturing stage of the product life cycle, denoted as A3a through A3f. These modules feed into a central plug-in tool that processes manufacture input data, combining it with the LCIA to determine the environmental impact. This will focus on embodied carbon outputs along with other environmental impact categories. The tool's sensitivity analysis component, powered by a Python script and accessible through an Excel user interface, allows for the examination of different parameters and their effects on the manufacturing process. The outcome of this analysis is displayed through graphs, providing a visual representation of potential optimization pathways for reducing environmental impact.

After initiating the design of the interface, we will conduct performance tuning of the ML models within the plug-in, optimizing for speed and resource efficiency to handle the computational load of running complex LCA analyses. Such an interface will allow users to input enhanced B–D data and live A3 data collected from the manufacturing process to produce immediate and accurate outputs of embodied carbon and other environmental impacts of the product. The principle of the developed tool is schematized in Fig. 4; the modules stored in the enhanced LCI data repository are parameterized models written in Python™, which calculate chemicals and energy consumption and substance emissions at the level of each production process (e.g., A3a cutting, A3b pre-soaking). Evaluation metrics that will be used to evaluate the effectiveness of the proposed tool are (a) simulation time, (b) ease of use by non-LCA experts, (c) the understandability of the interface, (d) the clarity and visual presentation of results, and (e) the usefulness of information to the decision maker (i.e., manufacture).

3.2 Challenges and Potential Mitigation

The proposed framework's first challenge is related to EPD's availability and quality. A significant concern is the frequent omission of critical information, such as material properties (e.g., density or grammage) of the reference flow. The EPD will be downloaded from different sources in different languages (e.g., EPD Norway, EPD Italy). Even though the EPD follows a similar format, NLP models often struggle to perform well across diverse languages and specialized domains due to the specificity of language and context [31]. The mitigation strategy is to build models that are either designed to understand multiple languages or are trained explicitly on domain-specific data, which can improve performance across different languages and specialized fields [32]. The second challenge is the applicability of developed ML-enabled tools to other categorical construction products (e.g., steel beams). Over-customization can be avoided by providing the functionality in the tool to allow users to revise and define the sub-steps in A3 (e.g., A3a) and group and

ungroup some sub-steps. The research group will consult and test the function with the industry collaborators (e.g., the American Institute of Steel Construction). Such flexibility and functionality will ensure the adaptability of the proposed tool to other products with different processes.

4 Preliminary Work

Since 2021, the research team has been working with a startup wood manufacturer to commercialize an innovative wood cladding panel product that has exceptional durability, strength, and toughness that is comparable to steel, yet with much lower carbon intensity. Meanwhile, compared to conventional wood, the innovative product is fire-resistant and dimensionally stable at varying temperatures, hence making it sustainable and resistant to extreme weather. To produce such high-performing products, iterative LCA has been used to optimize the manufacturing process; carbon emission and other environmental impact categories are used as measure units. The research team has conceptualized a Screen LCA framework (using a conventional LCA tool) that enables the integration of real-time A3 stage process data to produce a preliminary analysis for InventWood. Figure 5 illustrates the created framework that divides the A3 stage into sub-stages to ease input variables by InventWood. Those sub-stages are aligned with the manufacturing process

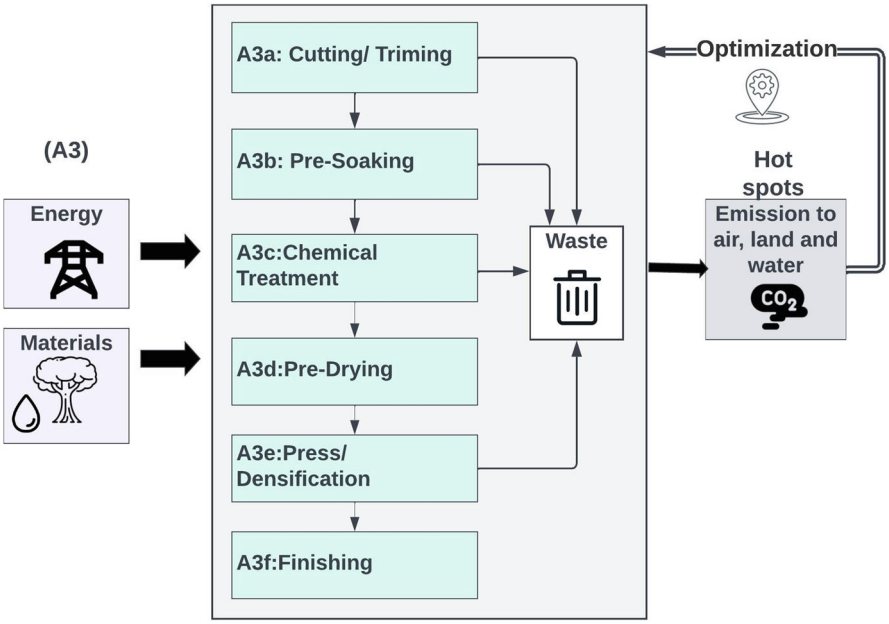

Fig. 5 Framework of integrating live A3 data

and can be easily understood by manufacturers who are not professional LCA professionals, making it easier for manufacturers to collect and input data. With such a framework, the team used the preliminary emission results to hone in on the most carbon-extensive sub-steps for improvement. For example, using the design data, we identified the top three carbon-intensive sub-processes as chemical treatments, press/densification, and pre-drying systems. Based on this, manufacturers have been working on optimizing the drying system to reduce carbon emissions and energy use. The manufacturing optimization process is ongoing, and the target time to commercialize wood panel products is three years.

5 Conclusion

The proposed research represents a fundamental methodology and data processing shift in environmental impact assessment in the building and construction sector. The proposed research is poised to bridge three critical knowledge gaps. First, by infusing ML into the screening phase of LCA, we aim to revolutionize data management, surpassing the efficiency and precision of conventional methodologies. Second, we plan to enhance the current LCI database, leveraging ML algorithms to remedy the prevalent absence of data from life stages B–D. The ML insights are designed to be transferrable, enabling the rectification of similar data voids across various sectors. Third, the research endeavors to conceive and validate a novel ML-enabled tool that seamlessly integrates with existing open-access LCA platforms. Implementing the algorithm within InventWood's manufacturing process offers a strategic showcase of its efficacy, promoting its uptake among small-to-medium manufacturers, who are normally lack of expertise and funding to hire professional life cycle assessment modeler. This targeted application will function as a live demonstration. The pilot testing will be invaluable for accruing user feedback, which will refine the tool's intuitiveness for businesses lacking specialized LCA knowledge. The empirical insights derived from this application are pivotal in formulating a set of guidelines and best practices. By validating the tool's benefits through measurable results and enabling sector-specific customizations, the research will establish a potent, accessible solution for small businesses aspiring to elevate their sustainability measures in an economically viable way.

1 Introduction

Nowadays, there is a noticeable shift toward putting more emphasis on reusing building elements rather than constructing new ones. This paper is dedicated to revealing the practical implications of reusing building materials from the demolition phase to construction process, as demonstrated through a case study—Grensen 9b in Oslo, Norway. With its ambitious goal of attaining BREEAM-NOR v6.0 certification at the "Very Good" level, alongside an 93% reduction in CO_2eq-emissions from building materials compared to a new build, Grensen 9b serves as a pilot study of the potential impact of practices on sustainable development within the building industry.

By scrutinizing the steps involved in identifying and preserving building elements, the study seeks to not only address the environmental consequences of reuse but also contribute to a significant reduction in the demand for using new materials, subsequently minimizing the associated carbon footprint.

The study explores design strategies that promote future reuse, aiming to significantly reduce carbon emissions and support climate change mitigation and resource optimization. It is part of a broader research project that investigates the feasibility and best practices for reusing building elements. The ultimate goal is to demonstrate the transformative potential of a sustainable material reuse platform, offering insights applicable across the building industry.

In Sect. 2, we introduce the methodology: concept of sustainability in reusing. Section 3 presents the case study and illustrates the findings from the case study: practical barriers in reusing of building materials providing systematic implications of mapping reusable building component in case study in Norway, while Sect. 4 concludes this paper.

2 Methodology: Concept of Sustainability in Reusing in Norway

2.1 Definition of Reuse in the Built Environment

2.1.1 Used Materials

Reuse in the built environment is not a new concept; it is rooted in common sense. Before the industrialization of the building industry, building materials were the result of hard work and not something to be wasted. The old Norwegian lumber buildings provide a great example of design for reuse—they could be disassembled, moved to another location, and reassembled.

As the industrial revolution progressed and an efficient global logistics ecosystem emerged, building materials became increasingly affordable. Consequently, the perceived value of materials no longer needed to exceed the calculated payback time for building projects. This has led to a significant volume of resources with plenty of technical lifespan left being treated as waste.

At the same time, our planet is undergoing a resource crisis. The extraction and processing of raw materials have catastrophic impacts on biodiversity, untouched lands, contributing to widespread air, water, and soil pollution, as well as significant CO2 emissions. Far from all environmentally certified supply chains can be trusted.

The contemporary circular economy movement aims to reintroduce common sense into the value chain of our built environment, this time addressing these environmental challenges.

To reuse a building material or component is to utilize it after it has already served a function in a building or other installation. It can be used as it is or can be modified, repaired, and refinished. It can serve its original purpose or be repurposed entirely. Material recycling involves melting, shredding, or processing a material so that it can be used in its shredded state, molded into a new product of the same material, or combined with other chemicals or components to create a new product.

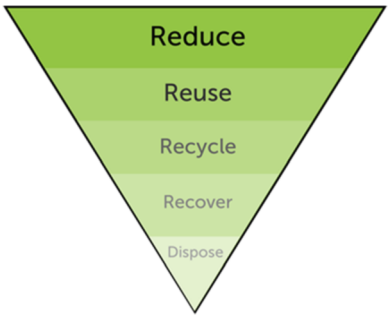

Fig. 1 The waste reduction pyramid shows the preferred means of reducing waste starting with reduce [1]

Reuse is ranked second in the waste pyramid (see Fig. 1, below waste reduction and above recycling. However, reusing is an effective way to reduce waste, and it could therefore be argued that it should be prioritized as both the first and second steps in waste and resource management schemes for building projects.

2.1.2 Design for Future Reuse

In the Guide for procuring mapping of reusable building materials [2], a material that is suitable for reuse is described with the following properties, which also describes what properties to design after for future reuse.

- Robust materials: Resistant and homogeneous materials and components that can reused for several generations of buildings.
- Flexible connections: Reversible connections between building components such as simplifies disassembly and reassembly. This can be the use of mechanical couplings, such as bolts or screws rather than gluing or welding.
- Remaining life: Building components with a long remaining life, that is high technical quality, little wear and damage.
- Volume: Large lots can yield a greater return on the effort to dismantle for reuse. Greater dividends can, for example, be in the form of greenhouse gas savings, financial savings, or possibility of turnover.
- Demand: Building components with cultural–historical value, local identity, sentimental value, high economic value or other special characteristics can increase the attractiveness of reuse.
- Environmental effect: Building components that provide large environmental savings when reused, for example, where production or transport causes large emissions or other environmental problems.
- Cost/benefit: Building components that provide cost savings when reused compared to buying a new product, that is, building components with high economic value.
- Associated drawings and documentation: Information on building components among other drawings, user-specific product information, product documentation, installation instructions, and information on building systems and maintenance.

2.2 Legislative and Regulatory Conditions for Reuse in Norway

In Norway, there have recently been made changes in legislation regulating the sale of used building materials. Effective 1 July 2021, it is no longer mandatory to re-document the CE marking of used building materials originally introduced to the market before 1 January 2014. However, this exemption does not apply to products intended for use in the main structural frame of a building. The responsibility for documentation now lies with the buyer and their consultants, who must sign off on the finished project.

The legislation changes regarding the mapping of reusable building materials, effective 1 June 2023, have greatly impacted the supply side of the market. It requires every refurbishment or teardown project over 100 m^2 or generating over 10 metric tons of waste to map any reusable building materials and compile the quantities and relevant mandatory parameters into a report. This is an essential first step toward establishing a viable market for reusable materials. Subsequent steps will involve the publication and promotion of available stock, as well as regulatory changes to set requirements for reuse in refurbishments and new building projects.

Another legislative change that could significantly benefit the reuse market is the removal of mandatory VAT on used goods sold for reuse purposes. Currently, such legislation exists for the B2C market, including typical thrift stores and secondhand furniture markets. With some adjustments, this legislation could also regulate the B2B market for reusable building materials.

2.3 Market Conditions for Reuse in Norway

2.3.1 Internal and Open Markets in the Building Industry

In the early stages of reuse within the building sector, external reuse was hindered by the requirement for redocumentation of the CE marking for many product groups whenever there was a change of ownership. This led to a common understanding that internal reuse within a single property portfolio manager was the most efficient resource management strategy.

As legislation changed without barrier of the documentation requirement, a new challenge emerged: the lack of an open two-sided marketplace to efficiently distribute the substantial volumes of building materials mapped and registered each year. Rehub.no, an online two-sided marketplace, was launched in 2021 to address this need. Although it initially had basic functionalities, its minimum viable product (MVP) format lacked the capacity to handle high volumes. A relaunch is scheduled for later in 2024, on a new platform designed to handle large volumes of data.

To facilitate the large volumes of reuse, it is crucial that each project has access to extensive databases containing materials available within the project's timeframe.

Relying solely on a database representing internal portfolios is insufficient to optimize resources across the entire building industry.

Timing is another critical factor in optimizing the reuse of building materials. Buyers require sufficient time to design with available reusable materials without incurring the added expense of intermediate storage for materials that may not yet be secured for final design. Accessing the databases of materials, a year or two in advance could secure an efficient process for the next project. Keeping internal databases off the open market until all internal use options have been exhausted, limits opportunities for other projects to utilize the materials in the portfolio. Opportunities for reuse can then be lost due to time constraints.

2.3.2 Markets Across Industries

One aspect of reuse is its ability to foster creativity and innovation. As projects seek to optimize resource utilization, reuse is creating markets across industries. Many sectors outside the building industry specialize in trading high-quality materials and have a tradition of waste management at the lower levels of the waste pyramid. The transport, offshore, and industrial sectors all represent such markets with significant potential for symbiosis with the building industry.

An example is the reuse of subway steel tracks that were originally destined for the scrap metal pathway as described in the case study Grensen 9b in Sect. 2 of this paper.

2.4 Impacts of Reuse

2.4.1 Resources

If the supply chain for any given product does not begin with derivatives of other production lines or recycled materials, it starts with the extraction of raw materials. Annually, raw materials amount to nearly 40 billion tons [3]. By 2025, it is estimated that the global volume of waste generated will reach 2.2 billion tons [4]. According to the same source, construction and demolition waste represent approximately 30% of that number.

Applying the estimated potential for reuse, which is 10% according to Norwegian reports [5], the potential for reuse is 66 million tons of waste each year. This equates to removing 66 million tons of waste from the waste stream, along with all the transport and post-consumer processes associated with these materials. Additionally, the corresponding amount of raw material extraction linked to producing 66 million tons of finished products, plus packaging, can be eliminated from the value chain annually. Altogether, this represents a powerful impact on resource conservation and waste reduction.

2.4.2 CO_2 Emissions

By reusing building materials, there are significant direct CO_2 reductions throughout the entire lifecycle of a material. The primary CO_2 reduction arises from the avoidance of using new materials, thus impacting the entire supply chain, theoretically from raw material extraction to delivery to the building site (A1–A4 stages). While a single project may not directly affect the volume of production, the cumulative effects must be attributed to the replacement of individual materials, creating incentive and logic in CO_2 accounting.

It is important to note that the new function of the used material may differ from its original use. For example, a used carpet may be reused as a sound-insulating layer under floorboards. In this case, the CO_2 reduction is attributed to the emissions avoided from producing a new sound-insulating layer, not the carpet itself.

Another aspect of CO_2 emission reduction through reuse is at the end of the material's life. By diverting the used material from the waste chain, CO_2 emissions from transport and end-of-life processing, such as recycling or incineration, are avoided. However, there are additional CO_2 emissions associated with transport, testing, storage, washing, refinishing, and the potentially shorter remaining lifespan of reused materials, which may result in an extra replacement.

Analyzing the total CO_2 reduction is crucial for making informed choices, particularly for significant building components. In Norway, there is a standard consensus that reused materials represent approximately 20% of the A1-A3 CO2 emissions of new materials, according to the methodology outlined in Futurebuilt's guideline [6].

2.4.3 Logistics

The impacts on logistics can be categorized into two main areas: logistics at the project or material level, and logistical impact on society as a whole.

At the project or material level, logistical impacts often necessitate additional planning, coordination, and risk management practices that are not yet standard in the building industry. Materials can be sourced from various places, including the refurbishment of the building itself, a physical marketplace, or a donor source such as another building or installation in a different industry. If the material comes from a donor source, a simplified chain of events might look like this:

1. Seller and buyer agree on the sale terms and responsibilities for the material at each stage. They also agree on a general timeframe for pickup.
2. The seller dismantles and packages the materials.
3. The logistics service and seller coordinate the timing and pickup location for the materials.
4. The logistics service picks up the materials and transports them to intermediate storage facilities.

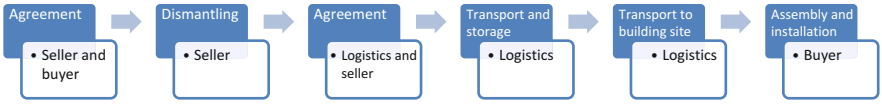

Fig. 2 Diagram of supply chain of logistics for material that comes from a donor source

5. The logistics service transports the materials from storage to the building site.
6. The materials are assembled and installed on the site (Fig. 2).

2.4.4 Waste

Waste poses a significant burden on the planet and society, despite heavy regulation in Western countries aimed at preventing pollution and logistical congestion. Many examples of western waste ending up in unregulated countries have been documented. To address this, as of 1 January 2021, Norway has implemented regulations prohibiting the export of plastics to developing countries. Furthermore, waste logistics companies are now required to document environmentally friendly treatment of all waste fractions [7].

In the building material supply chain, waste is generated during the extraction of raw materials, the production process, installation, and most significantly, at the end of life. After material reduction through design and cofunction, reuse is the single most effective way to reduce waste. The potential for waste reduction by reusing affects the whole material life cycle.

2.4.5 Economy

The transition to a circular economy is still in its infancy, but significant changes have occurred in the past 5 years regarding the actual and perceived economics of reusing building materials. In 2019, there was a prevailing belief, based on actual cases, that reuse automatically increased project costs. During this time of uncertainty, the expenses associated with research, technical testing, risk management, legal inquiries, chaotic logistics, and redesign often exceeded the costs of purchasing new materials. An example of the wide range of costs connected to reuse that could underline these perceptions, the project Kristian August gate 13, an ambitious reuse project finished in 2019, reported that reuse costs ranged from 66% more expensive and 63% saved costs compared to new materials (Excluding project design costs) [8].

With insights garnered from each reuse project over time, a clearer understanding emerges regarding the relevant costs, risks, and benefits associated with each product. Different segments of the building industry have recognized the value of developing cost-efficient processes for their respective product groups.

3 The Case Study: Grensen 9b

3.1 An Introduction to the Project

Hidden in a back alley in the heart of Oslo, Norway, lies a small office building slated for an overhaul to welcome new tenants. Grensen 9b, a 3400 m^2, six-story high refurbishment project, is owned by two pension investment funds: *Oslo pensjonsforsikring* (OPF) and *Pensjonskassen for Helseforetakene* i *Hovedstadsområdet (PKH).* They have set ambitious targets for reuse in this project and have enlisted Magna Construction Management to lead the process, with Ramboll Norge AS ensuring the project reaches its ambitious sustainability goals. MAD Architects and SANE Interior Designers are behind the new design, while the rest of the team has been handpicked by the project manager. Grensen 9b aims to achieve BREEAM-NOR v. 6.0 Very Good Certification and has also set a goal to meet the FutureBuilt criteria v. 2.0 for a circular building as part of the BREEAM certification.

3.2 Reflections Around the Impacts of Reuse in This Project

The project's ambitious goal to meet the FutureBuilt criteria v 2.0 for a circular building was just the beginning, as the project has aimed to exceed these goals. As of March 2024, as the project nears its completion, the status is as follows (Fig. 3):

The total saved resources from reuse in the project are almost 50 tons. These 50 tons only represent the reuse of added materials and does not consider the reuse of the existing building which we classify as retention of the existing building.

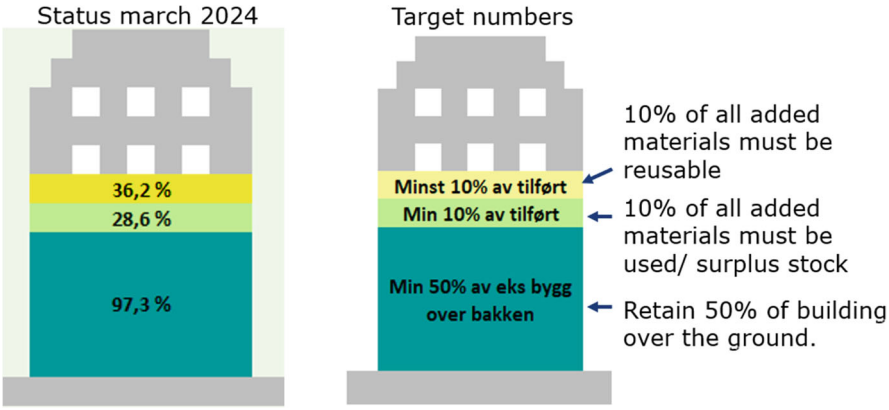

Fig. 3 Future Built goals on Veight % versus stats as of March 2024

3.2.1 CO2 Emissions

Most of the reduction in CO_2 emissions in this project comes from the reusing of the existing load-bearing structure, roof, facade, and floor slabs. This alone surpassed the goal of a 60% reduction in CO_2 emissions from building materials compared to a new office building. Therefore, the evaluation of whether to reuse a particular material or product was not solely based on its contribution to overall CO_2eq emissions but was assessed on a cost/effort versus effect basis. Factors considered included time and cost implications, potential impacts on the project timeline, adherence to Future Built weight percentage goals, and potential effects on CO_2eq emissions and resource consumption beyond this project. Throughout the project, the goal has been to develop use cases that are relevant and transferable to other projects on a larger scale, thereby creating value for the entire building industry.

3.2.2 Logistics

Grensen 9b is located at the end of a back alley in one of the busiest parts of Oslo. It is a small project with limited storage and logistical flexibility. This necessitates a well-organized building site and additional resources for handling the dismantled reusable building materials.

3.2.3 Storage

There are two options for storage: inside Grensen 9b and at the "Sirkulær ressurssentral," a storage facility dedicated to the reuse market on the outskirts of Oslo center. While there are numerous services offering various types of storage options, we chose these two for this project. However, this decision had both advantages and disadvantages:

Inside Grensen 9b:

- Challenges: The limited storage space within the small project area meant that the inventory had to be frequently moved to accommodate ongoing refurbishment activities. This resulted in time-consuming efforts and damage to the materials. Additionally, materials not packed in plastic were exposed to dust from the teardown process. While internal storage reduced costs associated with transport and external storage, the overall cost of moving materials internally exceeded the savings. In hindsight, external storage would have been a better option from the start.
- Benefits: Storage conditions inside Grensen 9b were generally dry and warm. CO_2 emissions from transport to and from intermediate external storage were saved.

External storage facility "Sirkulær ressurssentral":

- Usage: Primarily used for materials sourced externally.
- Description: The facility comprised a large tent repurposed from an outdoor construction project. The climate inside the tent mirrored the outside temperature and air humidity, although the materials were shielded from rain, snow, sun, and wind.
- Additional notes: Later into the storage period, an inflatable tent was introduced to provide partial warmth, but it was considered too late to utilize effectively. In hindsight, this decision may have been incorrect, as the dry and warm conditions of the inflatable tent would have been beneficial, particularly for wooden panels intended for use by carpenters.

3.2.4 Transport

Most of the materials sourced from Grensen 9b itself did not require transportation outside the building, except for those materials that needed cleaning at an external facility. Two examples of this are the metal tubes from the ventilation system and the glass bricks, which were picked up by the cleaning service provider and returned appearing brand new. However, materials sourced from other locations needed to be transported. In most cases, this transportation was organized using personnel and vehicles from the main contractor. For materials requiring off-site processing, such as steel beams and wooden materials, the welder or carpenter would arrange transportation to and from their facility.

3.2.5 Waste

Reusing played a significant role in reducing waste from the teardown phase of Grensen 9b. A total of 31.4 tons of building materials and components were salvaged from the teardown process and repurposed as high-value building materials in the finished product. Additionally, 32.5 tons of building materials and components were diverted from waste streams of external donor projects and reused in Grensen 9b, further contributing to waste reduction and the utilization of high-value building materials and components.

3.2.6 Economy

Although reuse has become a significant aspect of Grensen 9b's identity, the project stands out for achieving this level of reuse without incurring any additional costs. In fact, the cost per square meter is lower than that of other similar refurbishment projects in central Oslo. By reallocating funds from the purchase of new materials to the logistics and processing of used materials, the overall project budget has remained unaffected. Smart decision-making regarding what to reuse and where

has been a key factor in this success. For example, the team opted to reuse structural components only in the secondary structural system, such as staircases. Additionally, the project benefited from a highly competent team that understood how to manage the risks associated with the reuse of each item.

3.3 Practical Implications

Reuse is still in its early stage of development in the building industry, and for many participants in Grensen 9b, it marked their first encounter with it. While there are some good examples of best practices and pitfalls in reuse projects, there is still a lack of established infrastructure or procedures to rely upon. Moreover, building projects vary greatly in their contractual organization, which can significantly impact the reuse process. In Grensen 9b, the contractual structure involved client-managed subcontracts, with *Magna Construction Management* hired to represent the developer throughout the project phases. Having a consistent project team from the early stages through to the design phase and even handover proved to be impactful, particularly in considering the long-term implications of decisions regarding reuse made in the early stages.

Creating a consistent procedure for reuse was not initially a priority for this project. Instead, each member of the design team, management, and subcontractors sought opportunities for reuse within their own disciplines and networks. Despite this decentralized approach, driven by individual desires to make reuse work, the project achieved more than anticipated. Moving forward, it is our responsibility to share both successful strategies and lessons learned from Grensen 9b, and to outline general procedures that emerged from the project.

4 Discussion: Analysis and Findings

4.1 Analysis and Findings of the Impacts of Reuse in the Case Study

4.1.1 CO2 Emissions

Grensen 9b is close to, but not yet completed and therefore the final CO_2-calculations have not been completed, preliminary figures indicate total CO_2 emissions of 97,293 kg CO_2eq within the system boundaries set by *Tek17* [9]. These calculations encompass A1–A3 (production of material), A4 (transport to the building site), and B4 (replacement throughout the building's lifetime, set at 60 years). With a building area of 3400 m2, this equates to total CO_2eq emissions from building materials of 0.48 kg CO_2-e/m2/year. Comparatively, the reference number provided by BREEAM-NOR V6.0 is 6.8 CO_2-e/m2/year. As of November 2023, the project has achieved a 93% reduction in CO_2 emissions. These calculations were conducted by Ramboll Norway.

The primary driver of this reduction is the retention of almost all structural elements and the building envelope. While reuse has contributed to CO_2 reductions, it has not been the sole determining factor in achieving the project's goal of a 60% CO_2 reduction for Grensen 9b. For this project, the CO_2 calculation tool OneClick LCA was utilized. This program employs the same methodology as the FutureBuilt methodology for calculating emissions from reused materials, attributing 20% of emissions from A1 to A3 of the replaced new material if it is replaced by the same type of material.

4.1.2 Logistics

One of the key insights gained from this project was the recognition that storing materials within the building being renovated, with the aim of saving costs on external storage, ultimately proved to be more expensive. This was primarily due to the substantial resources required to continually move materials around within the building while the renovation progressed from one area to another.

It is estimated that approximately 400,000 NOK was spent on reallocating all the materials multiple times during the construction phase. Moreover, this internal storage approach resulted in damage to many materials and components, further adding to the project's costs and inefficiencies.

4.1.3 Waste

As the construction phase nears its completion, the project is compliant with Norwegian regulations, which requires that 70% of all waste must be prepared for reuse or material recycling. However, it is important to note that some final reports from the renovation company are still pending, and these reports will provide additional clarity on the project's waste management efforts. The project is scheduled for completion in May 2024 (Fig. 4).

4.1.4 Economy

For this project, the goal was to achieve as much reuse as possible without impacting the project's bottom line. The final calculation for Grensen 9b has not yet been completed as the project is ending in May 2024. So far, reuse has not increased the project's budgeted costs.

Areas where costs associated with reuse could have been reduced include the following:

Storage: Utilizing an external facility for storage could have reduced costs associated with reallocating materials internally multiple times.

Quality control of purchased used materials: Ensuring the quality of purchased used materials, such as carpet tiles, required more quality control measures beyond checking samples from the stock.

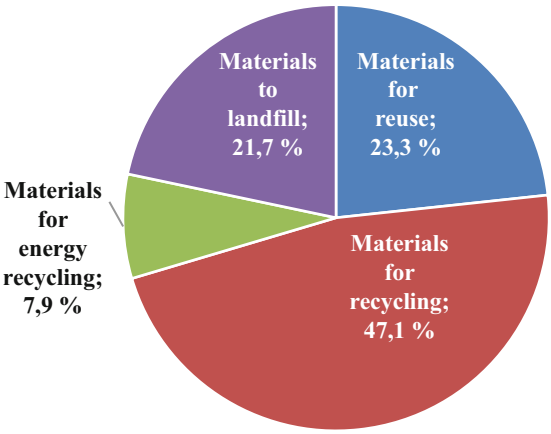

Fig. 4 Distribution of waste in Grensen 9b for demolition and construction phase

4.2 Conclusion: Lessons of Experience

Through analysis of the reuse in the building industry and case study such as Grensen 9b, it can be concluded that reuse of building materials, although slowly, is headed in the right direction. Grensen 9b provides a much-needed example of reuse being affordable and not impacting the bottom line. There are still many logistical challenges and risks to be managed on a commercial level, but with the right political and legislative incentives the building industry is eager to implement more reuse into our projects. A critical gatekeeper for higher levels of reuse to become plausible in the future is a well-stocked, functioning, two-sided marketplace for national exchange of reusable building materials and local physical and affordable storage across the country.

close resource flows within the economy holds the potential of avoiding greenhouse gas (GHG) emissions and reducing other environmental impacts [3]. However, most construction waste is landfilled, energy recovered, or downcycled at a low quality level, much owing to vast amounts of mineral materials being crushed and used for low-value purposes such as backfill [3]. Thus, there is a need to establish systems and practices for monitoring, measuring, and increasing circularity in relation to building and construction.

Several approaches have been developed to quantify the circularity potential in buildings [4]. Some of these are characterized by a broad scope of evaluation covering various circularity aspects in specification, design, and management [4, 5]. Others are strictly material- and component-oriented, based on life cycle assessment methods [6], or allowing for integration into digital design tools [7]. Additionally, a diversity of mass-based assessment systems is available via green building certification systems such as BREEAM and DGNB [8, 9]. However, there is a lack of circularity benchmarking systems to support the evaluation of performance. Reference systems for comparison are missing, meaning that circular buildings are mostly compared with alternatives of their own design or other exemplary buildings.

This article addresses these research gaps with a Norwegian example, by identifying current and future references for circularity performance of buildings and testing this reference in the FutureBuilt Circularity Index system. Our approach fills a gap in the practical planning and design of buildings that meets the need of implementing ambitious circularity policies.

2 Background

FutureBuilt is a Norwegian green building innovation programme. A FutureBuilt project has to fulfil a set of mandatory criteria (urban environment and architecture, social sustainability, innovation, GHG emissions [10], and transport) and elective criteria (plus house, circularity, biodiversity and storm water, landscape, and plastic use). This article focuses on the elective criteria, FutureBuilt's Circularity Index system.

The FutureBuilt Circularity Index system rates a building's circularity performance between 0% and 100% [11]. The indexing system discerns between building materials and fill masses used during construction ('Present—Building' and 'Present—Fill Masses') and building materials available at the end of life of a building ('Future—Building'), see Fig. 1, displaying results of a case study building that is an exemplary rehabilitation project with a high focus on circularity. Each of these phases are broken down into a set of categories: 'Conserved', 'Reused', 'Surplus', 'Recycled', 'New', 'Reusability', 'Recyclability', or 'Waste'.

A normative weighting system is introduced to emphasize the importance of reusing materials at the highest level of functional quality. Here, the present time is weighted above the future since it is a prerogative to reduce environmental impacts

Fig. 1 Calculated circularity index based on Futurebuilt's criteria for the case study building Kristian Augusts gate 23 (KA23)

now and there is a higher uncertainty connected to the future. The waste hierarchy pyramid is used to prioritize measures. Measures connected to the building are prioritized above measures relating to fill masses since measures relating to fill masses are regarded as an easy measure to implement. Therefore, 'Conserved' and 'Reused' have a higher weighting of 1 compared to 'Reusability' at 0.67, 'Recycled' at 0.5, 'Surplus' at 0.35, 'Recyclability' at 0.33, and 'New/Waste' at 0. In addition, the importance of current resource circularity ('Present—Building' and 'Present—Fill Masses') versus circularity at the building's end of life ('Future—Building') is also weighted 0.6, 0.1, and 0.3, respectively. It should be noted that the rating system is subjective to the choice of weighting factors and gives incentives according to timeline and the waste hierarchy pyramid. FutureBuilt's Circularity Index performance requirements start at 50% in 2020 and increase incrementally towards 95% in 2050. However, FutureBuilt wishes to have an empirical reference baseline in which they can compare different building projects to. This paper documents the methods and results used for establishing this reference circularity index baseline.

3 Method

A mixed methods approach is used to establish an empirical reference circularity index baseline for Norwegian buildings based on the FutureBuilt Circularity Index method. Scenarios for future circularity towards 2050 are also developed. Data is gathered from national statistics [12–19], GHG emission accounting reports,

building material inventories, pre demolition audit (PDA) reports, environmental product declarations (EPDs) [20], and industry interviews. Data is gathered from industry actors during the period 2020–2023.

In all, 83 building projects were identified, of which 47 have GHG emission accounting reports, 28 have building material inventories, and 18 have PDAs. Of these projects, 43 were detailed sufficiently to be included in the analysis, whereby 16 projects were used to map 'Present—Building—Reused/Recycled/New', 11 projects were used to map 'Present—Building—Conserved', 15 projects were used to map 'Future—Building'. In addition, four building projects have tested the FutureBuilt's Circularity Index as proof of concept, namely Kristian Augusts gate 13 (KA13), Kristian Augusts gate 23 (KA23), Nedre Sem gård, and Tradlab. These building projects have a high focus on circularity, whereby KA13 and KA23 are rehabilitated offices, whilst Nedre Sem gård and Tradlab are new buildings with a high focus on circularity.

In addition, three scenarios are developed for the trajectory of the reference circularity index baseline towards 2030 and 2050, namely, business-as-usual, European and national ambitions, and industry's expectations. The business-as-usual scenario takes the results from the reference circularity index baseline for 2020–2023 and projects results with a 1% increase from year to year towards 2050. This correlates with FutureBuilt ZEROs 1% annual increase in technological developments [10]. The European and national ambitions scenario is based on European and national legislation, goals, and ambitions for circular buildings, and includes the following:

- 2020: EU waste directive with minimum requirements on 70% waste sorting [21]
- 2023: Norwegian building code minimum requirements on 70% waste sorting [22]
- 2023: Norwegian building code requirement to PDA report [22]
- 2024: EU's Circular Economy Action Plan [23]
- 2027: EU taxonomy and Level(s) introduced for all new buildings [24]
- 2030: Political will to introduce restrictions on demolition of buildings [25]
- 2040: Percentage of building stock that is conserved increases to 50% [26]
- 2050: Full circular economy [3]

According to national statistics, Norway has around 4,300,000 existing buildings. Each year there is around a 2% change in this building stock whereby around 13,000 buildings are demolished (ca. 14%), 80,000 are newly built (ca. 84%), and 1400 are refurbished (ca. 2%) in Norway [16]. 'Present—Building—Conserved' is expected to increase from 2% in 2020–2023 to 16% in 2030. 'Present—Building—Reused' is based on an expected 5% increase by 2050, whilst 'Present—Building—Recycled' is based on an expected 35% increase by 2050. There is currently no legislation, goals, or ambitions relating to 'Present —Fill Masses', so this part of the scenario is based on responses from interviews. For 'Future—Building', a full circular economy is expected by 2050; however, there is no agreed upon definition of what a full circular economy is, therefore a moderate approach in line with FutureBuilt has been

adopted at 95%. Results for years between 2020, 2030, 2040, and 2050 are evenly distributed to create a trajectory.

The industry's expectations scenario is based on interviews with actors from the construction industry on future expectations relating to the development of circularity in the building industry. The interview objects were asked to base their expectations on their company's strategy and goals, as well as on the trends regarding circularity in their forthcoming construction projects. Based on this they were asked to give a value to each element of the circularity index (Conserved/Reused/Recycled/Reusability/Recyclability).

The scope of data collection was limited to the production phase (A1–A3 according to EN 15978 [27]) and to the following building elements: groundworks and foundations, superstructure, outer walls, inner walls, floors, roofs, balconies, and stairs, since these are the life cycle modules and buildings parts most often reported in GHG emission accounting reports, building material inventories, and PDAs. 'Present—Building—Surplus' is not included in the analysis and is therefore set to zero. The analysis is limited to a mass-based assessment.

In some cases, building material quantities had to be converted from meters, square meter, or cubic meter to kilogrammes. In other cases, it was necessary to ascertain the recycled content of common building materials, for example 90% for steel. Data gathered from 2020 to 2023 is averaged instead of choosing a representative year.

4 Results

According to national statistics, Norway has around 4,300,000 existing buildings. Annually, ca. 13,000 buildings are scheduled for demolition, approximately 80,000 new constructions and roughly 1400 existing buildings undergo conversion. This indicates a 2% annual change in the country's building stock, with approximately 84% being new constructions, 14% being demolished buildings, and 2% being rehabilitated buildings. Considering these national statistics, the FutureBuilt Circularity Index focuses on annual change and the current industry standard for 'Present—Building—Conserved' is set at 2%.

Figure 2 illustrates the outcomes of reviewing material inventory lists extracted from GHG emission reports during the data collection and mapping of building projects. This mapping exercise includes a small sample of buildings (43 projects) that may not be representative of the national building stock and highlights an area for further research. The results indicate the distribution of conserved, reused, recycled, and new building materials used in both new (a) and rehabilitated (b) buildings. For new buildings, approximately 96% comprise new building materials, 4% contain recycled content, with no instances of reuse. In contrast, rehabilitated buildings consist of approximately 78% conserved building materials, 20% new building materials, 2% reused building materials, and 0.4% of building materials with recycled content. The current industry standard for 'Present—Building—

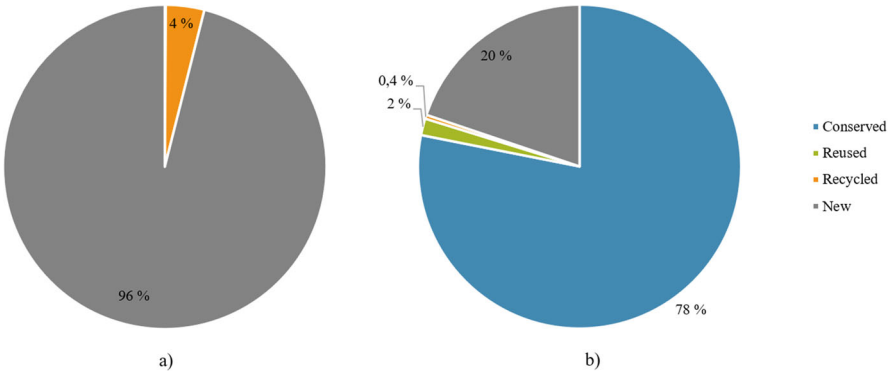

Fig. 2 Share of circularity (Conserved, Reused, Recycled, or New) for materials in new (**a**) and rehabilitated buildings (**b**)

Conserved/Reused/Recycled/New' is therefore weighted 2%/0%/4%/94% accordingly. Interviews with the construction industry revealed that 'Present—Fill Masses' are currently minimally conserved, reused, or recycled. This limited utilization aligns with statistics from Statistics Norway [18] and example projects [28]. For this reason, the current industry standard for 'Present—Fill Masses' is set at 100% new.

For 'Future—Buildings—Reusability', our examination revealed that none of the 15 PDA reports focus on quantifying reusability according to weight. In addition, there is no guarantee that today's materials and components will fulfil the same technical or regulatory requirements in the future. There is a notable variation in the system boundaries used across the different reports. However, it is evident that load-bearing structures, windows, and doors, fixed and loose fixtures, and technical equipment are the most frequently reported building components for reusability, as these are the building components that are typically most suited to reuse. Considering these findings, the current industry standard for 'Future—Buildings—Reusability' has been set at 0%. Statistics show that the average material recycling rate in the construction industry between 2013 and 2021 was 47% (excluding energy recovery). This has been used to calculate the current industry standard for 'Future—Building—Recyclability'. Taking these assumptions into account and utilizing the FutureBuilt Circularity Index system, the reference baseline circularity for Norwegian building projects is around 7% in 2020–2023 (see Fig. 3). The three future scenarios described in the methods section have been used to project a future scenario range from 35% to 80% circularity in 2050. In addition, FutureBuilt Circular (green line) shows the best practice criteria for FutureBuilt projects. Figure 3 also shows the results of four prestigious building projects that have a high focus on circularity and have tested the FutureBuilt Circularity Index. They have building circularity results ranging from 44% to 69%.

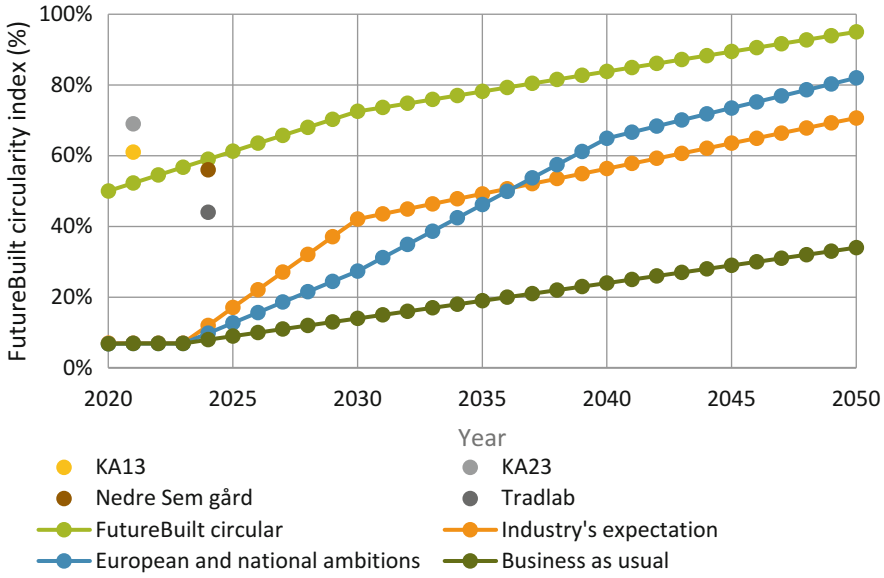

Fig. 3 Circularity projections towards 2050 in Norwegian buildings

5 Discussion

The results show that the reference baseline circularity for Norwegian buildings is around 7% in 2020–2023 when using the FutureBuilt Circularity Index, and that future projects are expected to vary from 35% to 80% circularity in 2050. The four projects that have calculated building circularity according to FutureBuilt's Circularity Index have achieved circularity according to FutureBuilt's definition in 2021 and have come close in 2023. The results show that it may be easier for rehabilitation projects (KA13 and KA23) to achieve a higher level of circularity than new builds (Nedre Sem Gård and Tradlab) since the weighty existing foundations and superstructure can be conserved and conserved/reused components score highly in the circularity index. This result implies that the normative weighting system functions according to intention, as rehabilitation is favoured over new construction. The FutureBuilt Circularity projections will become more ambitious to achieve with each passing year, and the building projects will therefore require further circularity measures to achieve circularity projections in the future. Regardless, all projects have achieved higher scores than those in the reference baseline and business-as-usual scenario.

The proposed current and future references for circularity performance of buildings are based on some assumptions and limitations. Firstly, there is a lack of harmonized definitions and methods. Secondly, the scope is limited to the production phase and main building elements since these parts are most often reported. Thirdly, the data collection period is from 2020 to 2023, and not just a single year, to

increase the amount of project data that could be collected. This is because there are few Norwegian projects that document circularity, and recent years have seen large changes due to the pandemic, increased construction activity, increases and decreases in building prices, increased material prices, difficulties with importing building materials due to the war in Ukraine, inflation, as well as increased interest rates. Finally, a large range of varying data sources have been used dependent on the kind of circularity data that was available at the time of study. Therefore, some data may be aggregated, missing, or overlapping. All these factors increase the level of uncertainty in the results.

In addition, the assumed future use of materials, reusability, and recyclability is based on scenarios for the current situation and does not necessarily account for future developments. This can give a lower score on the circularity index than if technological developments are accounted for. On the contrary, when evaluating the reusability of products, the reuse of materials may be technologically possible, but the market and industry may not be organized in such a way to make reuse economically competitive or feasible. Similarly, reusability and recyclability of products needs to be better defined as there is a large disparity in materials sent to recycling, materials that are de-facto recycled, the actual recycled content in new materials, and the amount of recycled content that can potentially be used in new products without affecting the technical performance characteristics of the product. There is also a question as to whether the circularity index should distinguish between internal and external reuse. For example, if building materials are reused within the same building project or if a building material is transferred from one building to another building project. Internal reuse is preferable over external reuse since it will most likely require less processing and transport for reuse, thus reducing GHG emissions. Internal reuse means that less resources are required for storing materials, and it is usually easier to plan for reuse.

PDA reports play an important role in advancing sustainable practices within the construction industry. However, existing PDA reports have significant limitations that hinder their efficient implementation. Consequently, establishing standardized data formats and centralized repositories for building material information could facilitate PDA efforts. The complexity of building materials further intensifies the necessity for standardized reports, including essential details such as material types, quantities, condition, and location within projects. The absence of standardized reporting formats leads to discrepancies in data collection, organization, and presentation, making it difficult for stakeholders to compare, evaluate, and effectively communicate PDA opportunities and challenges.

Future work for the circularity index could focus on harmonizing definitions as well as reporting on the scope, methods, and assumptions employed. For example, what if other weighting systems or units of measure were explored such as volume (m^3) or GHG emissions saved ($kgCO_2e$) instead of weight (kg) of building materials. A key assumption for full circularity relates to the availability of waste materials to cover the demand for construction services. The Circularity Gap Report for Norway 2020 shows how the demand for construction services in the Norwegian economy drives a material consumption of 58 Mt annually. In comparison, only 5 Mt of

material from all economic activities are cycled back into the economy, and 10 Mt are lost [28]. Research points to an untapped potential for European countries to recycle more construction and demolition wastes [3]. However, even if the 10 Mt could be cycled back into the economy, the gap between demand and available waste materials points to the need for drastically reducing demand for construction to achieve full circularity.

6 Conclusion

This article explores a mass-based circularity indexing system and identifies current and future references for circularity performance of buildings, for use in FutureBuilt, a Norwegian green building innovation programme. A mixed methods approach using statistics, EPDs, GHG emission reports, PDAs, and interviews is applied to establish a reference baseline for Norwegian buildings (i.e. 7% circularity) and scenarios for future circularity in 2050 (from 35% to 80% circularity). Actors in the Norwegian construction industry can evaluate the level of ambition for circular buildings by using this novel indexing system and benchmarking approach which can also be adopted to other national or regional contexts.

1 Smart Technologies in the Construction Sector

1.1 Potentiality of the Digital Era

Today, around 56% of the world's population (approximately 4.4 billion people) live in cities;[1] this trend is expected to grow, reaching about 68% by 2050 [1]. These numbers reveal the inherent potential in tackling climate change, such as the optimization and improved management of available resources; therefore, the construction sector needs to be closely studied, especially existing and historic buildings, which cover approximately 24–35% of the entire European building stock [2]. In this increasingly digital era, technological advancements represent crucial factors in future transitions, thanks to their potential to continuously improve information and communication technologies (ICTs), to spur on remarkable

advances in artificial intelligence [3], and to reinforce and spread the Internet of Things (IoT). IoT represents a quite well-known concept, which refers to the technological development path that allows frequently used devices to connect over the Internet and gives each its own identity in the digital world. It is based on the interconnection of "intelligent" objects that exchange the information they have, collect, and/or process, and it takes on its full meaning within the network that interconnects these objects. Digital ecosystems based on IoT, whether tangible or not, comprising both material and immaterial technologies, are generally designed to generate and collect complex data in real time and in a highly structured manner. In the construction sector, IoT conventionally refers to the introduction/adoption of intelligent digital technologies with various purposes, mostly aimed at enhancement and improvement, including the optimization of asset management. This latter aspect is increasingly subject to research to determine the field's experimental guidelines and practical solutions, aiming to play a strategic role in the broader strategy to mitigate climate-altering greenhouse gas emissions (GHGs) and energy resource scarcity while ensuring high standards of indoor comfort for end users.

1.2 Smart Technologies and the Heritage Environment

The impact of this breakthrough on buildings has been significant, exhibiting the fast spread of intelligent devices in the construction sector, which has led to the development of so-called smart buildings. The origins of smartness in buildings dates back to the introduction of the first information technologies and automations through building management systems (BMSs) [4]. However, this initial definition focused only on the strictly technical aspects, though recently, it has been considered also in building interactions and relationships with surrounding environments and occupants. Although most definitions of what constitutes a smart technology focus on the application of advanced technologies, connectivity, and data analytics for optimizing building operations and management [3], agreement on its definition remains elusive in that different researchers emphasize different aspects. The currently available smart building models cover multiple domain areas [5], even if, specifically in the field of cultural heritage (CH), some gaps remain.

The high potential for innovation, which is intrinsic to IoT, seems to only marginally apply to CH; even though it can be used at a strategic level in climate adaptation planning, operationalization through the development and implementation of concrete measures, including monitoring, is lacking [6]. The first explicit reference to smart heritage buildings was made by Thwaites [7], and since then, the literature has been populated with an increasing quantity of references related to smart heritage, conceived as an independent discourse that intertwines autonomous and automatic capabilities and the innovation of smart technologies with the contextual and subjective interpretation of the past [8].

In general terms, the concept of smartness, in this specific field, refers to the implementation of CH features through the adoption of smart technologies, to

promote interaction between people and the environment while collecting real-time data.

CH plays a key role in mitigating the causes of climate change in relation to its extension with respect to the built environment, and new smart technologies can augment its performance and improve its energy efficiency toward the decarbonization of the built environment.

2 Literature Review

2.1 Smartness of Cultural Heritage: Main Uses and Approaches

Although most of the existing literature has shown a relationship between smart city strategies (SCSs) and CH, emphasizing that SCSs should be built on the existing assets of the city in a way that incorporates its identity [9], research on the specificities of this relationship between urban smartness and CH remains limited, particularly when referring to strategies for climate mitigation. Many researchers have explored adjacent areas between innovative technology and heritage while referring to digital heritage, augmented heritage, and virtual heritage. For example, Chung et al. [10] investigated how augmented reality influences visitors' intention to come to heritage sites, while Cayla [11] examined new technologies' intersection with geological histories, specifically digital-mapping and data-recording processes. Technologies in use within the CH field can be divided into two main categories: enabling technologies and visualization technologies [12]. Enabling technologies are mostly related to data collection, allocation, storing, and exchange, and they include (i) IoT technology, understood as a huge network of various devices with embedded sensors for transmitting data connected to the Internet; (ii) cloud computing (CC), which complements IoT-enabled devices in that it allows the sharing of information and resources; (iii) wireless sensor networks (WSNs), usually dependent on autonomously distributed devices using sensors to monitor specific parameters, often related to the nearby environmental conditions; (iv) mobile broadband (MB), defined as the wireless Internet accessible through mobile devices [12], including those using Wi-Fi protocols; and (v) short-range wireless (SW) technologies, which allow for communication between various smart devices and objects near each other (also known as near-field communication, or NFC). Visualization technologies, on the other hand, are those that communicate information by encoding it as visual objects [9], making complex data more understandable, accessible, and usable. They could range from simple info-graphic representation to more advanced 3D modeling, and include Virtual Reality (VR), Geo-visualization, and Augmented Reality (AR) winking also at Artificial Intelligence (AI). As the concepts of smart heritage and the Internet of cultural things are becoming more and more widespread in the scientific literature, understanding the main scopes and research fields for the

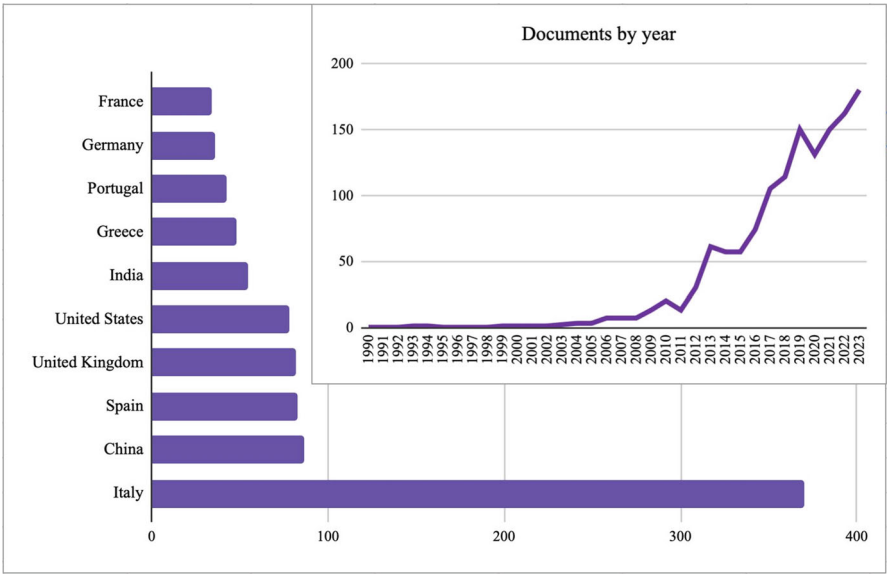

Fig. 1 Distribution of the main published documents sorted according to country (left) and year (right), by relating cultural/historical heritage with the diverse uses of smartness
Authors' elaboration from Scopus and ScienceDirect using a combination of the keywords: "cultural heritage" (and its synonymous/alternative forms) and "IoT/keys/digital technologies/ smartness." The Scopus advanced query (TITLE-ABS-KEY "cultural heritage" OR "historic* building*" OR "heritage" OR "ancient building*" AND TITLE-ABS-KEY "smart*" OR "ket*" OR "key enable technology*") generated more than 1300 documents, which were then filtered according to subject area and the main topic

exploitation of digital technologies for use in cultural assets is now a priority. To best link cultural/historical heritage with the diverse ways of applying smartness when searching in the main scientific online databases (mainly Scopus and ScienceDirect), Italy is the main country for the implementation of this kind of research (Fig. 1). The recent and rapid development of new technologies can also be traced to the time-wise distribution of publications on the topic, which shows a significant increase in papers starting from 2012 to the present (Fig. 1). The two academic disciplines most affected by the research are computer science and the social sciences, followed by engineering (Fig. 2).

In this chapter, a selection of the literature review results is presented.

These documents confirm that the topic is treated differently depending on the perspective. The primary divergence lies in the intended use of technologies to enable or visualize CH. Particularly well-explored areas include new procedures and tools for the valorization of the user's experience in visiting museums, archeological sites, historical archives, religious buildings, and cultural events. In particular, new frontiers feature instruments such as a novel mobile sensory-augmented context-aware multimedia guide [13], applications for assisting users in the exploration of single smart spaces [14], generative pretrained transformers

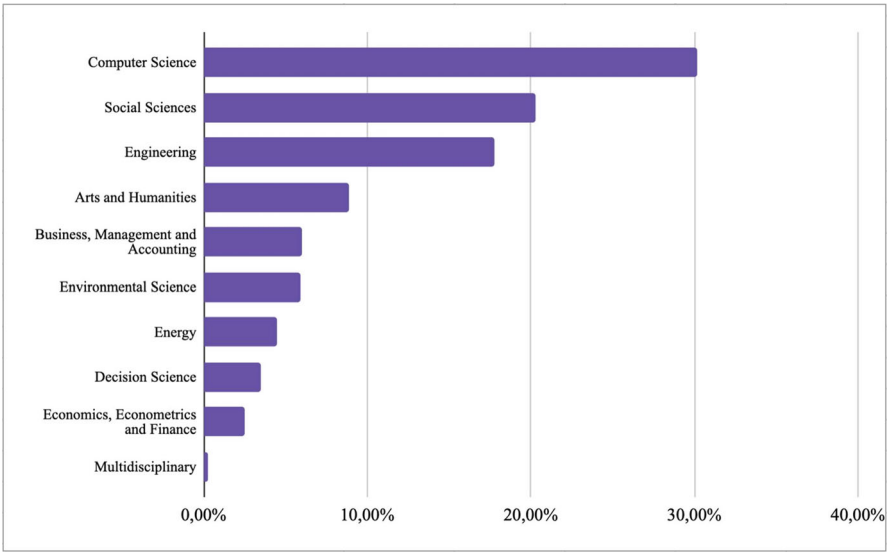

Fig. 2 Distribution of the main published documents by subject area, by relating cultural/historic heritage with the diverse uses of smartness. (Authors' elaboration from Scopus and ScienceDirect, as described in the caption of Fig. 1)

(GPTs) by OpenAI, large language models (LLMs) as digital storytelling machines [15], and the application of augmented reality for classical music concerts [16]. Another possible option is utilizing smart technologies to bolster urban management effectiveness by investigating citizens' needs from smart city advancement and how they align with community opinions in areas rich in cultural and natural characteristics [17]. The literature shows that a significant amount of research has focused on the wider concept of a smart (historical) city and its management. In this context, studies have aimed at listing the fundamental factors of cultural heritage management systems, classified according to the components of a smart city [18–20]. Conservation is the other main reason to implement digital technologies for CH. Innovative applications require the use of sensors and cyber-physical systems or AI for preservation to manage vulnerabilities, functional service provision [21–25], the safe movement of artworks [23], deterioration risks [26, 27], and security [28, 29]. Among the most used technologies related to CH are tools for 3D surveying and visualization [30, 31], useful devices for creating high-resolution digital archives that collect and manage information [32], and so-called heritage building information modeling (HBIM) [33–36]. The use of big data (BD) and statistical predictive models is increasingly developing platforms for data management (e.g., BD, cloud-computing, and edge-computing platforms) [37–39] and particularly for the analysis of energy consumption [40–42] and the external environmental performance of heritage buildings [43, 44]. The above literature shows how much the field of applications for these technologies is developing for the preservation, enhancement, and better management of historical heritage.

main scope	Building's type/use						Specific aim			
	Historical city	Heritage asset	Museum	Archeological sites/Historical archives/Cultural events/Religious sites	Building's materials	Artworks	User's experience enhancement/ Tourist guide	Management	Energy consumption	Indoor/ outdoor performance
Valorization	[14] [17] [24] [33] [34] [35] [36] [10]	[24] [33] [34] [35] [36] [31] [10] [11]	[13] [14] [58]	[13] [14] [10] [15][16]			[14] [15] [58] [16] [17] [20] [24] [10]	[14] [15] [17] [11]

Fig. 3 Literature review results: applications of digital technologies in CH and how they relate to building types and uses and to the aim of this study

Moreover, understanding how the research world is shifting toward this field is necessary to take advantage of technological developments to control the effects of climate change while proposing intervention strategies. The state-of-the-art is undergirded by a great number of studies that have addressed the procedures for the hygrothermal analysis of building components [45–49] for assessing indoor comfort and air quality [50, 51] as well as outdoor environmental performance [52–57]. For this kind of study, however, the use of digital technologies is often limited to advanced simulation tools and sensor systems for monitoring campaigns, and it does not reach the level of digitalization of other research areas. Figure 3 presents a summarizing matrix of the preliminary results of the outlined literature review.

2.2 Analysis of Best Practices

By focusing on the application of pervasive digital technologies to historical heritage, with the aim of mitigating climate change, a series of best practices can be identified for the exploitation of enabling technologies for redevelopment projects and/or for the recovery of historic buildings. According to the literature review, three best practices were considered particularly relevant to open up new reflections on specific innovative approaches to cultural heritage. Among the many cases in the review, three examples were identified, differing in the type of smart technology used and the scale of intervention. Notable examples include energy-efficient initiatives implemented on a local scale, focusing on delineating priority thermal zones within expansive architectural complexes. Additionally, design strategies for decarbonizing buildings can prioritize the integration of green systems over direct alterations to a historic envelope.

SHCITY—Smart Heritage City
The SHCITY project [68], funded by the Interreg VB South West Europe program, aims to develop an open-source tool for managing historic urban centers, focusing particularly on the walled city of Ávila, Spain. It utilizes data from cloud computing and sensor networks to monitor the risks, energy consumption, and visitor flow at the UNESCO heritage site. By integrating ICTs and interdisciplinary knowledge related to heritage management on an urban scale, the project extends the smart city concept to a smart heritage city, shifting the monitoring focus from individual buildings to the urban complex. This initiative has resulted in the creation of a sensor infrastructure and two open-source applications: SHCity tourist, for spreading information about the preventive conservation of heritage elements, adding social and economic value to the innovative approach, and SHCity manager, for public administrations. These tools improve the management of heritage assets, thereby also improving conservation efforts and decision-making processes. The systematization of these tools allows for the unification of different domains, such as preventive conservation and energy efficiency, enabling tailored configurations for various needs. Overall, this system improves the planning of maintenance interventions, leading to significant savings in management, time, and costs.

Complex of San Pietro in Vincoli, Rome
The sixteenth-century cloister designed by Giuliano da Sangallo in the complex of San Pietro in Vincoli in Rome was the subject of a study [69] aimed at investigating the different aspects related to internal and external thermo-hygrometric comfort by using predictive models and by analyzing its innovative materials and their repercussions on energy consumption. Starting from the analysis on the external spaces, virtual models were created that allowed for the evaluation of the impact of some innovative finishing surfaces on the microclimatic factors of the area. The research developed simulations and in situ monitoring campaigns not only within the cloister but also in the urban canyon of Via delle Carrozze, verifying the impact of strategies

aimed at increasing urban greening and/or the use of materials with a high albedo coefficient. The simulated models were then experimentally validated to verify their reliability in reproducing the investigated phenomena.

Palazzo Gulinelli Canonici Mattei, Ferrara
The eco-sustainable restoration project [70] of Palazzo Gulinelli, damaged by an earthquake, aimed to harmonize client requirements with the building's intrinsic purpose by utilizing digital technologies. Emphasizing eco-sustainability, it integrated Leadership in Energy and Environmental Design by the Green Building Council (LEED–GBC) certification mechanisms according to the Historic Building (HB) protocol. The approach relied on an integrated Building Information Modeling process. The restoration considered the details and characteristics of elements and materials, including diagnostics. Laser scanner surveys collected information for each element, which was then modeled and cataloged systematically. This database facilitated timely simulations, predicted processing times and costs, and managed maintenance interventions efficiently.

The notable actions undertaken in this recovery project are as follows:

- Restoring the existing proto-climatization system from the Victorian era, comprising light wells/vertical ventilation ducts that run from the underground space to the upper levels, with cooling provided by fountains in summer for building microventilation
- Establishing a rooftop garden, one of the first in Italy within a protected historic building
- Replacing an incongruous superstructure with a new technical structure made of Cross Laminated Timber (CLT) from certified forests, alongside the utilization of dry technologies and reversible installation systems for both ancient elements and new additions
- Designing and implementing a wireless electrical system to avoid disturbing historic masonry structures, complemented by energy consumption sensors (for Domestic Hot Water (DHW) and air conditioning) to optimize internal comfort through individual room regulation and reduce the overall energy consumption of the building, accounting for the nonsimultaneous use of school spaces

3 Conclusion: Toward the Smart Heritage Environment and New Perspectives for Research

In the era of data technology, exploiting data as a source of knowledge is a recurring and pervasive research topic. A primary area of interest that emerged following this discussion is that aimed defining an effective and innovative relationship of interest between the technological potential inherent in the world of sensors, the production and programming of data on shared platforms and of advanced modeling, and cultural heritage, addressed to develop efficient governance processes for preventive conservation and energy-efficient and environmental retrofit projects for buildings.

To this end, thanks to the conducted analysis, partially unexplored fields of investigation—systematizing concepts that until now pertained to independent domains—could be explored. Indeed, at present, the literature shows widespread applications of enabling technologies and IoT within the construction sector; however, most of these technologies have been poorly applied to historic buildings, for energy efficiency and, more generally, the mitigation of the causes of climate change. In addition, in this specific field, the literature shows a prevalence of research that comes from non-EU countries, with different climates and historic features than the Mediterranean ones, such as the role of the courtyards in the architecture of the past [62–65].

The results of this preliminary literature review are that a new perspective of research could focus on the use of pervasive technologies and digital innovation for a new type of smart management for CH, one that will effectively implement strategies for climate-change mitigation. In this field, the TECHSTART project, specifically the part that concerns the research unit to which the authors belong, has worked to study the so-called liminal spaces (porches, courtyards, cloisters, underground/attic spaces, etc.) of historic buildings to collaborate in the creation of smart environments by using enabling technologies as tools for investigation, knowledge management, and the enhancement of the passive functioning of liminal spaces of ancient cities for climate-change mitigation. The workflow developed by the research team integrates environmental monitoring campaigns, numerical simulations, statistical methods for data analysis, and advanced knowledge management systems, such as HBIM, with the goals of creating a simplified method for analyzing both single buildings and entire urban compounds and of creating a smart tool that automatically optimizes the management of liminal spaces to reach optimal outdoor thermal comfort.

Acknowledgments This chapter has been developed within the TECHSTART–PRIN2017 project (PI: M. Losasso, University of Naples), as part of the research activities conducted by the authors in the task group of the Department of Architecture at the University of Ferrara. This interdisciplinary research group consists of P. Davoli (Head of the task group), F. Conato, M. Calzolari, V. Frighi, V. Modugno, B. Caglioti, D. Vincenzi, G. Mangherini, L. Gabrielli (University of Ferrara), and A.G. Ruggeri (University of Venice). https://in-out-heritage.it/.

1 Introduction and Theoretical Background

There is a growing focus on improving building energy efficiency due to the global imperative to combat climate change and reduce greenhouse gas emissions [1]. Buildings account for a substantial portion of total energy consumption and carbon emissions worldwide. In Europe, it is estimated that a significant proportion of the buildings that will still be in use by 2050 already exist today [2]. Therefore, achieving energy efficiency in existing buildings through renovation is a crucial step toward meeting energy efficiency targets and mitigating the environmental impact of the building sector. The Renovation Wave initiative is one way that the European Union is encouraging increased energy retrofitting in the existing building stock.

However, the task of renovating existing buildings for energy efficiency is not straightforward. Unlike existing construction, which can be designed with the latest energy-efficient technologies and standards, existing buildings often present unique

challenges. These challenges arise from factors such as outdated building services systems, architectural constraints, budgetary restrictions, and the need to minimize disruptions to occupants during renovation [3]. Causes of building energy performance gap can be linked to all phases of the building life cycle: design, planning, construction, and commissioning and operation [4]. Energy systems in existing buildings are often operated in suboptimal ways. For example, this can be due to poor energy performance guidelines and documentation or because of too large control zones for heating, ventilation, and air-conditioning (HVAC) equipment [5]. Discrepancies between the design and operation stages can also be caused by lower-than-expected equipment efficiency, differences between simulated and experienced weather, and significantly different than expected occupant behavior [6]. Facility managers could mitigate many of the operational inefficiencies but are often afraid of making necessary adjustments for fear of getting blamed for bad outcomes [7]. A review of green retrofitting has revealed many barriers to effective retrofit implementation [8]. These include financial barriers, such as high investment cost and lack of life cycle cost knowledge as well as lack of energy efficiency information and skills by the designers, contractors, and building owners. Insufficient performance data of green building systems, risks of untested technologies, and poor communication and leadership are the other obstacles to successful energy retrofitting of projects.

Energy-efficient building renovations require effective collaboration among all stakeholders and project monitoring to ensure successful implementation. It involves technological advancements and changes in building management practices, workforce training, and other incentives [9]. Furthermore, building renovation projects involve a range of professionals, including clients, designers, contractors, and maintenance experts. Their insights and expertise are critical for navigating the energy-efficient renovation complexities. Information must also flow between designers and users of buildings, to ensure that the users understand how the building is supposed to be operated [10]. Facility managers should be tasked with continual improvement of building performance, but this mission should have already started during the planning stages of building renovation projects [11]. A multidisciplinary approach is needed so that resolving energy performance issues does not create new problems in other areas [12].

2 Methodology

This study aims to address the challenges and solutions of achieving energy efficiency in building renovation projects. To do so, qualitative data collection and analysis methods were employed based on which 21 semi-structured interviews were conducted in Finland. These interviews were conducted with experts representing client project management (five interviews); contractor project management (five interviews); architectural, structural, and HVAC design (five interviews); and building operation as well as maintenance (six interviews). Half of the

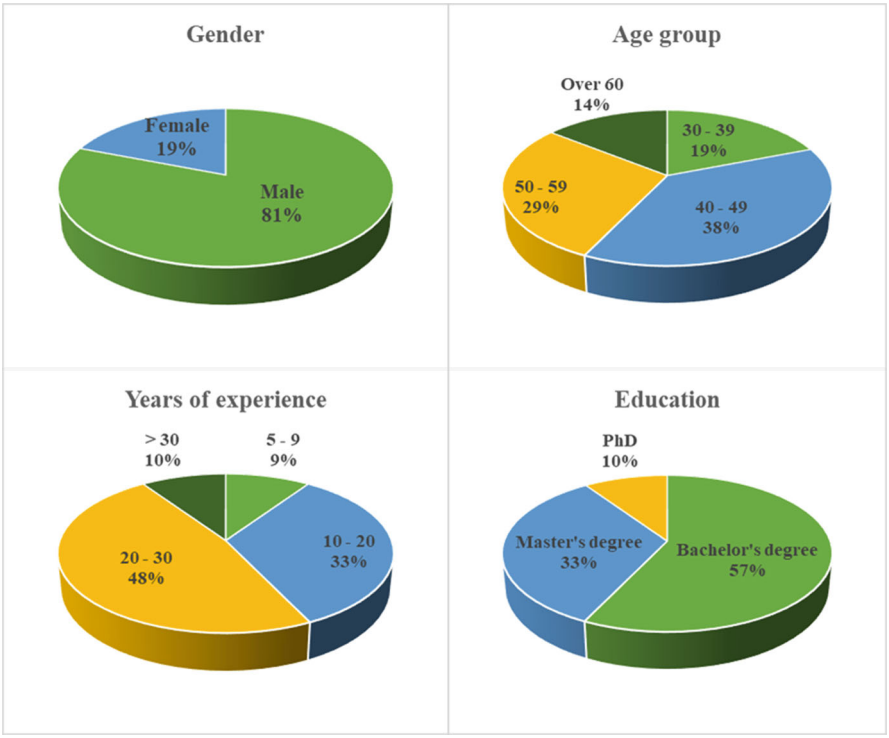

Fig. 1 Demographic information of the interviewees

interviewees' latest project was building construction and the other half building renovation. The demographic information (gender, age, experience, education) about the interviewees is shown in Fig. 1. Following the completion of interviews, they were analyzed through thematic analysis and content analysis methods [13]. Table 1 shows the whole process of the conducted research, including data collection and analysis.

3 Results

Analyzing the interview transcripts resulted in the identification of the challenges and enablers for realizing energy efficiency in building renovation projects. The most frequently mentioned challenges and enablers are shown in Tables 2 and 3, respectively.

Some of the challenges to energy efficiency come from the buildings themselves and are not easily resolved. There might not be enough physical space to install modern systems needed for enhanced operations or the structure might not be strong enough to support heavier equipment. In addition, many historical buildings have a

Table 1 The research process

Step 1	
Formulating the research questions	What are the challenges/barriers to achieving energy efficiency in building renovation projects? How can the abovementioned challenges/barriers be overcome?
Step 2	
Undertaking a literature study	The conducted literature study showed limited research-based knowledge on the topic under study
Step 3	
Selecting the data collection method	A semi-structured interview was selected as the data collection method
Step 4	
Conducting semi- structured interviews	A total of 21 semi-structured interviews were conducted in Finland with project professionals representing clients, design/planning experts, contractors, and building operation/maintenance experts The interviews were audio recorded based on the obtained consent from the interviewees
Step 5	
Transcription and translation of interviews	The conducted interviews were transcribed and translated into the English language by a native Finnish-speaking member of the research team
Step 6	
Coding	This was undertaken by inductively coding the extracted research data as a result of analyzing the interview transcripts. The labels of the codes were data-derived by the researcher
Step 7	
Validating the generated codes	The generated 51 codes in the previous step were reviewed again, and 18 of them were renamed. As a result of this effort, the remaining 34 codes were considered valid for thematic analysis
Step 8	
Thematic analysis	The validated codes were then analyzed through thematic analysis to see what themes the data are suggesting. Nine themes were established as a result of the thematic analysis The themes were established based on the sameness or similarity of the codes in terms of the meaning and/or title
Step 9	
Content analysis	The challenges/barriers and solutions/enablers representing different codes and themes were listed separately and synthesized based on the similarity or sameness of the title and/or meaning

protected status that prevents visible changes to their façade, while general rules on cityscape could, for example, forbid the use of energy-efficient but highly reflective glazing.

Other challenges, however, can be mitigated. Financing issues, for example, can be controlled by focusing more on life cycle costs compared to investment costs, as many energy efficiency measures have not only high initial costs but also significant cost-saving potential. Insufficient monitoring of energy use in different systems and

Table 2 Challenges/barriers to realizing energy efficiency in building renovation projects

Theme	Challenge/barrier	Reference
Existing building's architecture and structure	Insufficient space for new building services systems (e.g., low floor height, narrow shaft, small machine rooms)	(DM) INT 2, (PMClient) INT 2, (DM) INT 3, (PMContractor) INT 3, (PMContractor) INT 4, (DM) INT 5, (PMClient) INT 5, (PMContractor) INT 5, (PropertyMgmt) INT 5, (PropertyMgmt) INT 6
	Incompatibility of the existing buildings' structure, space, and technology with the modern building services systems (i.e., equipment)	(PMClient) INT 1, (DM) INT 2, (PMClient) INT 2, (PropertyMgmt) INT 2, (DM) INT 3, (PMClient) INT 3
Finance	High investment cost of replacing the old energy system with the new one with an uncertain payback period	(DM) INT 3, (PMContractor)INT 4, (DM) INT 5, (PropertyMgmt) INT 5
	Insufficient funding for energy efficiency measures	(PMClient) INT 2, (DM) INT 5
	Cost and time of reinforcing the structure of the existing building for installing modern and heavy equipment	(DM) INT 3, (PMClient) INT 1
Regulatory issues	Building protection issues for façade renovation	(PMClient) INT 1, (PropertyMgmt) INT 2, (DM) INT 3, (PMClient) INT 5
Building's energy system	Inadequate and inaccurate metering of energy consumption in heating	(PropertyMgmt) INT 3, (PropertyMgmt) INT 2
Building operation, maintenance, and optimization	Lack of highly intelligent building automation system for continuous and real-time monitoring and control of building operation	(PropertyMgmt) INT 3, (PMClient) INT 4

the lack of data analysis prevent or complicate the identification of energy efficiency issues. These challenges can be resolved by the addition of more detailed monitoring systems and the employment of staff specialized in energy efficiency. Modern energy systems are becoming more complex, and it should not be expected that people responsible for day-to-day building maintenance are also experts on

Table 3 Solutions/enablers of realizing energy efficiency in building renovation projects

Theme	Challenge/barrier	Reference
Competence development	Competent maintenance workforce for handling and optimization of modern and complex building services systems	(PropertyMgmt) INT 3, (PropertyMgmt) INT 6, (PropertyMgmt) INT 5, (PMClient) INT 5
	Providing practice-oriented training and education for maintenance and operation staff	(DM) INT 3, (PropertyMgmt) INT 4, (PropertyMgmt) INT 1, (PMContractor) INT 1
Building operation, maintenance, and optimization	Continuous monitoring and improvement/optimization of building operation	(PropertyMgmt) INT 4, (PropertyMgmt) INT 3, (PMContractor) INT 3
Project delivery	Adequate investment of time and money for design, planning, and implementation of renovation activities (including energy efficiency measures)	(PMClient) INT 2, (PMContractor) INT 1
	Documenting and using lessons learned in building renovation projects	(PMClient) INT 2, (PMClient) INT 5
Building's energy system	Detailed and purposeful measurement/metering of energy consumption as the insightful source of information for guiding building occupant behavior	(PMContractor) INT 2, (PropertyMgmt) INT 2
	Improving the resilience of the building energy system using hybrid systems	(PMClient) INT 4, (PropertyMgmt) INT 5

interconnected hybrid energy systems. Thus, education of staff for optimal energy system operation and identification of potential improvements in building portfolios are important tasks. An important improvement needed for project delivery is the proper sharing of responsibilities, such that the designers and builders remain invested in the correct operation of the building energy systems even after construction is finished.

4 Discussion

This study provides insights into the challenges and solutions associated with energy efficiency in building renovation projects, particularly in the context of existing Finnish building stock. An earlier study by Häkkinen and Belloni [14] presented

issues related to sustainable buildings in Finland, as reported by building professionals. Some of the biggest issues were lack of sustainability assessment methods for clients, short time perspective of developers, lack of client understanding of the benefits and alternatives in sustainable buildings, lack of designer knowledge about modern energy systems, lack of sustainability management team in the process, maintenance services not covering user guidance and building monitoring, overly high priority given to district heating and lack of sustainable refurbishment concepts. Similar issues have also been observed outside of Finland [8]. These include lack of life cycle perspectives, insufficient knowledge of solutions and their benefits by all the stakeholders, and lack of leadership and vision to commit to environmentally friendly buildings.

Many of the issues reported more than 10 years ago still remain. For example, there is still a need for improved monitoring to ensure that the building operates as designed and is maintained at that level. Despite significant developments in the uptake of new technologies like heat pumps, the low investment cost criteria are still common and traditional district heating solutions can be selected due to their ease of use and fear of alternative long-term investments. Maintenance staff still lack the knowledge to ensure optimal operation of buildings. All this implies the need for public knowledge sharing on various options and the need for new ways of operation and marketing for consultants and contractors, to give more weight to sustainable long-term solutions. The clients must be assured that even their complex energy systems will work as intended over their whole life cycle.

Although this study has made valuable contributions, further research and actions are needed to address the challenges and effectively implement the solutions outlined in this study. It is important to note that the study findings are limited to the European and Finnish context and may not be applicable to other regions with different building stock characteristics, regulations, and economic conditions. For this reason, future research should thoroughly examine regional variations to better understand the optimal options for energy-efficient building renovations and to identify useful universal principles that may be utilized in any country. Additionally, combining qualitative and quantitative data can provide a more comprehensive understanding of the economic and environmental impacts of energy-efficient renovations. Thus, long-term studies are needed on energy consumption, cost savings, and carbon emission reductions. This study examined issues that are specifically related to building renovation, but many of the building energy efficiency challenges are shared by new construction as well. Project delivery issues are one such example.

In addition, it is crucial to understand how occupant behavior impacts energy consumption in renovated buildings. Therefore, studying behavior change interventions and occupant engagement strategies can lead to more effective energy-saving measures. Finally, in-depth case studies of successful energy-efficient renovation projects can offer practical insights and lessons learned for industry professionals and policymakers.

5 Conclusions

This study aimed to explore the challenges/barriers to and the solutions/enablers of achieving energy efficiency in building renovation projects. This was accomplished through a qualitative study of semi-structured interviews. The opinions of project professionals representing client, design, contractor, and property management were obtained and analyzed. Accordingly, it is concluded that:

- Sufficient adequacy and accuracy of energy consumption metering and its public availability provide a valuable means for renovation planning and an insightful source of information for evaluating the added value of the completed renovation.
- Using hybrid systems improves the resilience of building energy systems.
- Up-to-date and practice-oriented education and maintenance staff training are necessary for harnessing the potential of modern energy systems.
- Creating more tempting incentives for the renovated buildings with high energy efficiency provides a reasonable justification for more investments.

This study recognizes the significance of the perspectives of project professionals and seeks to understand their views on the challenges and solutions in the field. The research also highlights the need for greater collaboration between all stakeholders. Additionally, this study provides insights into how technology can be used to streamline the building renovation process.

Acknowledgments This study was conducted as part of the research program "Hiilineutraalit energiaratkaisut ja lämpöpumpputeknologia" (HybE). We sincerely thank all the funders of the program: Paavo V. Suomisen Rahasto, Sähkötekniikan ja energiatehokkuuden edistämiskeskus STEK ry, Granlund Oy, Ramboll Finland Oy, HUS Tilakeskus, HUS Kiinteistöt Oy, and Senaatti-kiinteistöt. We also thank all the interviewees for their helpful collaboration in providing the research materials.

1 Introduction

In an era where environmental unpredictability and sustainability challenges are at the forefront of architectural design and urban planning, the resilience of the built environment has never been more crucial. The concept of resilience in this context refers to the ability of buildings to adapt and maintain functionality in the face of diverse and changing conditions [1]. Building's resilience is increasingly important

as the impacts of climate change have to be considered, which is anticipated to influence both building requirements and functionality. Specifically, for the purposes of this paper, it is important to note that climate change is expected to shorten the heating season in Norway to varying degrees based on geographic location, as referenced in [2]. Concurrently, there may be a proportional increase in the cooling season. This shift suggests that climatization strategies that are not designed to handle higher future loads might face operational challenges, and this would be an example of a lack of resilience.

In response to these evolving conditions, mixed-mode climatization concepts, which integrate natural and mechanical ventilation systems, are emerging as a paradigm of sustainable design. These concepts align with the concept of resilience by offering solutions to improve indoor air quality, reduce energy consumption, and ensure occupant comfort conditions [3]. However, as future climate scenarios are assessed, it becomes evident that hybrid ventilation systems in mixed-mode buildings might encounter challenges, particularly in adapting to the increased frequency of extreme weather events and fluctuating temperature patterns. This underscores the necessity for further research focused on analyzing hybrid ventilation in mixed-mode buildings, with an aim to ensure their sustainability, resilience, and efficacy in the face of evolving climatic conditions.

2 Related Studies

Multiple scholarly studies have been conducted to evaluate the resilience and adaptability of various building typologies in response to projected future climate scenarios. Attia et al. [4] performed a scoping review, examining existing definitions of resilience and exploring diverse approaches to achieving resilient cooling of buildings. The aim was to investigate the definition of resilience against overheating and power outage considering the scale of built domain and timeline of resilience. The study emphasizes a holistic approach to resilient cooling design, involving a combination of passive and active measures, renewable energy, and storage capacities, underpinned by the necessity of building operation systems and user collaboration for real-time optimization and adaptation. Farahani et al. [5] conducted an evaluation of the resilience of residential buildings in Finland, focusing on their adaptability to cold climate countries amid changing climatic conditions. Their results revealed that in Finland, residential buildings, both old and new, struggle with overheating during hot summers, with passive strategies like all-day ventilation boost and openable windows proving effective but insufficiently alone. Future building codes and retrofitting measures need to address this by incorporating sustainable technologies for cooling, especially under projected hotter conditions for 2050 and 2080. Chen et al. [6] studied an innovative resilient design framework incorporating climate uncertainties from 2020 to 2090 significantly enhances building life cycle performance, considering factors like infiltration, wall and windows U-values, and thermal mass. The framework's application in a cold region office building case study resulted in 44.0% reduction in life cycle carbon emissions

(LCCE), 8.2% in life cycle cost (LCC), and 4.3% in indoor discomfort hours (IDH), showcasing its efficacy in improving building resilience and sustainability under future climate scenarios. Gremmelspacher et al. [7] carried out a study on retrofitting residential buildings for future climate resilience. Simulations of four case studies in Denmark and Germany revealed a significant decrease in heating energy demand (up to 25% reduction) and a reduction in heating peak loads with retrofits. However, increasing thermal discomfort due to heat stress was also observed.

Furthermore, numerous researchers have concentrated on investigating the impact of passive ventilation strategies on the thermal resilience of buildings, and this chapter highlights some of the most recent studies in this area. Peterson [8] carried out research analyzing the energy efficiency of Danish office buildings in the face of climate change, deploying over 313,000 simulations. The study concludes that existing design methodologies might fall short of guaranteeing resilience. Findings project that by the 2080s, the demand for cooling could surge by more than 200%, whereas the need for heating could decrease to less than 50%. Schünemann et al. [9] carried out research to examine the effect of residents' window opening behaviors on overheating, using simulations in two residential structures in Germany. Their findings showed that effective ventilation, like fully opening windows during cooler hours, can significantly reduce overheating, while tilted windows lead to higher temperatures (up to 35 °C). Tavakoli et al. [10] critically reviewed recent research on thermal resilience in low-energy, non-residential buildings with ventilative cooling. Studies highlighted the effectiveness of passive interventions like solar shading and night ventilation in reducing overheating. However, future climate change poses challenges, with some regions likely to see diminished effectiveness of ventilative cooling strategies.

The literature review highlights a growing need to improve the resilience of climatization solutions, beyond just passive design methods, especially considering expected future climate changes. Particularly, there is a significant research gap in exploring the resilience of climatization strategies in colder climates, leading to uncertainties about their effectiveness in such environments. Our study focuses on testing an automated window opening system that enhances hybrid ventilation in buildings located in colder areas, particularly with an eye toward future climatic conditions. The main goal is to investigate if hybrid ventilation can use less energy than traditional mechanical systems while keeping indoor temperatures comfortable, offering a potentially more sustainable option for future building designs.

3 Methodology

3.1 General Considerations

Figure 1 shows the modeling process for generating climate data scenarios (steps 1–3) and implementing them in the building energy simulation software (BES) for analysis of indoor thermal climate and air quality along with their energy use for different heating, ventilation, and air conditioning (HVAC) scenarios.

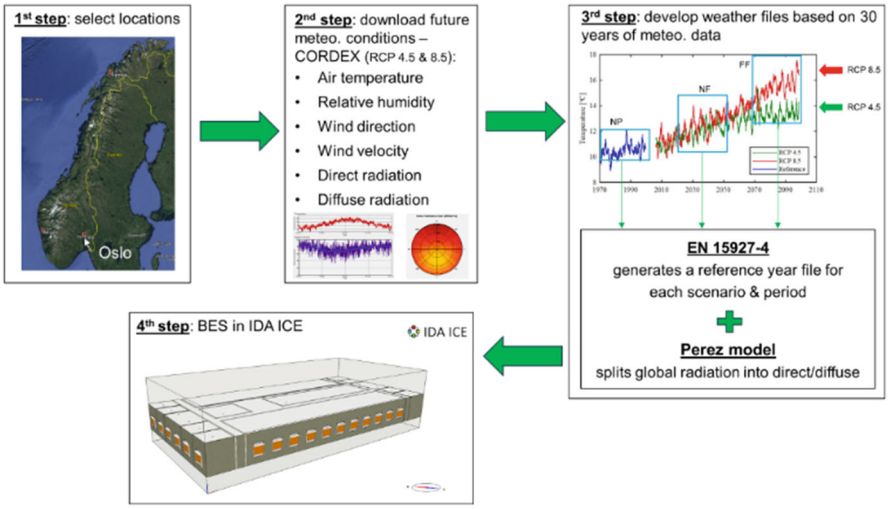

Fig. 1 Scheme of the procedure process, for generating climate data scenarios and running indoor climate and energy simulations, used in this study

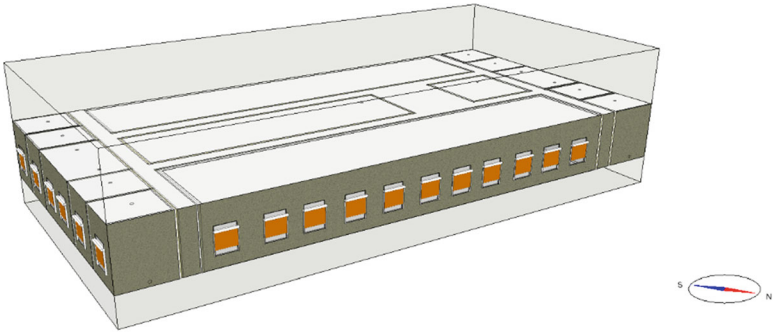

Fig. 2 3D model of office building in IDA-ICE

3.1.1 Case Study

In this study, we examine an office building topology with total floor area of 763 m^2 that serves as a representative example of a floor plan archetype prevalent in Norway, the model floor is depicted in Fig. 2. This topology integrates a variety of spaces, including individual offices, open office landscapes, and meeting rooms. The building envelope and technical properties adhere to the stipulations outlined in the Norwegian Building Code, TEK 17 [11]. Factors contributing to internal gains—namely occupancy, lighting, and equipment—along with their respective utilization profiles, were established in accordance with the Norwegian technical specifications used for evaluating building energy performance against SN-NSPEK 3031 [12].

The window design incorporates a dual-part configuration, with the upper segment being operable, measuring 0.4 meters in height, and the lower segment, non-operable, extending 1.8 meters in height, complemented by an automated external solar shading system. The building properties, internal gains, external shading control, and mechanical ventilation specifications are described in [13].

3.1.2 Ventilation Control and Space Heating Strategies

Our study examines three distinct approaches to ventilation and space heating:

- **Strategy 1**: Employs a full Variable Air Volume (VAV) mechanical ventilation system, enhanced with CO_2 and temperature control. It features water radiators along external walls, particularly beneath windows, for space heating.
- **Strategy 2**: Utilizes a hybrid ventilation system, combining mechanical ventilation with the option to open windows for additional airflow. This setup is activated when mechanical ventilation alone does not achieve desired thermal comfort or CO_2 levels. Space heating is provided through the same method as in Scenario 1.
- **Strategy 3**: Also adopts the hybrid ventilation strategy outlined in Scenario 2 but differs in its heating and cooling approach, utilizing floor heating and cooling systems for temperature control.

In our hybrid solutions, we carefully adjusted the air flow rate to prevent façade openings from operating during the coldest times of the year. This approach, while conservative, reduced the risk of cold air influx compromising indoor comfort. This strategy is grounded in our practical experience with designing robust real-life systems in a Nordic climate. Detailed information on airflow rates applied in different ventilation strategies for two distinct building typologies is presented in Table 1. The simulations were performed in the BES software IDA-ICE 5.0.

Table 1 Airflow rates in different ventilation control and space heating strategies

Ventilation strategies		Strategy 1	Strategy 2	Strategy 3
Cell offices	Max ($m^3/h/m^2$)	7	3.5	3.5
	Min ($m^3/h/m^2$)	7	3.5	3.5
Meeting room	Max ($m^3/h/m^2$)	2.5	13	10

3.1.3 Weather File Building Methodology

A set of future and contemporary weather files were created, using validated methodologies [14, 15], to evaluate the energy performance of three ventilation strategies under future conditions in relation to contemporary scenarios.

Two distinct emission scenarios were considered (Fig. 3): RCP 4.5 (mid-emission scenario [16]) and RCP 8.5 (high-emission scenario [16]), worst-case scenario. These scenarios account how the climate can change in the future given different scenarios of development and response to climate change, mostly in terms of demographic and socioeconomic development as well as technological evolution and land use change [17]. Three different periods were considered (Fig. 3): the *near future* (NF, 2020–2049), *far future* (FF, 2069–2098), and a *reference period* or *near past* (NP, 1970–1999).

Oslo, classified as a Dfb by Köppen classification [19], that is, humid continental climate, was selected for analysis. Table 2 presents climate assessment for this location for several periods in terms of temperatures, heating degree days (HDD), and heating season (HS). The rise in air temperature across all layers is evident, especially toward the century's close under the RCP 8.5 scenario. Naturally, this warming leads to a reduction in both HDD and HS across all examined periods and scenarios. The HDD and HS were calculated using the methodology described in [2].

Then, the weather files were prepared following the methodology presented in standard EN ISO 15927-4 [20], adhering to a 30-year interval, as recommended by the *World Meteorological Organization* [21]. Each weather file is created based on multi-year records of, at least, temperature, relative humidity, and global radiation (first tier) and wind speed (second tier). The *Finkelstein–Schafer statistic* is calculated for each month of the multi-year period and each meteorological parameter. This will result in a ranking. Then, the three lowest overall ranking months are selected. The final month selection is carried out based on wind speed data.

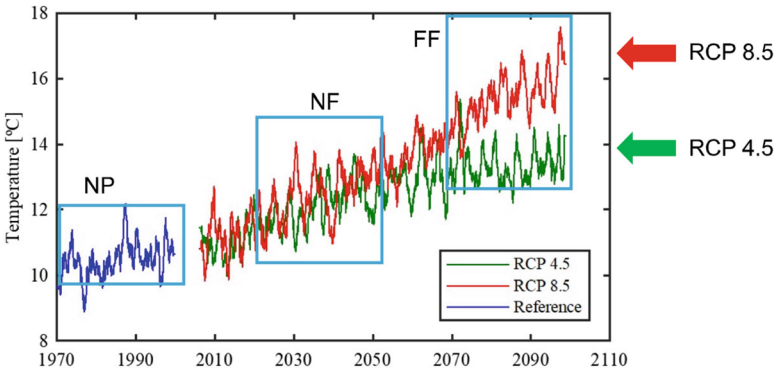

Fig. 3 Annual outdoor air temperature variation from 1970 until 2100 based on data retrieved from CORDEX. (Figure adapted from Ref. [18])

Table 2 Climate conditions comparison—historical climate (Ref.) and near future (NF) and far future (FF) for scenario RCP 4.5 & RCP 8.5—in terms of air temperature, heating degree days, and heating season for Oslo (NO) based on multi-year data (30 years of data each)

Location: OSLO, NO		Temperature (°C) Percentile 1°	Percentile 50°	Percentile 99°	Heating degree days, HDD (°C)	Heating season, HS (days)
Reference		−21.1 ± 3.1	0.9 ± 1.0	18.0 ± 1.8	5779 ± 349	308 ± 17
RCP 4.5	NF	−16.1 ± 2.9	3.4 ± 0.8	18.9 ± 1.5	4890 ± 293	268 ± 13
	FF	−13.4 ± 3.4	4.6 ± 0.8	20.4 ± 1.4	4460 ± 310	251 ± 9
RCP 8.5	NF	−16.4 ± 2.9	3.3 ± 1.0	19.4 ± 1.4	4906 ± 346	268 ± 15
	FF	−10.2 ± 3.7	6.5 ± 1.0	22.4 ± 1.4	3822 ± 361	227 ± 13

Subsequently, the Perez model [22, 23] was employed for splitting the global radiation into its direct and diffuse components and writing to the energy plus weather (EPW) format commonly used by BES, using the authors' developed code [15].

4 Results and Discussion

This section discusses the results from simulations that test energy use and indoor climate under different ventilation strategies in an office building, considering three ventilation systems and five climate scenarios.

Figure 4 displays the energy consumption of the building under three scenarios and five sets of climate data. When looking at the five climate scenarios, there is a noticeable increase in cooling needs, especially under climate scenarios RCP 4.5 and 8.5, for both scenarios in all HVAC cases. The largest increase is seen in Case 1, with fully mechanical ventilation, where cooling needs jumped up to 170% under the RCP 8.5 scenario compared to the standard climate scenario. However, the need for heating energy drops by about 60%. This trend is similar in Cases 2 and 3.

Interestingly, the highest energy savings due to warmer climates are found in Case 3, with savings of about 40% under the RCP 8.5 FF scenario, compared to around 16% in Case 1. This is likely because of longer periods of window opening in Cases 2 and 3, which use hybrid ventilation (as shown in Fig. 5). It highlights the effectiveness of hybrid ventilation as a passive design strategy for reducing energy consumption and improving indoor temperatures in cold climates.

Figure 6 displays the changes in average monthly temperatures in a south-facing office under two conditions (Case 1 and Case 2) and different climate change scenarios. For both cases, the operative hourly temperatures stay within the acceptable range set by Norwegian building codes, that is, a maximum of 50 hours above

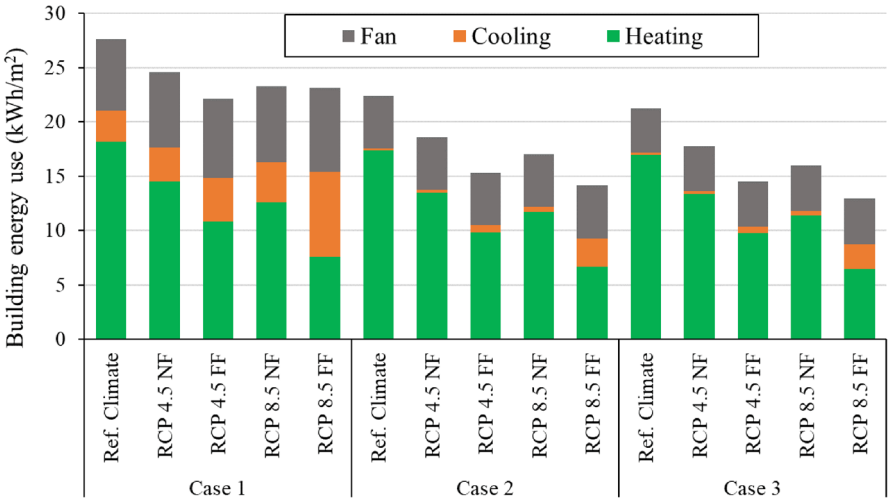

Fig. 4 Energy use of the office building across three different HVAC strategies

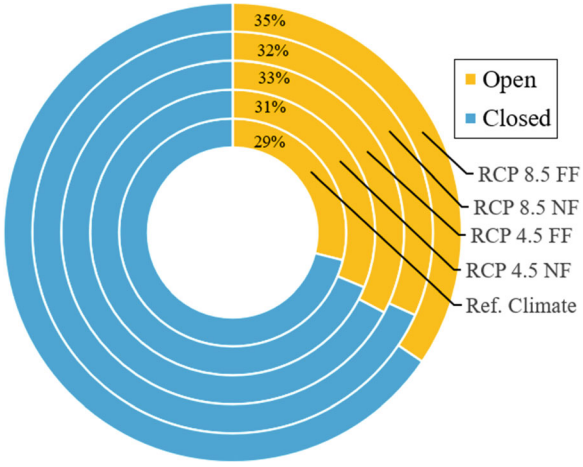

Fig. 5 Percentage of window opening in Cases 2 and 3 across various climate change models

26 °C. However, in the climate change scenarios identified as FF, the average indoor temperature remained higher compared to other climate scenarios.

Figure 7 shows a carpet plot of CO_2 variation during the year in a south-facing office for Case 2, for both the reference climate and the near future climate scenario.

As noted earlier in Figs. 4 and 5, under climate change scenarios, an increase in outdoor temperature facilitates the reduction of indoor CO_2 levels. This reduction is facilitated by prolonged window opening, which increases air exchange rates within the room. Such findings underscore the viability of hybrid ventilation systems, particularly in regions with cold climates and low pollution levels, exemplified by

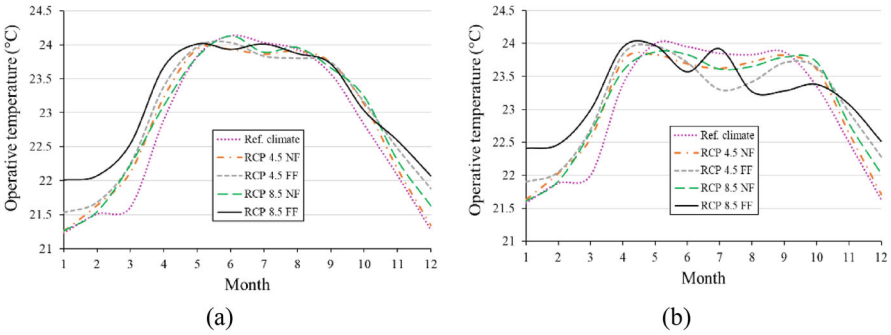

Fig. 6 Average monthly temperature changes in a south-facing office for: (**a**) Case 1 and (**b**) Case 2

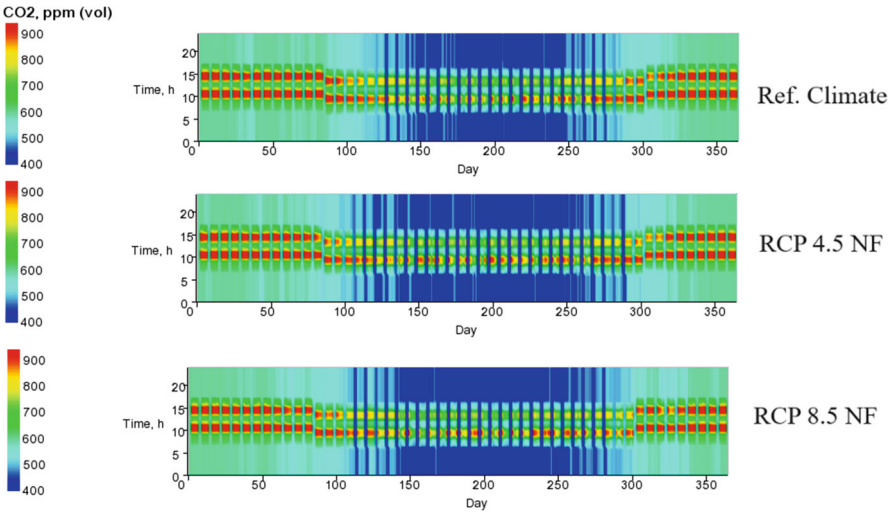

Fig. 7 Carpet plot of yearly CO_2 variation in Case 2 for the reference and near future climate

Norway. This is further supported by the expanded coverage of light and dark blue regions in Fig. 7. This trend is also observed in FF climate scenarios but to a greater degree.

5 Conclusions

This study embarked on an investigation into the resilience of climatization strategies within the context of architectural design and urban planning, focusing primarily on the adaptability of buildings in cold climates amid changing environmental

conditions. By exploring the efficacy of hybrid ventilation systems in office buildings, specifically under future climate scenarios, we aimed to bridge the gap identified in the literature regarding the resilience and sustainability of climatization solutions. The results of our simulations, analyzing different HVAC strategies under a range of climate scenarios, reveal significant insights into the performance of hybrid ventilation systems. Particularly, the findings demonstrate that hybrid ventilation, facilitated by automated window opening, presents a promising strategy for reducing energy consumption while maintaining comfortable indoor temperatures. The adaptability of this approach to varying climate conditions—especially considering the projected increase in cooling demand and the corresponding decrease in heating requirements—highlights its potential as a resilient climatization strategy.

Moreover, the extended periods of window opening in scenarios employing hybrid ventilation underscore the system's ability to leverage natural ventilation effectively, thereby reducing reliance on mechanical systems. This not only contributes to energy savings but also ensures a healthier indoor environment by facilitating improved air quality, as evidenced by the observed reduction in CO_2 levels.

In conclusion, our research underlines the importance of integrating passive design strategies, such as hybrid ventilation via window opening, into the architectural design and urban planning discourse in cold climate. Given the projected shifts in climate conditions and the increasing emphasis on sustainable development, such strategies offer a viable pathway to enhancing the resilience and sustainability of the built environment in cold climates.

1 Introduction

The world shares the same principal mission to reduce energy consumption and pursue a sustainable development path for all. To achieve this goal Energy utilization in buildings is a critical issue right now. Because buildings are a major primary energy consumer in the world energy sector, at about 40% of the total global energy consumption [1–3]. In this way, optimizing building energy utilization is imperative in the network of global energy needs, with considerable energy investment funds needed for viable plans, development, and the operation of buildings [2]. Subsequently, the energy productivity of buildings is broadly recognized as a basic

arrangement for handling energy deficiencies, carbon outflows, and their unfavorable environmental impacts [3]. Various activities have been attempted to present imaginative energy-saving innovations and promote ecofriendly buildings [4]. From those activities, net zero energy building, and net positive energy building are sustainable energy thematic areas.

A net-zero-energy building (NZEB) is characterized as one whose total sum of energy used annually is approximately equal to the total sum of the renewable energy produced on-site for the building's use [5]. Due to advancements in building innovation, renewable energy systems, and academic research, the development of NZEBs is quickly becoming more feasible [7].

An NZEB is seen as a promising arrangement to improve productivity within the worldwide development industry by combining energy productivity with the integration of nearby renewable energy sources [4]. Customizing building frameworks and plan strategies to suit particular territorial climate conditions is fundamental to realizing the vision of NZEBs. As laid out by the Universal Energy Office [5], accomplishing net-zero-energy outflows by 2050, a necessity to meet the 1.5 °C Paris Agreement target, requires expanding the development of renewable energy innovations, increasing energy effectiveness, decreasing methane emissions, and extending net-zero energy goals. According to the International Energy Agency report entitled as World Energy Outlook 2023; "These technologies hold the potential to achieve over 80% of the fundamental emissions cuts by 2030."

A tropical climate is characteristic of regions in the tropics, which lie between the Tropic of Cancer and the Tropic of Capricorn. In most of the literature, tropical climates' monthly average temperature throughout the year is above 18 °C [6]. In tropical climates, renewable energy sources, particularly solar energy, are abundant. Research endeavors into solar energy utilization encompass a broad spectrum of applications, spanning from the capture of low-temperature thermal energy applications [7] to the integration of photovoltaic systems within building structures [8–10].

The design of NZEBs in tropical climates should follow a hierarchical approach that prioritizes passive design features, followed by active energy-efficiency measures and finally by renewable energy technologies. The passive design features of NZEBs aim to reduce the cooling and ventilation loads of buildings by optimizing the building orientation, shape, envelope, shading, natural ventilation, daylighting, and landscaping [11]. Active energy-efficiency measures aim to reduce the energy consumption of mechanical and electrical systems, such as air conditioning, lighting, electric appliances, and controls, by using high-efficiency equipment, sensors, and automation. Renewable energy technologies aim to supply the majority of the energy demand of buildings by using solar, wind, biomass, or other sources, either on-site or off-site [1].

Recently, NZEBs have been growing rapidly in developed countries, though facing challenges and barriers. More than 90% of over 300 NZEB projects listed on the International Energy Agency (IEA) Solar Heating and Cooling (SHC) Program task 40 world map are located in the developed regions of the European Union (EU) and the United States [12]. This chapter endeavors to offer an overall assessment of the most recent progression in achieving net-zero-energy

developments in tropical climates while recognizing the essential obstacles and exploring the potential prospects for sustainable development in these regions. By overcoming these obstacles and taking advantage of the openings, significant headway can be made toward a greener, more energy-efficient future. More specifically, the main objective of this chapter is to provide a compressive systematic literature review on the recent progress, challenges, and opportunities in achieving net-zero-energy buildings in tropical climates.

2 Research Methods

This chapter aimed to assess the recent progress in constructing net-zero-energy buildings in tropical climates, with a particular focus on the challenges and opportunities associated with optimizing building energy. Various research articles were summarized for this purpose. A methodical combination of string-detecting searches in the Scopus database and secondary snowball search techniques were employed. This comprehensive approach was selected to bridge the gap in existing literature. Peer-reviewed articles written in English and published between 2014 and 2023 were considered for this review, using the title, abstract, and keywords fields in the databases. In total, 1261 records were initially extracted, and removing duplications reduced this number to 66 articles. After thorough analysis, 23 articles were chosen for inclusion in the review.

The study relied solely on original research publications and resulted in a detailed overview. Table 1 presents the keywords employed in the article search process, and Fig. 1 illustrates the criteria for inclusion and exclusion at various stages, adhering to the Preferred Reporting Items for Systematic Reviews and Meta-analyses (PRISMA) guidelines.

Table 1 Summary of keywords and their respective definitions

Keyword	Definition
Net-zero emissions	Achieving a balance between the volume of greenhouse gases emitted and the volume removed from the atmosphere
Decarbonization	The process of reducing carbon emissions from energy production, transportation, and industry
Energy efficiency	Improving building design and systems to minimize energy consumption
Renewable energy	Sources like solar, wind, and geothermal that produce clean energy
Passive design	Designing buildings to maximize natural heating, cooling, and lighting
Active energy	The energy consumption of mechanical and electrical systems, such as air conditioning, lighting, electric appliances, and controls, by using high-efficiency equipment, sensors, and automation
Grid integration	Integrating renewable energy sources into existing power grids

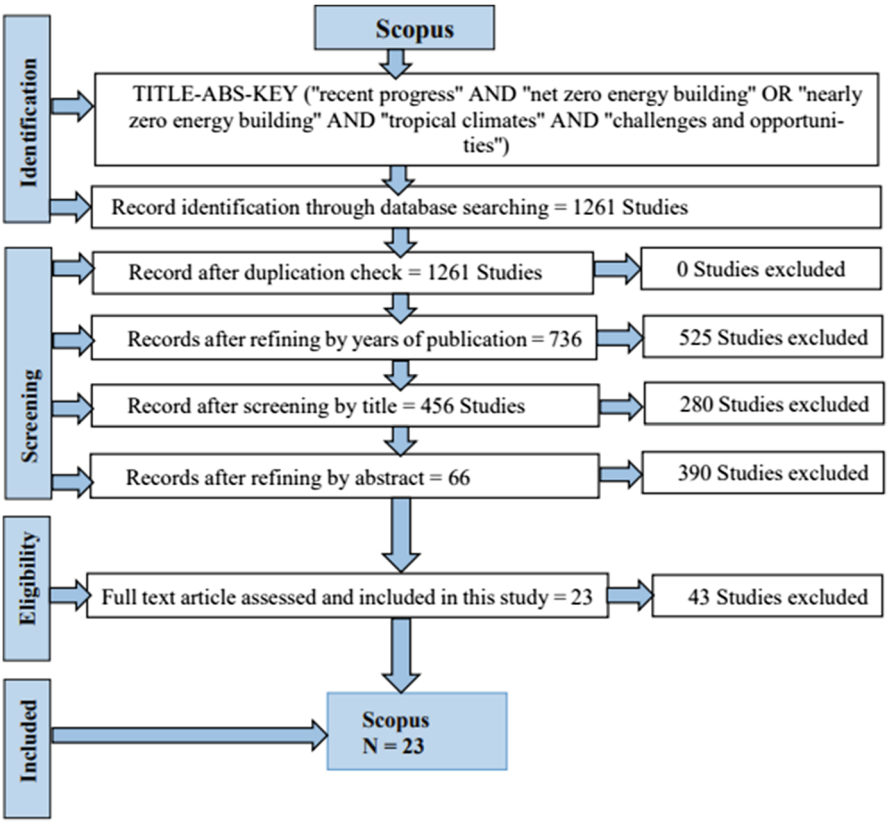

Fig. 1 Flowchart of the article search for this study

3 Results and Discussion

Figure 2 illustrates the annual publication trends of research articles focusing on nearly zero-energy buildings (nZEBs) from 2014 to 2023, in accordance with the inclusion and exclusion criteria outlined in the PRISMA guidelines. Different research articles show that significant progress has been made since 2000 in response to global warming from carbon emissions; researchers have focused on new building technologies and sustainable science and technology. After that, the research areas became a sensitive issue in reducing global warming by introducing the concepts of nearly zero-energy buildings, net-zero-energy buildings, and zero-emission buildings (Table 2).

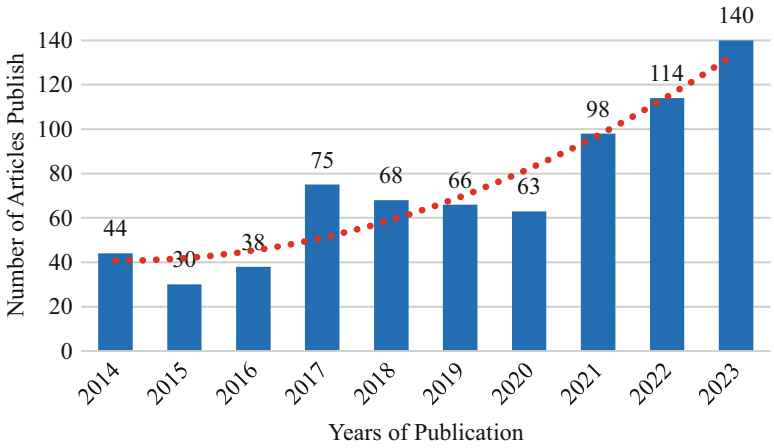

Fig. 2 Net-zero-energy building research trends over time

3.1 Recent Progress in NZEBs

No clear picture of the recent progress of NZEBs in tropical climates is available, but the Net Zero Stocktake 2022 report shows that the share of national emissions categorized by states' and regions' net-zero targets is similar for G7 countries and China, at around 40–50%, where the United States and EU countries' states and regions cover around 30–40%, but other countries' states and regions cover below 20% of net-zero targets [18]. Similarly, among G7 countries, about 70% of people living in large cities are categorized by net-zero targets; the same figure holds for the European Union; the United States covers about 60% of its population with a net-zero target; and China has a low population coverage rate, below 20% [18]. The global net-zero target has nearly the same coverage rate due to the population living in large cities, and the coverage rate for all states and regions is 36–37%.

3.2 Opportunities

Various studies have been carried out on the opportunity to build sufficient energy demand to construct NZEBs. Among them, Uspenskaia et al. [14] and others presented empirical evidence from the smart city project SPARCS on the challenges and barriers to constructing net-zero/positive-energy buildings and districts. The growing demand for energy-efficient buildings, advances in technology and construction materials, and government policies and incentives promoting NZEBs are some of the drivers of constructing NZEBs [19, 20, 23]. Similarly, another study has shown several building-integrated photovoltaic/thermal (BIPVT) applications and

Table 2 Summary of opportunities for and challenges to adopting net-zero-energy buildings

	Opportunities	Challenges	References
Barriers to and driving forces of industrial energy-efficiency improvements in African industries: a case study of Ghana's largest industrial area	Cost reductions from lowered energy use Threats of rising energy prices	Lack of access to funds/ financial constraints Lack of management awareness Weak energy policy frameworks Weak information systems	[19–22]
Challenges for and barriers to net-zero/positive-energy buildings and districts: empirical evidence from the smart city project SPARCS	Growing concerns about climate change and energy security Increasing demand for energy-efficient buildings Advancements in building technologies and materials Government policies and incentives promoting NZEBs	Lack of awareness and knowledge about NZEBs among stakeholders Lack of incentives and regulations to promote NZEBs Limited availability of skilled labor and professionals Technical challenges in integrating renewable energy sources	[2, 19, 23]
Building-integrated photovoltaic/thermal (BIPVT) systems: applications and challenges	Produce electrical and thermal energies Remove cooling and heating loads from buildings Reduce the electricity bills of a building Reduce operational energy costs Decrease the carbon emission of the building Act as thermal insulation Increase building value	The BIPVT systems are required to overcome some barriers that still limit their increased adoption, including the considerations of maintenance and replacement, standards and codes, building loads, cost-efficiency, and social and psychological factors Overheating of the system and building The use of highly expensive materials Feasibility dependent on the national and local supporting policy The electricity cost exceeding than that of grid electricity	[15]
Solar power utility sector in India: challenges and opportunities	Availability of solar energy Availability of wasteland Minimum dependency of solar installations on external costs	Technological barriers, policy and regulatory barriers, financing barriers, transparency, and accountability	[19, 20, 22, 23]

	Opportunities	Challenges	References
A review of hybrid renewable energy systems: solar and wind-powered solutions—challenges, opportunities, and policy implications	Energy reliability: storage units can store excess generated energy, offering a buffer when renewable sources are not generating power Grid stability: in on-grid configurations, energy storage can help in load leveling Optimized use of resources: advanced control systems can intelligently manage energy storage Microgrid capability: in microgrid systems, storage units can enable the system to operate independently of the central grid if needed	Technical challenges: integration complexity, intermittency, infrastructure development, energy storage, and power quality Economic challenges: high initial costs, return on investment, uncertainty, and market maturity Environmental challenges: land use and resource assessment Regulatory and policy challenges: inconsistent policies, grid integration policies, licensing, and standards	[19, 20, 23]
Overview and future challenges of nearly zero-energy building (nZEB) design in Southern Europe		Lack of local governance and a national strategy to create an infrastructure for nZEB implementation Societal and technical barriers to nZEB implementation Lack of policy framework Lack of access to funds	[19, 20, 23]
A review of net-zero-energy buildings in hot, and humid Climate: experience learned from a case study on 34 buildings	NZEBs tend to adopt advanced energy-efficient designs and technologies Natural ventilation and other passive technologies can effectively help NZEBs reduce their cooling energy use Solar energy is the most abundant	The adoption of advanced technologies in NZEBs is strongly influenced by their countries' building energy codes and standards A key barrier is their high upfront cost Lack of personnel for NZEB design, construction, operation, and management	[1]

has identified challenges and opportunities, such as removing cooling and heating loads from buildings, reducing buildings' electricity bills, reducing operating energy costs, and reducing carbon emissions, and increasing the value of buildings [16, 18].

By promoting energy-efficient and low-carbon buildings, many cross-cutting challenges and opportunities can emerge for the construction industry and its stakeholders [20]. They are associated with lower energy consumption, zero carbon

emissions, and macroeconomic benefits through indirect cost savings from improving energy security and resilience; creating jobs; improving the health, productivity, and comfort of building occupants; and enhancing assets [21]. These benefits are also well aligned with and contribute to various United Nations sustainable development goals (SDGs).

3.3 Challenges

The challenges identified in this study include, but are not limited to, political, economic, social, and knowledge barriers.

- Policy barriers: Policy design and implementation often require extensive coordination across government agencies and different levels of government, which also includes inconsistent policies, grid integration, licensing, and standards books [22].
- Economic barriers: These barriers include increasing the upfront costs of more-energy-efficient buildings and equipment, a lack of available capital to meet upfront costs, and a poor understanding of the life-cycle costs of maintaining high performance in operations [16, 19–23].
- Social barriers: The behavior and social practices of building occupants significantly influence the gap between a building's predicted and actual energy performance. These factors are complex and thus difficult to address and are strongly influenced by emotional rather than rational decision-making [13, 16]. Studies have shown that whether or not residents are directly responsible for energy bills has a strong influence on their energy-consumption behavior in buildings [24].
- Knowledge barriers: These range from a lack of professional capacity to design and construct high-performance buildings to a lack of capacity or training in policy design and implementation [19, 20, 23].

Overcoming these obstacles by implementing policies that realize benefits will inevitably entail costs. The design and implementation of a carbon-reduction and energy-efficiency policy for buildings, as in any policy, will generate many costs and benefits, which must be taken into account when evaluating the cost-effectiveness of the policy. Therefore, determining the cost-effectiveness of a policy is both a technical and a political calculation [23]. On the contrary, several studies have shown that the preceding points impact both the opportunities and challenges related to the global energy crisis, sustainability strategies, a future-oriented green society, and government policies and regulations.

4 Conclusion

This chapter highlighted the challenges faced in constructing NZEBs in tropical and humid climates, where adoption remains limited when compared to temperate and developed regions. The key challenges identified include the high initial costs of building NZEBs, a lack of design and operational expertise, and difficulties in implementing effective policies. To overcome these barriers, supportive policies and incentives, such as financial support and standards for development, need to be implemented to encourage the wider adoption of NZEBs. Raising awareness among and educating stakeholders, using abundant renewable energy sources, and considering user behavior and comfort are also essential strategies. Efforts to promote NZEBs in tropical climates could help to reduce carbon emissions and ensure reliable energy supplies while addressing rising electricity costs and environmental concerns.

1 Introduction

Nowadays, sustainability has become a highly influential concept and a decisive factor in economic, social, and environmental decisions of developed countries. Buildings, which serves as an important component in the society, have a prevailing role as a hub for the realization of sustainable development. In order to facilitate and implement sustainability in both the construction and use of buildings, advanced assessment methods such as BREEAM have been developed by the Building Research Establishment (BRE) in the United Kingdom since 1990. Relying on dedicated criteria and specified processes, multidisciplinary teamwork toward sustainable development can be coordinated and realized (Lowe, Watts, Jack, Norman, 2011) [1]. The framework of BREEAM can promote integration of diverse knowledge and know-hows from different experts.

However, the dilemma of optimizing energy performance while maintaining a comfortable indoor climate is a notable paradox, particularly evident in educational buildings. Achieving energy performance to passive house level can be difficult due to the energy demand of cooling, while maintaining an optimal indoor climate for BREEAM certification.

As mentioned, the optimized project values, such as PPD (Predicted Percentage of Dissatisfied) or PMV (Predicted Mean Vote), are primarily derived from an integrated approach involving various experts. However, these parameters are largely based on subjective perception, underscoring the importance of user-oriented studies to address this dilemma.

This study concentrates on a pilot project, specifically highlighting one of the Norway's most environmentally friendly schools, which has attained BREEAM certification at the Excellent level. The objective is to evaluate the relationship between energy performance and indoor climate by user-oriented interviews and field inspections. The investigation goes beyond theoretical analysis, aiming to uncover practical correlations among energy supply solutions, building envelope, and technical details.

This paper draws from a bachelor's project conducted by three students [2] at Oslo Metropolitan University. Their contribution adds a practical and objective dimension to the research by interviews and field inspections.

In Sect. 1, we introduce the certification systems in Norway-BREEAM NOR. Sect. 2 presents the case study with a detailed and objective exploration of the challenges faced in achieving both energy efficiency and an optimal indoor climate in educational settings. Sect. 3 illustrates the findings and concludes this paper.

2 Methodology: Case Study

The study employs a qualitative research methodology, specifically through case study interviews. The complexity of paradox of energy optimization objectives while maintaining optimal indoor climate conditions for educational buildings underscores the reason of the chosen case study approach. By examining a real pilot case study, employing in-depth interviews and practical fieldwork, this methodological approach offers a robust framework for elucidating the interrelationships among certification processes, indoor environmental quality, and energy performance parameters. The questionnaire is based on and compared to standardized values for school buildings from Örebro model based on a World Health Organization strategy at the early 1980s (Andersson, K. Fagerlund, I. Bodin L, and Ydreborg B, 1988) [3]. The questionnaires of MM060 were chosen based on the background of the project, as outlined in Tables 8 and 12 of the School Environment manual (Andersson, K. Strihd, G. Fagerlund, I. Aslaksen, W) [4–7]. To check whether the indoor climate is good, we look at survey responses related to an Örebro survey. If people are happy with the indoor climate, their answers should match

Örebro's reference values. This study presents preliminary findings from the early stage of the proposed research topic. Future research aims to explore how indoor climate evaluation can be leveraged to optimize technical settings.

2.1 The Case Study

Zero-emission educational building—This school was chosen as the case study for its ambitious environmental goals, which pose a challenge in maintaining a comfortable indoor climate while minimizing energy consumption. The data for the study were collected through interviews conducted using Google Forms (Fig. 1).

The project aims to set a pilot project in environmental and climate-friendly construction in 2022. With ambitious goals set by the municipality to achieve BREEAM-Excellent certification, passive house standards, zero-emission building (ZEB-OM) status, and the extensive use of cross-laminated timber.

The school, designed to accommodate approximately 360 students and 45 staff members within a total gross area of 4500 m^2, a multifaceted team of experts, including external consultants specializing in zero-emission buildings, has been assembled to tackle the project's diverse requirements. In meeting the municipality's requirement for ZEB—O ÷ EQ [8] compliance, a comprehensive renewable energy

Fig. 1 The case study

solution has been devised, primarily leveraging solar energy. For heating, a demand-controlled ventilation system was chosen over traditional methods. The centralized heating system incorporates a highly efficient liquid-to-water heat pump, thermal storage capacity, and geothermal heat pumps for both heating and cooling needs. The choice of extensive use of cross-laminated timber is committed to reducing carbon emissions. The school aims to be a living embodiment of sustainability principles, fostering synergies between education and environmental stewardship.

The bachelor's project focuses on examining critical aspects of the building's energy efficiency and indoor climate quality in relation to the achieved BREEAM certification. This involves conducting field work, interview, and analysis to assess the interrelations between high-energy performance and indoor climate.

2.2 Energy Efficiency and Indoor Climate

Through fieldwork, interviews, and energy analysis, it was found that while the focus on energy efficiency could be achieved, it comes at the expense of user comfort in terms of indoor climate. The survey revealed firstly dissatisfaction among students and teachers regarding indoor temperatures, with classrooms often feeling too warm. Compared to standard guidelines of indoor climate from BREEAM(Hea03) [9], temperatures were consistently higher than recommended, possibly influenced by the survey's timing in April, a period marked by fluctuating outdoor temperatures. For instance, starting at 5°C at 8:00 am, temperatures rose to 14°C by 1:00 pm. Such temperature swings could cause discomfort indoors, exacerbated by the building's effective insulation, and extensive window coverage. Secondly, the survey explored symptoms related to poor indoor air quality, with a significant number of respondents reporting such issues, indicating a need for indoor environment enhancements.

2.2.1 The Perceived PPD/PMV Versus Required PPD/PMV According to BREEAM/Hea03

The results of the in-depth interview on perceived thermal comfort are presented as PPD and PMV values with the graph in Fig. 2. Despite the participants of the study being distributed across four different rooms, the graph shows that one point of the case study that represents the average of all responses regardless of various locations of the room. The perceived PMV values presented here are based on responses from the survey participants (refer to Appendix 1[10]) and not representing a precisely calculated result. Even though the calculated PMV value for a building is more detailed and includes several factors such as room air velocity, operative temperature, metabolism, clothing, and relative humidity than the perceived PMV value. However, this perceived PMV value can be used to provide an overview of how the building's occupants perceive the PMV value.

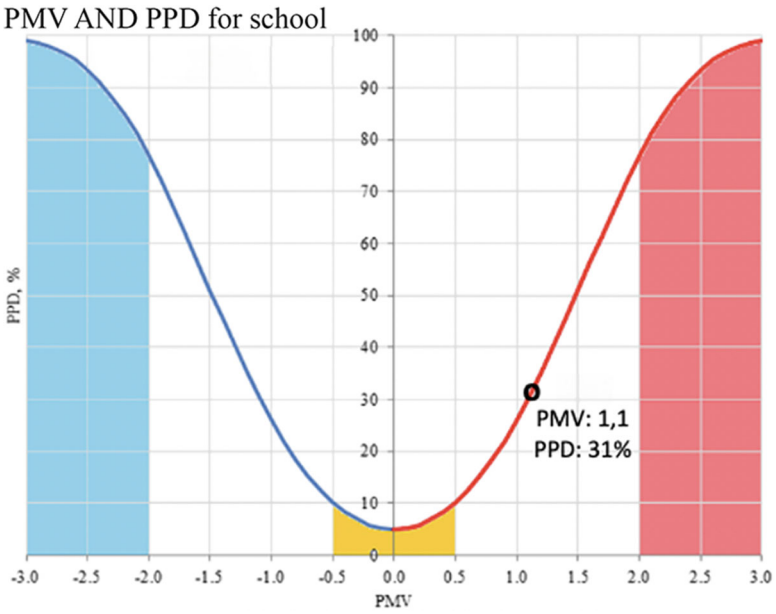

Fig. 2 The PMV/PPD value of the case study (PPD is shown as a function of PMV with the requirement from NS-EN ISO 7730:2005, Table A.1, category B marked in yellow)

In the BREEAM-NOR 2016 manual, Chapter HEA 03—Thermal Comfort, points can only be achieved if the PMV and PPD values in the building's regularly occupied area meet the requirements in category B from Table A.1 in NS-EN ISO 7730:2005 [11]. The requirement is a PMV value between -0.5 and 0.5 with a corresponding PPD value below 10%, as illustrated by the yellow shaded area in Fig. 2.

The survey resulted from in-depth interview in a PMV value of 1.1 and a PPD value of 31%, which is much higher than the values used when the building was certified. This suggests a general dissatisfaction with the thermal indoor climate among students and teachers at the school, with reports of excessively high temperatures in the classrooms than calculated PPD/PMV which is documented according to the requirement from HEA03 for BREEAM. Compared to the standard *Ergonomi i termisk miljø* (see Fig. 3) according to NS-EN-ISO 7730:2005, this result is far above what is expected of modern buildings, as the lowest level (class C) requires a PPD $< 15\%$ while the case study has a PPD of 31%. This may be caused by the survey being conducted in mid-April, a period with highly fluctuating outdoor temperatures, which is also reflected in some responses shown in Appendix 1 [10]. The day the survey was conducted is also an example of this, with a temperature of 5°C at school start at 8:00 a.m. increasing to 14°C when the responses were submitted at 1:00 p.m. (climate data according to YR [12]).

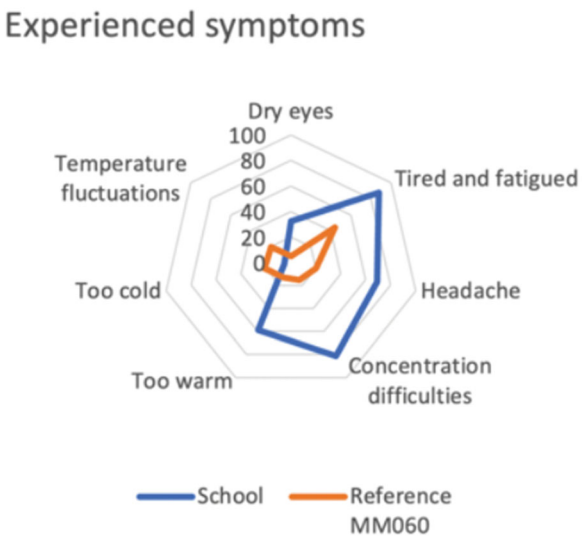

Fig. 3 Frequency of perceived indoor climate-related symptoms of the case study in percentage compared to reference values

The survey also revealed whether participants have experienced one or more symptoms commonly associated with an unsatisfactory indoor climate. The results are presented as the percentage of participants who have experienced the respective symptoms and are illustrated using a rose diagram in Fig. 3.

The results shown in the rose diagram are based on survey answers, so they only give an example to check if results are different from the reference frequency using Table 1 in the School Environment manual according to the Örebro model. The rose diagram shows differences according to School Environment Table 1 for six out of eight symptoms people were asked about. The symptoms people often experience in this survey include feeling too hot, dry eyes, tiredness, headaches, and difficulty concentrating. This shows clearly that people are not happy with how warm it is indoors. To ensure objective results from the survey, interviews were conducted with a total of 74 participants from four different classes. It is improbable that factors like insufficient sleep, allergies, or unengaging teaching influenced the outcome.

The survey results can help to identify which indoor climate factors might be causing the reported symptoms. In this case, it seems that participants feel there's poor air circulation or not enough ventilation in the classrooms. This could be because the need for cooling wasn't properly estimated, leading to insufficient ventilation.

The gray graph in Fig. 4 represents the energy consumption recorded by the SD system from January to April, while the orange graph illustrates the projected energy demand at the design phase.

Figure 4 indicates that the energy consumption in January exceeds projections by over 10,000 kWh, suggesting potential underestimation of heating needs during that period. Subsequent months show a stabilization in consumption, with February slightly higher than expected and lower consumption in both March and April.

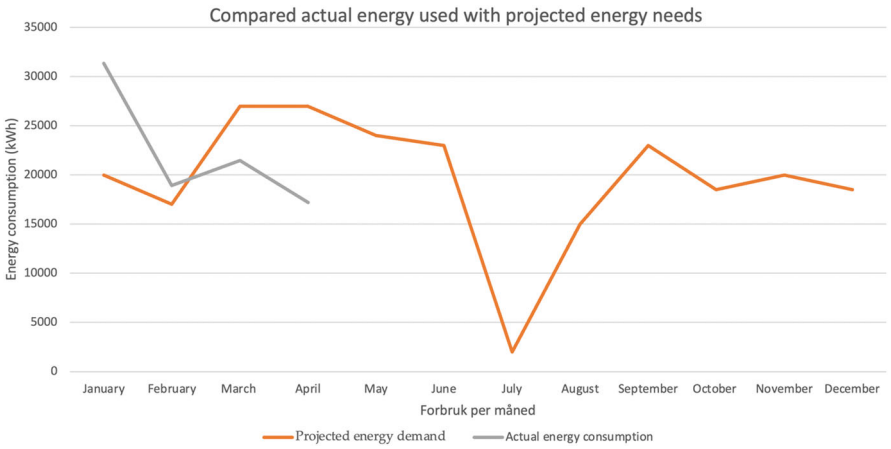

Fig. 4 The comparison of energy consumption between the designed and actual usage from January to April without additional energy consumption

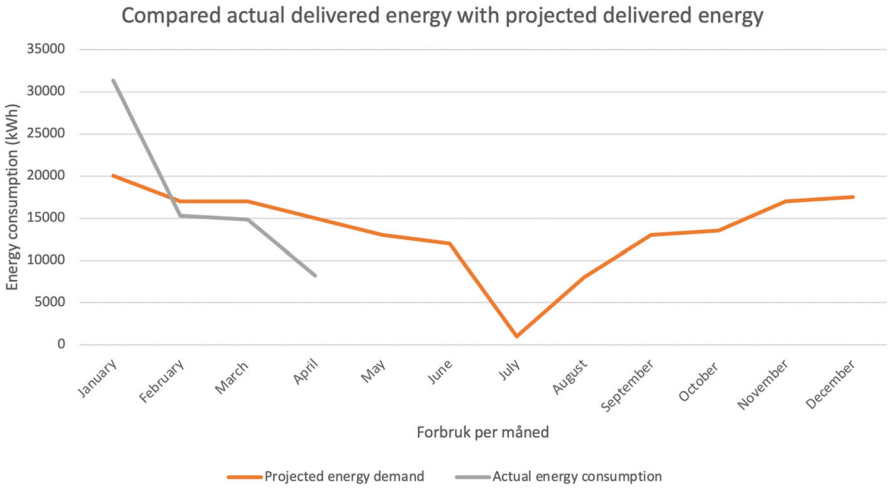

Fig. 5 The actual energy consumption from January to April compared to the projected energy demand with additional energy consumption

Further insights into the source of additional energy consumption are provided in Fig. 5, which displays the case study's delivered energy consumption alongside projected values.

It is evident here that the actual energy consumption in January contrasted similarly to Fig. 5. Thus, the building actual energy consumption was 1.5 times more than projected energy demand in January. For the remaining period, delivered energy consumption was slightly lower than projected, attributed to higher-than-expected electricity production from solar panels and slightly lower total consumption.

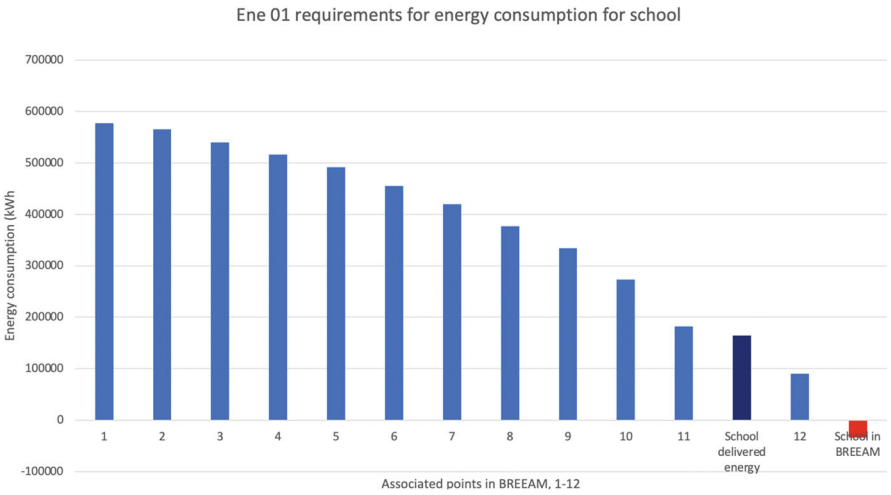

Fig. 6 Comparison of energy performance for BREEAM and energy production

The school is equipped with a 338 kWp solar panel system, contributing to climate-neutral operation and achieving ZEB certification. There is a correlation between energy efficiency and ZEB certification, and the school's potential to improve student comfort through data from the BMS is further examined. The school achieves maximum points for energy efficiency, largely thanks to solar power production.

In the BREEAM-NOR certification of the case study, the building earned 12 out of 12 points in the Ene 01 category by achieving over a 100% improvement from energy grade C. Despite delivered energy comprising 69.7% of the projected annual consumption, the certification overlooks the building's energy load as long as energy export is significant. This is exemplified in Fig. 6, where the blue columns represent the case study's various requirements for maximum annual energy consumption, and the dark blue column denotes the projected consumption of delivered energy used for point allocation for the certification.

Figure 6 illustrates that for the case study to achieve full compliance in this aspect of the BREEAM-NOR manual, there is a requirement for an annual consumption not exceeding 90,000 kWh to achieve 12 points. During the building's certification under Ene 01, a consumption of −34,348 kWh was assumed, reflecting an expected export of self-generated solar energy of 200,000 kWh subtracted from the projected consumption of delivered energy, totaling 164,000 kWh. This adjustment stems from compliance note SN5 in the BREEAM-NOR manual. If only a solar panel system sufficient to cover the remaining 30.3% of the building's energy consumption had been installed, scoring in Ene 01 would have been based solely on the building's delivered energy of 164,000 kWh, resulting in 11 out of 12 possible

points. This raises questions about the actual benefits derived from the 1656 m^2 of solar panels installed. It is plausible that all the solar panels were installed to ensure an overproduction of solar energy greater than the building's consumption of delivered energy, thus guaranteeing full compliance with Ene 01 in the BREEAM-NOR manual. Therefore, compliance note SN5 shifts the focus of Ene 01 away from rewarding energy-efficient buildings to favoring those with high-energy production.

2.2.2 Discussions and Findings

One proposed solution involves adjusting the cooling system or reducing morning heating to maintain comfortable temperatures throughout the day. However, careful consideration is required to balance comfort and energy consumption. Alternative approaches, such as improving insulation or implementing shading mechanisms, could also be explored to create a more conducive indoor learning environment.

A more energy-saving solution during periods of greater outdoor temperature variations would be to reduce heating early in the day and accept a slightly lower temperature in the morning hours. These are two solutions that would contribute to an indoor climate where the conditions for a good learning environment are more present.

With such large temperature variations in a relatively short time, clothing that was suitable at the beginning of the school day may become too warm later on during the interview time. This effect could also be exacerbated by the building being highly insulated while having large window areas that allow in a lot of sunlight.

PMV and PPD values that are so far from the recommended range indicate that measures should be taken for improvement. A natural measure in this situation would be to investigate if room cooling system be fine-tuned based on external factors throughout the day, although this would contribute to increased energy consumption during such periods.

In the case study, even though the energy performance standards for BREEAM certification were met, the PPD value is critical and should not be compromised, as it is central to the building's purpose. A suitable indoor climate is essential for effective daily learning.

The frequency of reported symptoms in this survey is suggesting that measurements should be taken to improve the situation. If the cause is seasonal, simple short-term measures might help. The Norwegian Institute of Public Health (*Folkehelseinstituttet*) has suggested some relevant measures, such as ensuring students leave the classroom during breaks to let in fresh air or adjusting the timetable to manage the number of people in the room. Longer term measures could include improving lighting and using external shading device to prevent high temperatures in the classrooms. These measures can help make the school a better learning environment and reduce the frequency of reported symptoms.,

3 Conclusion: Lessons of Experience

The case study,a BREEAM "Excellent" educational building, was investigated regarding its thermal indoor climate in relation to BREEAM themes of energy, materials, and indoor climate. Energy consumption was closely linked to the thermal indoor climate, necessitating a study of energy consumption and indoor climate environment.

An Örebro survey revealed that the majority of students (77 interviewees) experienced the indoor climate as too warm, with temperature fluctuations being either too cold or too hot. This led to inquiries into why the temperature was perceived as too warm and whether the actual energy consumption deviated from the projected [13]. By utilizing the cooling system, which had not previously been used at the school, the PMV value could be reduced, and thermal comfort is improved. However, implementing a cooling system could potentially impact energy efficiency and thus negatively influence BREEAM scoring.

In providing this recommendation, careful consideration was given to whether the building could still achieve full points in the BREEAM energy section, despite increased energy consumption from cooling. Analyses showed that actual consumption for March and April, when high temperatures were reported, was lower than projected. This suggests that the school has the potential to improve thermal comfort while retaining BREEAM points.

The question of whether electricity produced from the PV system returned to the grid should count positively in the energy balance was also considered. While BREEAM's benefits for the external environment are evident, improvement in the indoor environment remains uncertain. The balance between energy efficiency and thermal comfort should be considered in future measures to optimize user experience. This emphasizes once again the importance of post-occupancy evaluation to compare projected values with actual delivered values.

It is crucial to note that it is still in the early stages of the research project. Conducting a more extensive user survey in the future to assess ongoing perceptions of building comfort would yield more accurate results. Establishing a feedback system for continuous monitoring could also be considered.

1 Introduction

1.1 Complexity in Construction

The complexity of the construction industry has, over time, attracted the attention of many researchers, who have analyzed its main causes in order to reduce the possible negative effects. The dimension of some projects often leads to delays and cost overruns, which makes the construction industry one of the most dynamic, risky, and challenging business activities in existence [1]. Being aware of this situation facilitates anticipatory planning, both from a technical and a managerial point of view. Complexity is a significant criterion in choosing an appropriate organizational form for the project, influencing its temporal, economic, and qualitative objectives by

contributing to the specification of planning, coordination, and control requirements [2]. Among the main factors that make a project complex, the one that has the greatest impact is organizational complexity, which is generated by insufficient utilization of communication channels and limited generation and utilization of information [3]. It is therefore evident that a crucial aspect in managing complexity within the construction sector is the involvement of individuals in the process, who consequently generate, transmit, and exchange information. Additionally, social, cultural, cognitive, and operational complexities further compound the task's intricacies, escalating as the available time diminishes [4]. The emergence of the 4.0 revolution underscores a shift in how buildings are conceived, constructed, and operated. Digital technologies like Building Information Modeling (BIM), artificial intelligence, and the Internet of Things (IoT) are reshaping industry practices, offering efficiencies and innovations. However, they bring forth challenges in data handling, cybersecurity, and workforce preparedness. Additionally, the integration of advanced materials with smart, sensitive, and active functionalities demands a careful design approach to navigate the opportunities and risks associated with their widespread adoption [5]. In this context, the aim of this paper is to codify the meaning and characteristics of smart architectures capable of addressing and managing this complexity, establishing a structured framework to assist designers in making decisions that will be easily digitalizable, and facilitating the dissemination of sustainability via a BIM-based workflow.

1.2 Smart Architecture

In light of the simultaneity and heterogeneity of management of the generative factors of contemporary complexity, the architect, as director of the building process and interpreter of social needs is faced with contemporary challenges that impose paradigm shifts on the way of living and perceiving reality. It turns out to be increasingly valuable to create an architecture that, as enunciated by Mies van der Rohe, is a process of searching for truth and constructive clarity brought to its exact expression [6]. It is inferred that architecture only achieves constructive coherence if it is able to process, integrate and resolve an open matrix, capable of interpreting design instances by intercepting an ever-increasing and changing flow of information, facilitating the task of the architect as an intellectual who must manage, at different scales of detail, the evolution of a multidisciplinary process. Currently, the term "smart feature" within the realm of architecture commonly refers to sophisticated materials and technologies meticulously designed to intelligently adapt to their surroundings. These elements can react intelligently to external influences, altering their properties, structure, or functions accordingly [7]. Accordingly, this notion has led to the conceptualization of smart buildings as systems capable of adapting, responsively, not only to the variability of external conditions but also to the continuously evolving needs of their occupants [8]. Indeed, Casini [9] defines a smart building as the evolution from a nearly zero-energy building, where alongside

the utilization of high-performance materials and technologies, there exists the potential to dynamically control the building's environmental parameters, contingent upon changes in external or internal conditions. In order to avoid confusion between the definitions of *smart building* and *smart architecture*, semantic researches were conducted within the Department of Architecture at Ferrara University.[1] This research first investigated the meaning of the adjective *smart,* followed by an examination of the term *architecture.* The outcome of this research led to the definition of smart architecture as "an architecture that, through innovative methodologies and/or tools, responds to the current needs of society" [10].

1.3 Metamodules

Throughout history, architects have frequently utilized modular elements to create architecture that can effectively address social needs and challenges during pivotal moments in society. The module, which can have varying interpretations depending on the context and time period, is typically associated with hierarchy, standardization, and repetition. The principles of modularity suggest the use of consistently logical criteria to generate ordered relationships between parts and an indefinite number of variables.

Modularity in Architecture One of the earliest examples of modularity can be found in vernacular architecture, particularly in the housing typology of the Nuraghe. Their shape is due to the construction system that characterizes them, the "tholos," which, consisting of rings of blocks arranged progressively tighter from the base to the top, has given classic nuraghi their distinctive conical tower shape. Each nuraghe and human settlement constituted an integral part of a complex system, resulting in a vast array of specific contexts in which the Nuragic communities adapted their settlement methods in response to the terrain, resource distribution, demographic and social development, and internal and external competition dynamics. With the demolition of the city walls and the development of extra-moenia cities, a logical flow of information with causal connections between statements became necessary. In the nineteenth century, the construction feasibility of the module was crucial for the development of urban plans in major European cities, such as the Projecte de reforma i Eixample de Barcelona by the engineer Idelfonso Cerdà y Suñer and the redesign of the city of Paris by the then prefect of the department of the Seine, Georges Eugène Haussmann. Although they have different methods and purposes, both urban plans exhibit a modular principle in the construction characteristics of the urban block and in its relationship with the infrastructure network it connects to. In the first half of the twentieth century, Le Corbusier departed from the concept of a regulatory grid and theorized the Modulor as a tool for controlling

[1] Semantic research conducted within the International Doctoral Program in Architecture and Urban Planning. Doctoral candidate: Ilaria Spasari, Supervisor: Fabio Conato.

proportion and an open system not consisting of a sequence of measurements but rather a conceptual dimension [11].

The second half of the twentieth century was marked by the advent of globalization, a phenomenon that perceives the world as a single entity comprising new forms of interaction that transcend national borders [12].

Metamodularity in Contemporary Architecture The semantic evolution of the module, from a simple measuring tool linked to specific construction techniques and materials to an expression of a specific idea, prompts us to consider a possible new configuration of modularity.

Considering the complexity of contemporary architecture, both economic and social, it is necessary to codify architecture in order to respond to contemporary needs with innovative methods and tools. Contemporary architecture is characterized by intrinsic complexities that are difficult to visually perceive [13]. It is produced in multiple locations and is embedded in a social context marked by global cultural, social, and technological revolutions [14]. For these reasons, the modular codification of smart architecture tends to transcend material constraints and abstracts to an informative level, becoming a metamodule.

The metamodule consists of a core of smartness indicators which are related and coherent information that creates order among its parts. It systematizes the complexity of contemporary instances with the vastness of innovative design components and solutions that respond to these instances, using a multi-scale approach.

BIM and Metamodularity The informative nature of the metamodule is easily digitizable as it is based on attributing information to specific architectural components or sets of components. This is compatible with BIM software, where three-dimensional modeled objects are associated with both geometric and non-geometric information. The meta-module consists of an information system that can enrich a digital model. For example, a meta-module template can be created within a BIM Authoring software that incorporates all predetermined Smartness Indicators, associating them as non-geometric properties to specific three-dimensional objects. Through exporting the digital model in an open format file or IFC (Information Foundation Classes), the meta-module contributes to the interoperability among the actors of the building process. This allows them to be aware of the consequences and design interactions of their individual intellectual actions.

2 Smartness Indicators

In order to identify the smartness indicators that make up the metamodules of the smart architecture, categories (see Table 1) have been identified that correspond to the main characteristics that the smart architecture must possess to meet the needs of contemporary society. The identification of categories and therefore the needs of contemporary society have been carried out through the analysis of the main regulations issued in the last 50 years, literature reviews on Scopus and Web of

		Educational Aspects

Science, and through the observation of case studies of contemporary architectures that have generated both positive and negative effects in the context in which they were built. The numerous legislations enacted since the 1970s have focused on the primary need of contemporary society: livability in a more sustainable world. For this reason, sustainability is identified as the foremost category of requirements. It has been subdivided into three subcategories based on the three pillars defined by the 1987 Brundtland Report: environmental, economic, and social. The indicators within these subcategories serve as tools and/or characteristics through which contemporary architecture addresses the needs of society. Thus, the environmental subcategory encompasses passive strategies inherent to environmental design, those aimed at obtaining environmental certifications, and those enabling the achievement of a favorable Life Cycle Assessment (LCA) result. Regarding LCA, it has been decided to consider environmental LCA (e-LCA), which is the environmental component of Life Cycle Sustainability Assessment (LCSA) [15]. Similarly, the economic aspect of sustainability is represented by optimal parameters of Life Cycle Costing (LCC), such as labor cost, material cost, annual capital charge, and end-of-

life costs. The social aspect of sustainability is expressed through Social Life Cycle Assessment (SLCA) indicators, which encompass workers' categories (child labor, fair salary, working hours, social benefits, job satisfaction), consumers (health and safety, consumer privacy, transparency), the local community (safe and healthy living conditions, community engagement, local employment), society (public commitment to sustainability issues, contribution to economic development, technology development), and the Value Chain (fair competition, respect for intellectual property rights). Another social aspect of sustainability is related to the comfort and satisfaction of users and workers [16], which can be measured through values of daylight, external views, high-frequency lighting, natural ventilation, indoor air quality, thermal comfort, microbial contamination, acoustic performance, presence of color, and vegetation [17]. The second category of smartness indicators is represented by dynamicity, indicating an object's ability to change its initial condition in response to external stimuli. It is expressed through indicators of versatility, multifunctionality, and adaptability, which vary in significance depending on the scale (urban, architectural, and technological). The third category of smart indicators has been identified as coherence, meaning the architecture's ability to remain faithful to both the external objectives imposed by the client (environmental, urban context, comfort, and building typology) and to express its essence at all project detail scales (also through variations in progress both in the design and construction phases). Finally, the last category of smart indicators is the controllability of information flow in the design and construction process, addressed to architects' competences in solving design challenges through innovative strategies, years of experience in the realization of a specific work, and their ability to continually update themselves on new methods and operational tools.

3 Results and Discussion

3.1 Decision Support Matrix's Structure

The categories of indicators selected represent the main demands that contemporary architecture must respond to. If specific design solutions or best practices satisfy these demands, they constitute sets of structural information for smart architecture. Therefore, the four demand categories of sustainability, dynamicity, coherence, and controllability can be assimilated to four generative metamodules of smart architecture. Consequently, the sub-categories identified earlier become sub-metamodules, which, in turn, contain sets of smartness indicators.

Based on these considerations, a decision-support matrix structure (see Table 2) was developed to assist architects in managing the multiple pieces of information during the design process. The matrix consists of metamodules, which are sub-metamodules that contain smartness indicators at various scales of project development. To ensure easy digitization, the project development scales have been assimilated to the LODs (Level of Developments) commonly used in BIM (Building Information Modelling).

Table 2 The decision support matrix's structure, characterized by metamodules declined at each LOD

Decision support matrix structures

3.1.1 Sustainable Metamodules

Environmental Design Best Practice and Their Integration in the BIM Workflow

As an example, this contribution delves into the informative contents of the sustainable metamodule, specifically the "environmental" sub-metamodule, which contains smartness indicators related to environmental design (highlighted in red in Table 2). These indicators were identified through previous research activities carried out by the Department of Architecture at the University of Ferrara and have been adapted to the various project LOD (see Fig. 1).

Integration into the BIM workflow According to ISO 19650 BIM standards, information metamodules can be inserted into BIM authoring software and associated with specific design objects as non-geometrical data at various LODs. The IFC classification allows for customization, enabling the metamodules to be added to the BIM as customized property sets (see Figs. 2, 3, and 4). These can then be extracted through a quantity take-off, which is useful for updating the merged model in a shared environment and improving interoperability with building process stakeholders.

4 Conclusion

The article discusses the pressing problem of complexity in the construction sector and its implications for contemporary architecture. It highlights the need for a proactive approach to managing this complexity, examining the main organizational, social, cultural, and technological issues. The emergence of digital technologies such

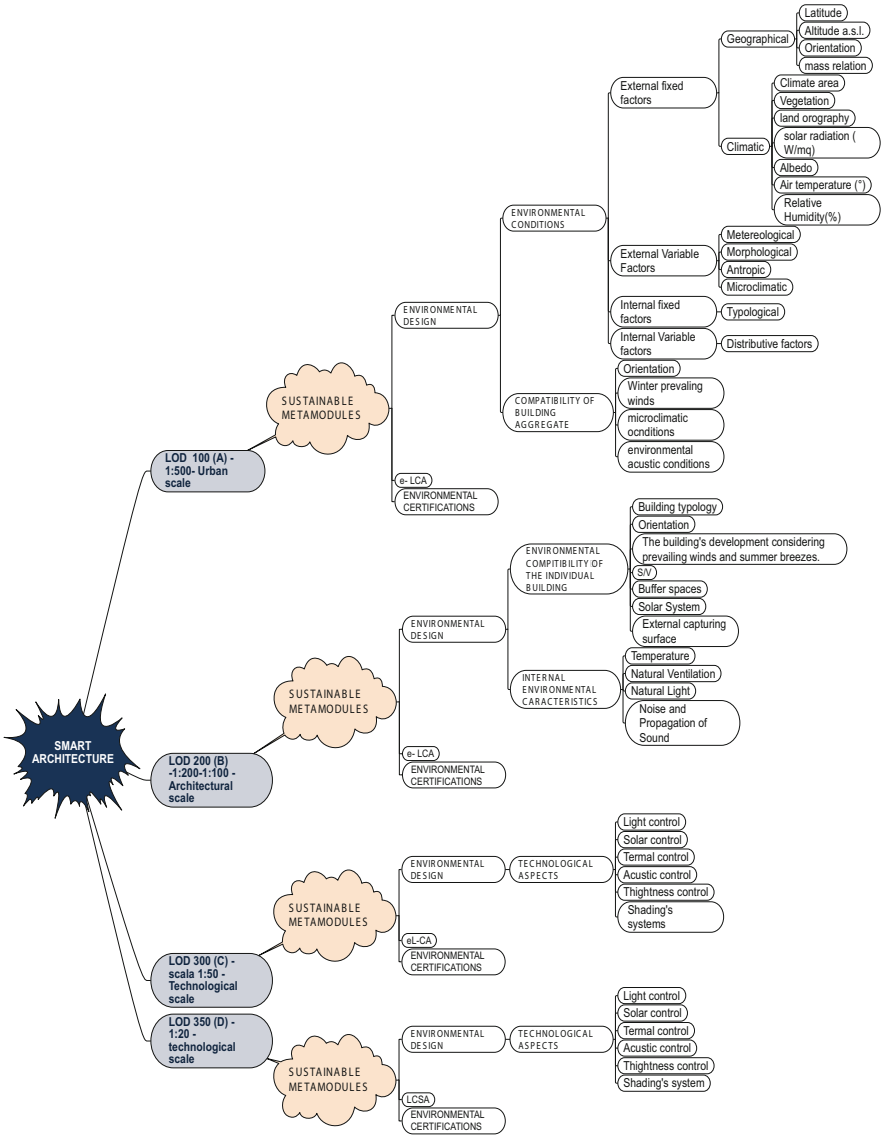

Fig. 1 Development of sustainable metamodules at each LOD: environmental design aspects

as Building Information Modelling (BIM), artificial intelligence, and the Internet of Things (IoT) requires a more conscious design approach that can manage the potential and risks associated with their widespread use.

The concept of smart architecture has emerged as a response to the multifaceted nature of contemporary complexity. It is defined as an architecture that meets current needs through innovative methodologies and tools, integrating materials and

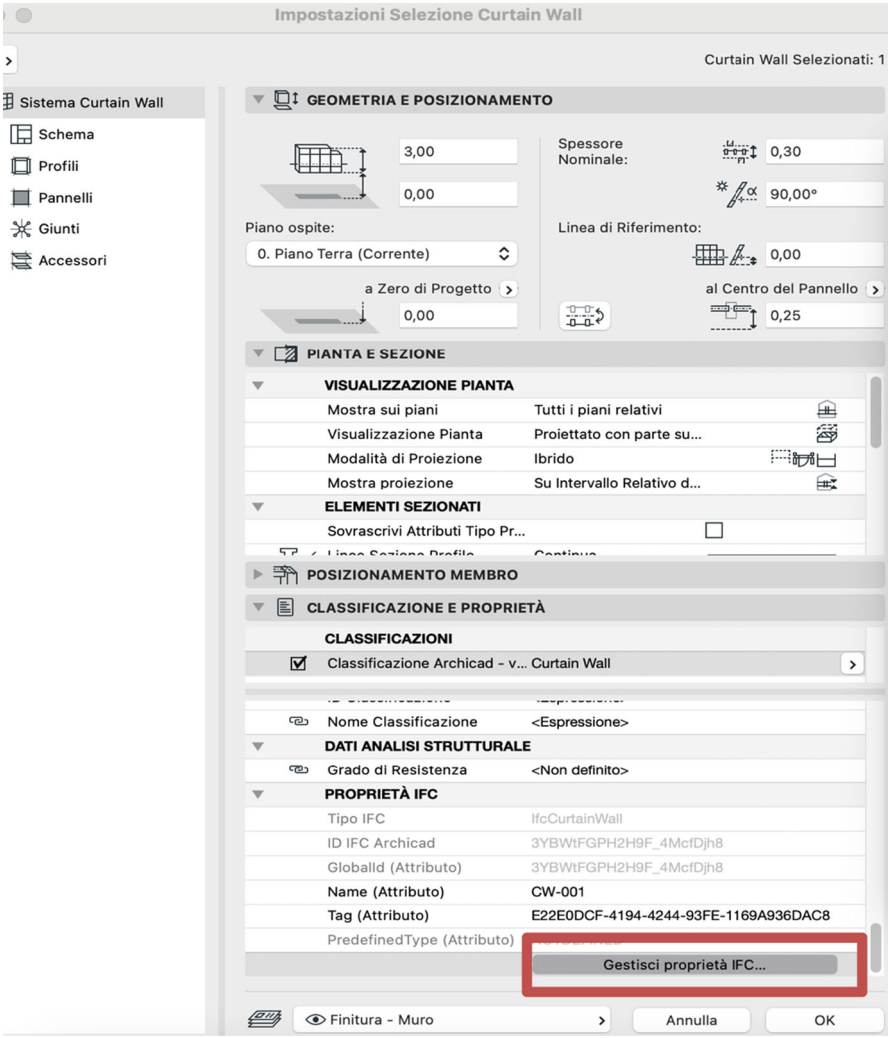

Fig. 2 The image illustrates the integration of sustainable Metamodules in a BIM-based authoring, throughout the insertion of the smartness indicators as property sets, associable as IFC properties to BIM objects. STEP 1: Click on "Manage Properties"

technologies to create buildings that adapt and coexist with the surrounding environment and occupants. The research highlights the importance of semantic research to clarify the distinction between smart buildings and smart architecture and emphasizes the role of the architect as an interpreter of social needs and manager of the construction process.

The concept of metamodule has been stated as a systemic approach to smart architecture that transcends material constraints and reaches the level of knowledge. The metamodules and their sub-metamodules consist of smartness indicators, which correspond to the key characteristics that smart architecture should possess. The

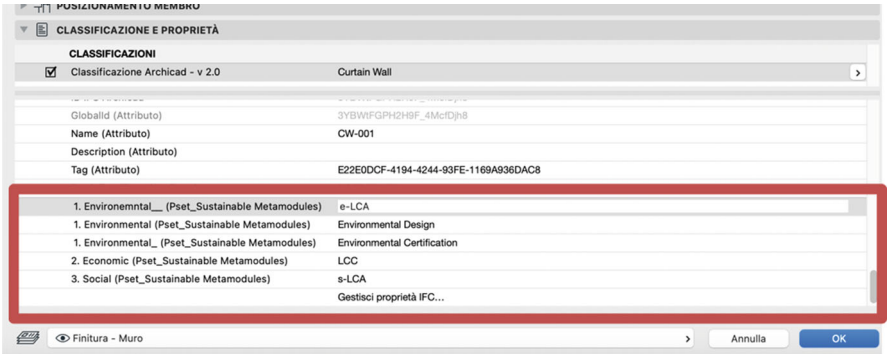

Fig. 4 STEP 3: The Pset metamodules are allowed to be filled as in the IFC classification of the designed object

Building Information Modelling (BIM) system provides a framework for addressing social demands and design challenges, facilitating the creation of a decision support matrix in choosing specific design solutions. BIM also enables easy digitization and integration of metamodules into the design process, facilitating interoperability among the stakeholders of the building process.

1 Introduction

The circular economy (CE) model is increasingly popular among variable actors [1–3]. The construction industry actors thus seek innovative ways to implement circularity principles for minimizing resource consumption and waste generation [4]. This seeking has revealed many different circularity strategies, approaching different life cycles of a building and construction process. Various frameworks have evolved due

to the efforts of many scholars, industrial partners, and governmental institutions to pave the way for circular transformation. The construction stakeholders need more reinforced collaborations to allow for a vital transformation since the industry has a complex organizational structure [5–8]. These collaborations are supported by systematic regulations and clear roadmaps [4]. As there are fundamental managerial challenges in the construction industry [9], the European Commission (EC) published a report about circular building design principles among seven target groups (TG): (i) building users, facility managers, and owners; (ii) design teams; (iii) contractors and builders; (iv) manufacturers of construction products; (v) deconstruction and demolition teams; (vi) investors, developers, and insurance providers; and (vii) Government/Regulators/Local authorities [10]. However, this report only introduced waste management, adaptability, and durability as the fundamental circularity approaches by claiming macro-objectives.

Despite the proliferation of frameworks, the current ones focus on specific aspects such as resources, materials, buildings, digitalization, or city policies. However, the collaboration between stakeholders in all building processes should be strengthened for a robust transformation. But, the concept of stakeholder engagement for a comprehensive circular transformation at three distinct scales is still in its early stages. This study, therefore, presents a unique framework that enables stakeholder collaboration at three scales. By reinforcing stakeholder collaboration in the circular supply chain, this framework offers a novel approach to the circular construction industry to enhance material-building-city integration and foster a regenerative environment.

This study takes a unique approach by investigating the strategies from the perspective of the target groups defined by the EC. It then develops a framework from the stakeholders' perspective at the micro, meso, and macro-scales. The study adopts the micro-scale for materials, meso-scale for buildings, and macro-scale for cities. Methodologically, it conducts a systematic literature review to gather the circular economy strategies from target groups and scale-based approaches. A key innovation of this study is using natural language processing (NLP) to demonstrate the topics of the strategies. This methodology allows for a comprehensive understanding of the strategies in the circular construction industry. The study also defines critical success factors (CSFs) that align with the strategies on a common platform. This is the first study to employ NLP in this context, and its main contribution is the definition of thirty-seven CSFs to enable stakeholder collaboration at multiple scales. Furthermore, the output of the study is the REVERT framework, which underscores the essential synergy between resource, envisagement, validation, entity, regulation, and technology to support actor collaborations at material, building, and city scales. Thus, approaching the gap in the existing frameworks, the REVERT framework reinforces the material-building-city integration by supporting stakeholder collaboration in resource extraction, design and assessment process, organizational capabilities, governmental policies, and digitalization.

2 Methodology

This study aimed to develop a circular transformation framework reinforcing the stakeholder collaboration at the micro, meso, and macro-scales to promote a regenerative environment through the material-building-city trinity for environmental, economic, and social sustainability. The exploratory research method, therefore, was applied to construct insights. It examined the circular economy strategies (CES) from scholars' perspectives and focused on the target groups defined by EC.

This study conducted a systematic literature review to extract the circular economy strategies in the literature. One main keyword query representing the "circular economy and construction industry" was merged with one additional query (see Table 1) representing seven target groups defined by the EC. Seven queries were questioned on the Scopus database, and results were limited to English articles published from 2018 onward as of the data update on December 05, 2022. The scopus database was selected because it contains more results than the other databases. The literature results were deeply analyzed, and the strategies in the articles presented by the scholars were listed on an Excel spreadsheet. Material-related strategies were listed on the micro-scale, building and design-related strategies on the meso-, and city and stakeholder-related strategies on the macro-scale. Additionally, target group numbers, paper IDs, scales, and strategies were applied as the data labels during the listing process.

Table 1 Main query and additional queries defined for systematic literature review

Target groups	Main query	Additional queries
Building users, facility managers, and owners	("circular economy" OR "circular*") AND ("built environment" OR "construction industry" OR "construction sector" OR aec OR aeco)"	AND ("building user" OR "facility manager" OR "owner")
Design teams		AND ("design team" OR "architect" OR "engineer" OR "designer")
Contractors and builders		AND ("contractor" OR "builder" OR "constructor")
Manufacturers of construction products		AND ("manufacturer")
Deconstruction and demolition teams		AND (("demolition" OR "deconstruction") AND ("firm" OR "company" OR "organization" OR "worker" OR "employee"))
Investors, developers, and insurance providers		AND ("investor" OR "developer" OR "insurance provider")
Government/ regulators/ local authorities		AND ("regulator" OR "local authorit*" OR "policymaker" OR "policy maker")

Following that the Excel spreadsheet was processed in the Jupyter Notebook environment. Lemmatization by the 'nltk.stem', stop word removal by the 'nltk.corpus', and tokenization by the 'nltk.tokenize' functions included in the natural language toolkit (NLTK) library were applied to tokenize the circular economy strategies. After the tokens were listed row by row by natural language processing (NLP), the script employed 'wordcloud' function to indicate the frequency of the words in each token at three scales. As a further step, the latent dirichlet allocation (LDA) topic modelling algorithm by the 'gensim.models.LdaMulticore' from the 'gensim' library was applied across three scales. The output of this process enabled the building of critical success factors (CSFs). The critical success factors (CSFs) covered similar lemmatized tokens. The heatmap plots were appealed to demonstrate the density of lemmatized tokens in each CSF at both the target groups and the scales. Hence, circular economy strategies appeared in the most and the least. Consequently, CSFs constructed the new framework to encourage all stakeholders to pave the way for the circular transformation for regenerative development by enabling the material-building-city trinity.

3 Results

3.1 Quantitative Results

The quantitative literature results from the Scopus database screened 112 articles in total for seven target groups: (TG1) building users, facility managers, and owners, (TG2) design teams, (TG3) contractors and builders, (TG4) manufacturers of construction products, (TG5) deconstruction and demolition teams, (TG6) investors, developers, and insurance providers, and (TG7) Government/Regulators/Local authorities. After screening, the articles were deeply analyzed to eliminate the irrelevant and synthesize the results. After synthesizing, some articles were transferred from the existing group to the relevant group, and strategies in 97 articles were critically evaluated for all target groups in the synthesizing process (see Fig. 1). The second group (design teams) demonstrated more results, followed by the seventh (policy makers) and third groups (contractors and builders), respectively.

Micro-scale, meso-scale, and macro-scale strategies listed separately on the Excel spreadsheet, exposed 84, 91, and 88 rows, respectively. The Excel file (.xlsx) processed by Python on the Jupyter Notebook resulted in 804 lemmatized tokens at three scales (206, 337, and 261, respectively), which proved the excessive circular economy strategies. The 'wordcloud' function utilized the lemmatized tokens to demonstrate the word clouds in Fig. 2, indicating the frequency of words in tokens at three scales. Based on these outputs, it was interpreted that materials and resources showed repetition with reuse, recovery, recycling, bio, process, storage, value, generation, value, secondary resources, and loop at the micro-scale. Building and design at the meso-scale highlighted reuse, demolition, maintenance, management,

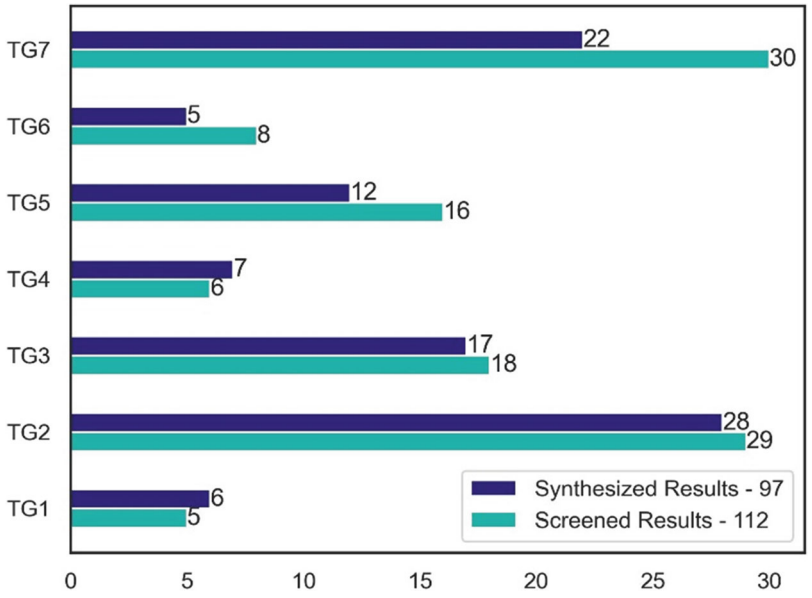

Fig. 1 The number of literature results and snow-balling results based on TGs

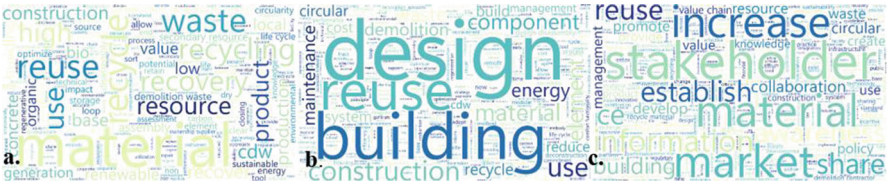

Fig. 2 The keywords in the strategies at micro-scale (**a**), meso-scale (**b**), and macro-scale (**c**)

recycling, components, and elements. City and stakeholder-based understanding at the macro-scale revealed the establish, reuse, recycle, market, share, collaboration, information, management, and policy.

The 804 results of the lemmatization process manifested many strategies that could cause chaos due to the unprecedented activities of many stakeholders in accomplishing the projects. Therefore, clearer understanding was required. This purification was significant as the researchers put great efforts into improving circular understanding. Consequently, the authors of this study analyzed the strategies by considering the lemmatized tokens and constructed thirty-seven CSFs to cover similar tokens. These CSFs accommodated similar tokens and optimized the allocation of circular strategies. They focused on all activities during the whole life cycle of a building process, from raw material extraction to end-of-life.

3.2 *Qualitative Results*

After employing topic modelling, the qualitative result highlighted the most common strategies among seven target groups and three scales. Following this step, generating CSFs was significant in developing a naïve roadmap referring to the needs of all target groups. Analyzing 804 lemmatized tokens and topic models pioneered constructing CSFs. Corresponding CSFs categorized the similar lemmatized tokens, and thus, thirty-seven CSFs were constructed. Figure 3 indicates the quantitative distribution of lemmatized tokens in each CSF by scales and target groups.

During the construction of the CSFs, the most common and unique strategies in the articles were considered to develop a comprehensive framework, including environmental, economic, and social approaches. Hence, a fully sustainable and circular transformation was enabled in the construction industry. Therefore, the heatmaps in Fig. 3 demonstrated the comprehensiveness of CSFs for the most common and unique strategies. Six main dimensions comprehended the thirty-seven CSFs for an understandable and monitorable framework interpreted in Table 2. Resource, envisagement, validation, entity, regulation, and technology dimensions included the CSFs for developing the REVERT framework.

Through this framework, the resource dimension referred the material and resource-oriented factors, including strategies such as maintaining the technical quality of resources and materials, closing, slowing, narrowing, regenerating, and optimizing resource loops [11–13], enabling zero-waste building and construction [14, 15], estimating material stock [16–18], and implementing agricultural waste biomass and low-impact and regenerative materials [19–23].

Fig. 3 Quantitative distribution of the CSFs by scales and target groups

Table 2 Critical success factors (CSFs) for REVERT framework

CSF	Critical success factors (CSFs)
RESOURCE	
CSF1	Adapting narrow/slow/close loop understanding
CSF2	Avoiding any kind of resource waste
CSF3	Encouraging material and resource optimization
CSF4	Managing stocks and flows for resource and waste
CSF5	Promoting use of agricultural waste biomass
CSF6	Promoting use of low-impact, durable, healthy, bio-based, and high-quality materials
CSF7	Promoting use of secondary resources
ENVISAGEMENT	
CSF8	Developing comprehensive disassembling methods
CSF9	Developing design methods to enable reuse and recycling
CSF10	Enabling interchangeability and versatility for building components
CSF11	Encouraging building optimization
CSF12	Promoting adaptability for building design
CSF13	Promoting retrofitting of existing buildings
VALIDATION	
CSF14	Assessing carbon for all life cycle phases and promote carbon accounting
CSF15	Constructing resource chain for circular flow
CSF16	Deploying new facilities to manage resource processes
CSF17	Promoting cost-benefit analysis and encourage low-cost construction
ENTITY	
CSF18	Adjusting policies for circular transition
CSF19	Demarcating understanding for needs and corresponding stakeholders
CSF20	Developing awareness for climate change and sustainability
CSF21	Encouraging circular businesses models
CSF22	Encouraging local businesses to promote new materials
CSF23	Encouraging personal trust and instrument/resource sharing between stakeholders
CSF24	Enhancing collaboration and communication of stakeholders
CSF25	Offering affordable and comparative prices
CSF26	Promoting knowledge for circular transition
CSF27	Promoting supply chain management among all actors
CSF28	Supporting resource allocation and resource management among suppliers and users
REGULATION	
CSF29	Adopting circularity principles for cleaner production
CSF30	Promoting building certification, energy labeling, and legislation
CSF31	Promoting capital investment and competitiveness
CSF32	Promoting R-imperatives
CSF33	Supporting stakeholders activities by legal legislation and increasing commitment to legal framework
TECHNOLOGY	
CSF34	Creating digital passports for materials
CSF35	Integrating industry 4.0 technologies for automation of design-construction-deconstruction process

CSF36	Promoting LCA for materials and construction processes (pre-design, design, construction, maintenance and demolition)
CSF37	Promoting scheduling and management/track system

Envisagement dimension referred the design and building-oriented factors including the strategies such as circular design methods, building adaptability, and retrofitting [24–32]. Validation dimension referred the assessment-oriented factors including the strategies such as assessing biogenic carbon [33], resource processes and chain [34–37], and low-cost construction [17, 20, 38]. Entity dimension referred the organizations and supply chain-oriented factors, including strategies such as circular business models [13, 15, 39–41] and local business models [22, 42], knowledge increasing [34, 36, 37, 43]. The regulation dimension referred the legislation-oriented factors, including strategies such as adopting circularity principles and R-imperatives [4, 44], building certification [20, 45], capital investment, and competitiveness [12, 46]. The technology dimension, lastly, referred the digitalization-oriented factors, including strategies such as creating material passports [13, 18, 47], automating processes [12, 18, 48], monitoring, and scheduling systems [18, 34, 46, 47].

4 Conclusion

The circular economy has many strategies that might make it complex for stakeholders to implement. It is essential to evaluate the circular economy from the perspective of all stakeholders to create a shared understanding. Reinforcing stakeholder collaboration in the construction industry is vital as the circular transformation requires intense responsibility. Numerous frameworks have evolved to accelerate the shift towards circularity. On the other hand, the existing frameworks do not support stakeholder engagement, which is an enabler to achieving a circular transformation. Besides, there needs to be more assimilation of the three scales for circularity initiatives. The micro, meso, and macro-scales should collaborate to create material, building, and city trinity and to take bold steps towards achieving a circular economy.

Stakeholder engagement at three scales accelerates the circular transformation process by promoting solid relationships. Therefore, the REVERT framework fills this gap by encouraging stakeholders at three scales to participate in regenerative development. It includes critical success factors to provide a clear roadmap. It demonstrates the fundamental dimensions of a circular transformation: resource, envisagement, validation, entity, regulation, and technology. Many strategies in the literature include the emergence of R-imperatives, the need for low-carbon, bio-based, and regenerative materials, adaptable design principles, and competitive

environments for circular and local businesses. It is essential to encourage actors to follow the most common strategies to get more circular and to enable a strong collaboration to implement the strategies at the material, building, and city scales for a regenerative industry. Accelerating the synergies between actors for the material-building-city trinity, regulating legal frameworks, and supporting innovative technologies help stakeholders see the bigger picture and foster a smooth transition towards a circular economy. Thanks to the REVERT framework, three pillars of sustainability are achieved since the framework considers not only the environmental dimension by focusing on low-carbon and regenerative materials and R-imperatives but also the social and economic dimensions by strengthening the collaborative synergies. Consequently, this study is the first since it employs NLP to demonstrate the tokens in the circular economy strategies in the literature, and it is an innovative study as it focuses on the stakeholder perspective to support the collaboration. This provides a dynamic understanding for future studies.

1 Introduction

It is widely acknowledged that the built environment significantly contributes to greenhouse gas emissions. Studies have indicated that integrated technical installations play a crucial role in achieving zero-emission buildings by optimizing energy efficiency and reducing environmental impact. García-Monge et al. [1] demonstrated that regulating heating, ventilation, and air conditioning (HVAC) systems based on CO_2 concentration levels could lead to energy savings ranging from 40% to 70%. This range of energy savings underscores the importance of integrated technical installations in enhancing energy efficiency.

However, there is evidence indicating that buildings are not meeting performance expectations, leading to a significant gap between what is expected and what is happening. Ardehali et al. [2] reported that inadequate commissioning and poor

M. Kioumarsi, B. Shafei (eds.), *The 1st International Conference on Net-Zero Built Environment*, Lecture Notes in Civil Engineering 237,
https://doi.org/10.1007/978-3-031-69626-8_88

maintenance practices often lead to increased energy consumption and reduced equipment lifespan. Lawrence and Keime [3] assessed two school buildings and uncovered widespread dissatisfaction among occupants, along with higher energy usage and associated costs than initially thought.

While numerous studies have focused on materials and energy aspects, there is a noticeable gap in research related to the impact of integrated technical building installations (ITB) processes on reducing emission from buildings. The contemporary building complex presents more complicated functional requirements, as well as challenges in managing greenhouse gas emissions. It is therefore crucial to examine the whole ITB process, especially for buildings with ambitious environmental goals. The early involvement of ITB role in the building process is important to allocate the resources for planning, commissioning, handover, and aftercare. The integrated installation is crucial for both Heating, Ventilation, Air Conditioning (HVAC) installations and building automation systems (BAS) from the design phase onward.

The integrated installation is vital to ensure the realization of zero-emission buildings in the sustainable design process through multidisciplinary coordination during the commissioning phase. In this regard, testing schedules and responsibilities should align with local regulations such as NS3935 [4], and multidisciplinary coordination is crucial for forming an interactive basis to address system errors.

During the handover and aftercare phase, integrating Post Occupancy Evaluation (POE) is essential. This involves reviewing design intent, gathering feedback from building users, and optimizing the entire system for zero-emission buildings.

This study focuses on the application of the Integrated Technical Building (ITB) process through a detailed case study of a project aiming for a zero-emission building. The study provides a comprehensive analysis of how ITB is applied, detailing the integration of different technical systems, installation procedures, and reaching ambitious environmental goals: passive house standards, zero-emission building. By examining this case study, the research seeks to demonstrate how ITB contributes to achieving ambitious environmental goals in procedural details and operation.

The paper documents the various stages of implementing the ITB process, from initial design and planning to integration with building automation systems (BAS) and ongoing aftercare. It identifies best practices that lead to significant reductions in carbon emissions and energy consumption, offering insights into how the process facilitates a more sustainable building process.

A key component of this research is the emphasis on the early adoption of integrated systems and continuous monitoring throughout the building's lifecycle. This includes the use of advanced technology, energy management systems, and automation, all working in harmony to minimize environmental impact. Through the case study analysis, the study explores common challenges and proposes solutions that other projects with similar environmental objectives could adopt.

The paper is structured as follows: The Sect. 1 of the paper introduces the ITB process within construction projects in Norway. A case study implementing ITB process aimed at achieving a zero-emission educational building, exploring the

practical barriers encountered during the ITB process implementation in Norway, and providing systematic resolutions is presented in the Sect. 2. Finally, the Sect. 3 presents the main findings of the chapter.

2 Integrated Technical Building installations in Norway

Modern buildings in Norway usually contain various technical systems including lighting, heating, cooling, ventilation, sun shading, building automation, fire detection, access control, intrusion alarm, surveillance cameras, energy monitoring meter, elevators, and data/telecommunication. Along with continuously stricter demands for lower energy usage, improved indoor climate, increased security, and enhanced user experiences, the technical installations have become more advanced and integrated.

In Norway, the standard-NS 3935 has defined the roles and responsibilities for stakeholders, consultants, and contractors to ensure proper functioning of technical installation. The standard is designed to establish a clear understanding of the process ensuring successful procurement of integrated technical building installation, and it ensures smooth interaction and coordination between the building's technical systems to satisfy the business, environmental, and safety requirements. The standard covers different phases of a project, emphasizing the importance of an ITB coordinator who maintains focus on the interaction and economy of technical systems from planning to handover.

The role of the ITB coordinator is critical [5] in bridging the gap between different functions and stakeholders. While not accountable for the technical content, this individual serves as the primary point of contact, facilitating communication and coordination across diverse teams. They serve as a control mechanism and resource ensuring technical solutions are addressed throughout all stages of a construction project, from initial planning to handover. The ITB coordinator not only facilitates collaboration but also implements necessary actions.

In some cases, the ITB coordinator may take on additional tasks beyond the standard role, such as providing technical support if the client desires both technical oversight and facilitation throughout the project. This individual has expertise in automation from HVAC or electrical engineering and can provide technical support alongside their ITB responsibilities. The role of the ITB coordinator naturally evolves based on experience and expertise.

A key document/tool for the ITB coordinator is the interface matrix (NS3935, 2019) [4]. This document, reviewed with various contractors/disciplines alongside the ITB coordinator, outlines responsibilities for each deliverable. ITB specialists are required to have good knowledge for each system to ensure compatibility and functionality.

The systematic completion is a term often associated with ITB process. The systematic completion describes the process of ensuring that the building meets its technical and non-technical requirements, which is outlined by BA2015 [6] starting

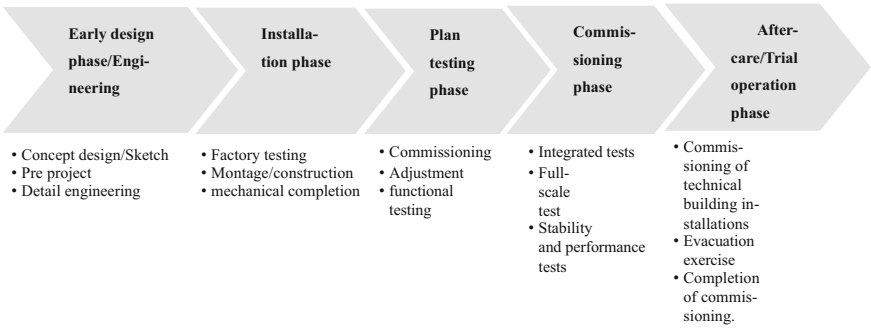

Fig. 1 ITB process according to NS6450: 2016

from early stages of the project until the building is fully operational with functional technical systems.

BA2015, was a nationwide effort to improve the construction industry in Norway. Key players teamed up with SINTEF, NTNU, and Metier to make construction more efficient and sustainable. It aimed to enhance both industry practices and partnerships by adopting and refining processes, systems, and knowledge. The objective was to establish Norway's construction industry as a global leader through the integration of customized international best practices. BA2015 prioritized practical action, focusing on implementing proven methods and knowledge to achieve results.

The processes from the early phase to the delivery are outlined in NS6450 [7] (see Fig. 1 below). Commissioning is a period during which there is an opportunity to uncover errors in equipment, settings, setpoints, etc., before the building is finally handed over to the client. The processes for this are described in NS6450 and could just as well be included in NS3935 for ITB as it is a crucial part of an automation delivery.

Utilizing the standard requires that the client plans for testing, commissioning, and trial operation and describes these processes in the tender documentation. Commissioning takes place after occupancy to test the technical building installations under actual internal load and usage which again have an impact to the justification for setting of various technical systems.

2.1 The Case Study: The ITB Process for Zero-Emission Educational Building

The case study aims to pioneer environmentally friendly construction from 2022, with goals including BREEAM-Excellent certification, passive house standards, zero-emission building (ZEB-OM) [8], and extensive use of cross-laminated timber. Ventilation and heating systems are designed as a combination of demand-controlled

Table 1 The early premise of the interface matrix

System component description	Project planning	Delivery	Assembly	Cabling/ connection	Function	Integration
Non-load-bearing external walls						
Glass facades						
Windows, doors and gates						
Exterior cladding and surface						
Inner surface						
Solar shading						

ventilation system with sensors, geothermal heat pumps integrated with solar energy systems for both heating and cooling needs. All sensors and energy meters are connected to the Building Management System.

Early Design Phase The ITB coordinator has been engaged from the pre-project phase to establish the concept and standards for planning, commissioning, handover, and aftercare. This early involvement led to the client's bidding documents incorporating the building functional description, as well as the establishment of ITB coordination premises such as the technical room diagram and interface matrix.

The interface matrix, as shown in Table 1, is used to identify and clarify all interfaces in the project, where the interface between the plumbing contractor, electrical contractor, ventilation contractor, and building automation can be managed by the main contractor.

In this table, the symbols represent the following: (construction), (lock and fittings), (plumber), (ventilation), (electro and automatic) for project planning, delivery, assembly, cabling/connection, and function interfaces. (BMS), (top system), (access control), (fire), (EOS) for the integration interface.

This symbolic approach simplifies the repetition and makes it visually easier to understand the interface matrix. Technical room diagram (see Tables 2 and 3) for climate requirements and equipment delivery is made according to the standard NS6450. Contractors must adhere to these specifications to ensure the HVAC installation meets all building functions and requirements. Outdoor conditions are

Table 2 The early premise of technical room diagram part 1

	Room type	Description	Person load	Dimensional indoor temperature (°C)		Air volume (m^3/t)	Ventilation type
Room: trinnarealer	Classroom	Teaching room	30	Summer: 19–26	Winter: 21–24	Per person: 26 Per emission: 7.2	VAV
	Group room	Ordinary group room	6	Summer: 19–26	Winter: 21–24	Per person: 26 Per emission: 7.2	VAV

Table 4 The commissioning plan from detail engineering

Activity	System number		Start	Duration
Assumption				
Mechanical completion—from progress plan			12.10.2022	
Delivery			02.12.2022	
Main systems—into the building				
Trafo and supply to main switchboard				
Fiber				
Builder deliveries—TE coordinates timing and duration with BH				
Network equipment assembly				
Deliveries VA (outdoors)				
Grease separator with pump sump	731	001	12.10.2022	1
Deliveries TE				
Roller grille in front of canteen	= 249	001	12.10.2022	1
Roller grille at the amphitheater	= 249	002	12.10.2022	1
Locks and fittings—door pumps and door automation	= 547	001	12.10.2022	10
Lift	= 621	001	12.10.2022	1

determined by the nearest representative weather station. The highest and lowest 3-day average temperatures from the Meteorological Institute are used for design outdoor temperatures. Climate requirements must be met year-round, even without internal loads. The project's Technical Room Diagram sets indoor climate standards, including ventilation rates according to guidelines from the Labour Inspection Authority and regulations on environmental health for schools [9], in Norway.

Detail Engineering, Installation, and Aftercare Phase The premises have been developed to the commissioning plan according to NS6450 [7], as shown in Table 4, in collaboration with various technical contractors (plumbing, electrical, and ventilation). These contractors are tasked with executing the commissioning and testing of their respective systems. The ITB coordinator is responsible for overseeing technical start-up operations, including monitoring, programming, and preparing for commissioning and testing, as well as recommissioning of building services and control systems.

The specifications outlining the ITB responsibilities and mandate are detailed within the contract agreement forms between the main contractor and the ITB coordinator.

The ITB coordinator also responsible for design reviews and offers advice on suitability for ease of commissioning.

From Commissioning to Aftercare Support In the case study, the ITB coordinator has assumed the responsibility for aftercare support for building occupants. This includes scheduling meetings between the aftercare team or individual and building

occupants or management from initial occupation, introducing available aftercare support such as the building user guide and training schedule and content.

Essential information about the building, including design intent, instructions for efficient operation, and details about building systems, is provided and communicated.

Seasonal commissioning, in accordance with standard NS6450:2015 [7], has been conducted as per the contract from the detailed engineering phase. Testing of all building services occurred under full load conditions and periods of extreme occupancy (e.g., heating in midwinter). Interviews with building occupants have been conducted to identify user problems, as illustrated in Table 5.

The project has achieved ambitious environmental goals, including BREEAM-Excellent certification, passive house standards, and zero-emission building (ZEB-OM). In the case study, the ITB systems process enables the integration of various technical systems in an energy-efficient way. This integration has significantly facilitated the optimization of energy consumption during the installation, integration, and operation of complex technical systems. Different sensors are interactively connected to the central system, allowing for energy optimization through automatic control.

Table 6 below demonstrates how this setup aids in identifying potential malfunctions or deactivations in the cooling component of the ventilation system during the trial operation phase, particularly in the heating season.

3 Conclusion

As the complexity of building technical systems evolves, the need for a deeper understanding of both technology and sustainability becomes increasingly important. Neglecting to integrate sustainability knowledge can damage the project progress. This again emphasizes the critical role of multidisciplinary comprehension, particularly in sustainable building practices like integrated technical building (ITB) processes.

This achievement of the case study is related to consistent adherence to predefined standards and transparent working requirements for the ITB process, spanning from project inception to post-project care. The ITB coordinator's closely oversight throughout commissioning and recommissioning phases ensures alignment with specified standards-NS3935, 2019 [4].

The early engagement of ITB experts with clients is also crucial in following precise requirements, ensuring quality assurance, closely monitoring, and providing support at every project stage. Addressing deviations promptly and refraining from assuming control of automation systems until all essential components are in place is highly important. Commissioning emerges as an opportune moment to fine-tune building automation, aligning it seamlessly with tenant needs while optimizing energy efficiency. Effective project planning, robust competence, and capacity

Table 5 The plan of the trial operation phase

Component group	Component	What is checked?	Scope	Inspection method	Note/recommended method	When

Ventilation cooling OE502	0	0

form the cornerstone of project success, particularly in energy and sustainability endeavors. The contractual framework delineates various requirements for the commissioning plan, empowering the ITB coordinator to engage the process.

In summary, the research's detailed approach to implementing ITB, including recommended standards, tools, and procedures, serves as a valuable reference for other construction projects targeting high-energy performance and sustainability. It underscores the potential of ITB in optimizing energy efficiency and reducing the carbon footprint of buildings, ultimately contributing to broader sustainable development goals.

Overall, the study provides a roadmap for achieving zero-emission buildings, demonstrating that integrating advanced technical systems and adhering to rigorous environmental standards can lead to successful outcomes. The findings are particularly relevant for architects, engineers, project managers, and policymakers seeking to design and implement green buildings that meet stringent environmental requirements.

1 Introduction

Climate change leads to many undesired effects in cities, such as extreme weather episodes and air temperature anomalies, which result in a reduction in safety and life quality of urban inhabitants. It is becoming increasingly important to better understand the local impacts of climate change to develop more suitable adaptation and mitigation strategies. Urban heat islands (UHIs), defined as urban areas with higher temperatures than the surrounding rural areas, are one of the consequences of urban growth. They are the result of heat absorption and re-emission by improperly designed urban infrastructure [1]. Typically associated with low- and mid-latitude cities, they are a worldwide phenomenon, becoming a source of concern in northern settlements likewise [2].

In the past years, UHIs have been studied extensively. Although their main drivers across different climates are generally known, a complete understanding of this phenomenon and its dynamics is still missing, both at the global or regional scale [3–5] and when it comes to their local patterns and various contributing factors [6–8]. Reports show that UHIs are becoming more severe in urban areas with higher energy consumption and where urban planning fails to provide a sufficient amount of open and green spaces for effective ventilation and cooling or surfaces with high albedo. However, these UHIs drivers vary across different urban areas.

Therefore, to mitigate UHIs with a more targeted approach and to account for them in planning strategies and scenarios, it is important to explore the local seasonal and spatial distribution of UHIs and its links with urban morphology. This is because previous studies into the local driver of UHIs indicate that they are significantly impacted by particular features of urban morphology, such as impervious surface ratio or building density. These studies used statistical methods [9–13] or various modeling approaches [14–17]. When investigating the spatial and temporal distribution of UHIs and their links with urban form, historical weather data is necessary for the analysis or model validation. However, this sort of spatial data is not widely available in many urban areas. One possibility to fill this gap is to employ the rapidly evolving low-cost sensing technologies [18].

It is important to note that although there is already a lot of evidence concerning these phenomena, many previous studies focus on urban areas with specific spatial or climatic conditions. As a result, their implications are not easily transferable to other urban areas. Studies addressing northern European cities are still too scarce and this gap needs to be addressed as these cities are also affected by the UHIs effect. For example, it is predicted that in the city of Oslo, the temperatures will rise by over 5 ° C in the warmest month by 2050 [19]. Addressing this gap may be facilitated by the growing popularity of low-cost personal weather sensors in the city. Recently, their number has increased so significantly that the private weather stations are also becoming a source of valuable observations for scientists, including the Norwegian Meteorological Institute [20]. As a result, researchers now have access to high-coverage observations throughout Oslo, which supports the studies exploring the distribution and local drivers of UHIs.

The objective of this study is to verify the potential of weather data crowdsourcing with a high spatial resolution for UHIs intensity estimation. To this end, this chapter focuses on exploring the use of the low-cost observations from Netatmo weather stations in Oslo, where UHIs phenomenon has not yet been fully investigated. It estimates the seasonal temporal distribution of UHIs in the city, providing an updated basis for further investigation. In addition, this study helps to better understand UHIs determinants in urban areas in this climatic region and shows directions for further research into the relationship between urban form characteristics and UHIs effect. In the future, this may bring more guidelines for the integration of UHIs mitigation within the urban planning practice.

2 Materials and Methods

2.1 Study Area

The study focuses on the local climate and built environment in the capital of Norway, Oslo. The municipality (59°54 N, 10°44 E) has a population of over 700,000 inhabitants. It is located at the head of the Oslo fjord, enclosed by the peri-urban forest zone of the Marka Belt (see Fig. 1), which is an area restricted from development [21].

According to Köppen climate classification, its climate is defined as Dfb, i.e., warm-summer humid continental [22]. The occurrence of UHIs was identified in Oslo in previous studies [19, 23], but it is important to further monitor this phenomenon and look further into its links with the spatial structure of the city. In addition, Oslo is an interesting case study to better understand UHIs drivers due to its varied urban morphology and land uses (downtown high-density areas, residential zones with different morphology, large and vegetated areas) and complex topography. Another advantage is the availability of high-resolution long-term weather data from low-cost weather stations, supplementing municipal monitoring systems. Oslo municipality has very ambitious climate goals, i.e., to become zero-emission by 2030, and it is looking into sustainable solutions for climate change adaptation [24]. Hence, the prospects of using low-cost weather data to better evaluate local climate and predict UHIs will be of key importance to design better spatial policies in the city.

2.2 Weather Data Acquisition

The study uses observations from low-cost Netatmo weather stations [25]. They are a passive crowdsourced method and a useful and promising tool to collect local weather data of high spatial resolution for the UHIs effect quantification,

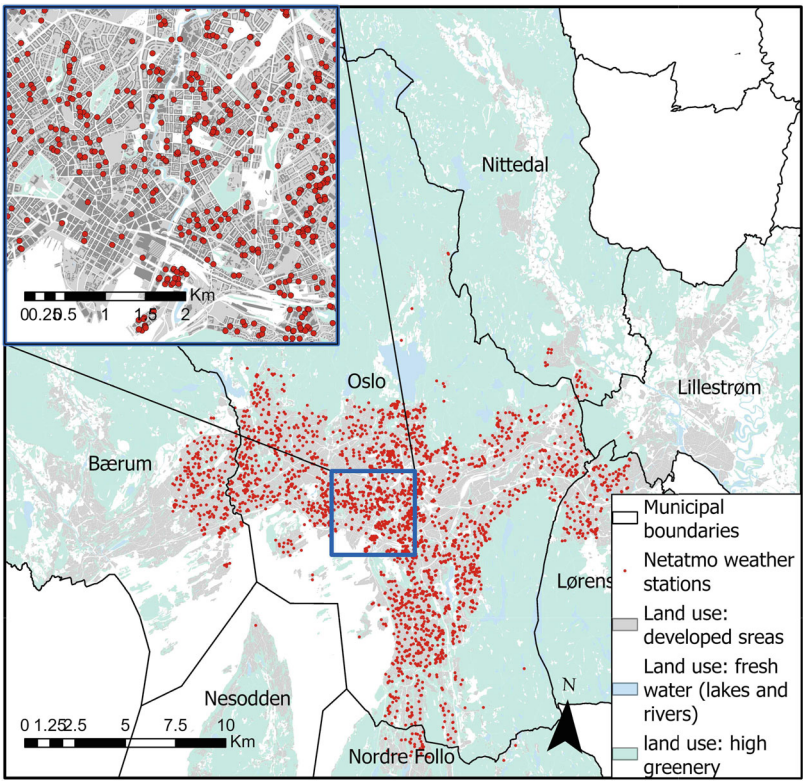

Fig. 1 Oslo municipality and the location of 2826 Netatmo stations (2626 of which were active in 2023)

supplementing greatly the data from municipal weather stations. The Netatmo observations were retrieved using a dedicated macro-enabled Microsoft Excel workbook MeteoDataXL that automatically and independently downloads historical hourly meteorological observations directly from Netatmo's weather API [26].

The whole year of 2023 was selected for the analysis in the study. A list of more than 2800 stations operating in 2023 within the borders of Oslo municipality and the adjacent areas was collected and initially mapped in ArcGIS Pro [27] to check for any errors, such as repeating points and clearly wrong coordinates. This may happen as the Netatmo weather units are calibrated by the users and errors may occur. All such stations were deleted from the dataset. Then the list was used to automatically download the hourly temperature observations with the MeteoDataXL notebook from January 1 to December 31, 2023.

2.3 Data Quality Check

The high coverage with Netatmo stations offers the potential to investigate the relationship between UHIs and the urban morphology characteristics [28]. However, the data needs to be subjected to appropriate validation [29]. Although Netatmo sensors were tested in climate chambers [18, 30] and in field tests [28], the main problem, which is still not fully resolved, is the unshielded design of the units, resulting in warm bias caused either by direct solar radiation or proximity to building walls due to emitted heat [31]. Among the first studies to address the quality control of Netatmo sensors for UHIs quantification were those done for Berlin [28, 30] and for London [31]. Data processing scheme (quality check) was proposed and further developed and tested in subsequent case studies. The scheme is a combination of data processing and statistical methods, which now consists of several steps summarized in Table 1.

A separate quality control scheme was also proposed by other authors, consisting of a "buddy check" (removing observations with a high deviation from the mean neighborhood observation), removing isolated stations (as their values cannot be cross-referenced) and a spatial consistency test (spatially grouping the values and for each region and removing outliers) [35, 36]. However, so far, the quality scheme

Table 1 Data processing scheme

Problems and solutions	Reference
Invalid metadata (latitude, longitude, altitude, time-stamp) *Solution*: Removing values from stations with uncertain (e.g., repeating) latitude and longitude	[28, 30, 32–34]
Obviously erroneous values (e.g., sensors placed indoors or close to a heat source) *Solution*: (1) Comparing temperature data from Netatmo sensors and from municipal weather stations and removing observations when the difference between measured temperature is beyond the range of reference thresholds.	[12, 14]
(2) Using only Netatmo observations and eliminating outliers	[31–34]
Missing values (temporary disturbances in sensor operation, resulting in insufficient observations for a given day or month) *Solution*: Removing hourly values for a given day if there is less than 80% hourly data per day, removing monthly values for a given month if there is less than 80% daily data per month	[28, 30, 32, 35]
No solar radiation shield (e.g., sensors placed in direct sunlight) *Solution*: (1) Comparing temperature data from Netatmo sensors and from municipal weather stations and removing observations when the difference between measured temperature is beyond the range of reference thresholds.	[30]
(2) Comparing temperature data from Netatmo sensors and global radiation and temperature data from municipal stations for selected day-time values, and removing observations when there is a significant link between Netatmo observations and solar radiation (systematic radiative filter error), and when the difference between measured temperature is beyond the range of reference thresholds (single value radiative error)	[28, 33]

proposed by Meier et al. (2017) [28] and Napoly et al. (2018) [32], later modified by Feichtinger et al. (2020) [33], are so far considered the most advanced ones and were used in subsequent case studies (e.g., [37]). In one of the most recent works, Fenner et al. (2021) proposed a modification of the scheme so that it does not require additional data (e.g., temperature or solar radiation from municipal stations) but uses only the Netatmo sensors data [34]. Despite not using solar radiation data, the scheme is very rigorous. It consists of the following steps:

m1—Metadata Check,
m2—Distribution Check—removing statistical outliers—any observations in the upper and lower part of the hourly distribution (1% and 95% quantile),
m3—Data Validity—when too many values are flagged as false due to the procedure in—m2 step (more than 20%) then removing values for a given month for this station,
m4—Temporal Correlation—removing values when the Pearson correlation coefficient between the individual station and the median of all stations is lower than 0.9 for a specific month,
m5—Spatial Buddy Check (additional outlier detection in the given neighborhood)—mean and standard deviation are calculated for stations within the given radius, and the values in the lower and upper part of the distribution are flagged as false,

Optional steps:

o1—Temporal Interpolation—filling in the missing hourly values for a single time step by interpolating from the two closest values from the same station,
o2—Daily Validity—removing hourly values for a given day if there is less than 80% hourly data per day,
o3—Validity in Time Period—removing monthly values for a given month if there is less than 80% daily data per month,

It was recently updated and published as an R package CrowdQCplus [34], which performs the full data quality check scheme or its selected steps.

In this study, CrowdQCplus was used for the retrieved Netatmo data, only step o1 was omitted. Despite the initial metadata check in ArcGIS Pro, step m1 was also included. Collected observations were used for further analysis if went through the data quality check scheme.

2.4 UHIs Intensity Calculations

The UHIs intensity was selected to calculate the spatial distribution of UHIs. This indicator is calculated as the difference between the 2 m temperature for each grid point (°C) and the 2 m average temperature (°C) measured at all rural stations [38]:

$$\mathrm{UHI}_i = T_i - \overline{T_{\mathrm{rur}}} \tag{1}$$

Since the Netatmo observations were at different heights and the urban thermal gradient is too complex to easily recalculate it to 2 m, the Netatmo observations were used as they are, without accounting for the height difference. The rural stations data were retried using the MeteDataXL workbook, which also downloads data from Frost API [39] and AgroMetBase [40] in Norway. According to the Copernicus definition, the rural area is represented by the rural classes of CORINE land cover covering grassland, cropland, shrubland, woodland, broadleaf forest, and needleleaf forest [38]. The CORINE land cover inventory is updated every 6 years, and the latest update was from 2018 [41]. It was retrieved for Oslo and its adjacent areas directly from the Geonorge portal of the Norwegian Mapping Authority [42]. The CORINE classes and the rural stations selected for UHIs intensity calculations are shown in Fig. 2.

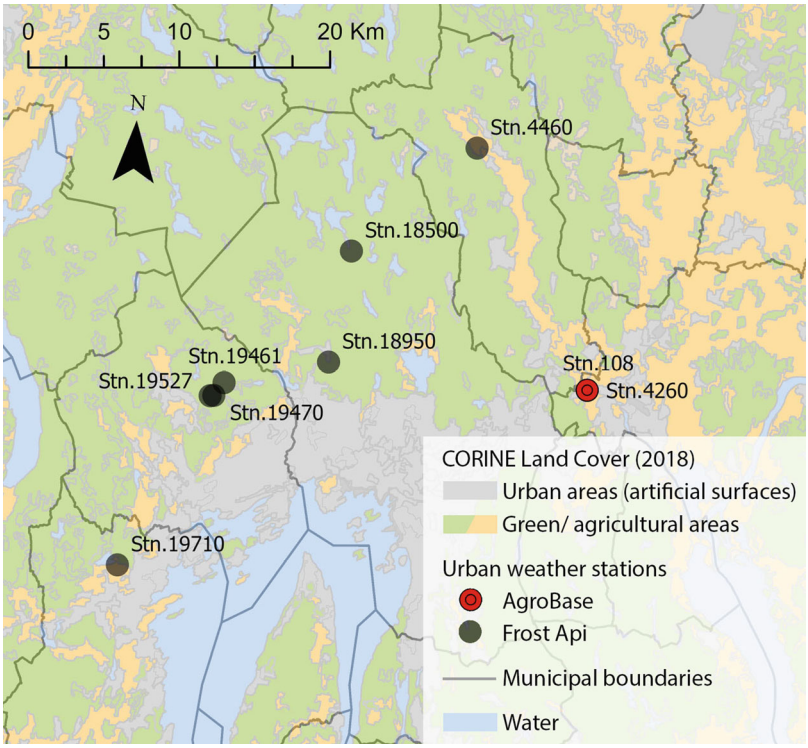

Fig. 2 CORINE land cover inventory for Oslo and the AgroMetBase and FrostApi stations that were used for the UHIs intensity calculations

3 Results

3.1 Data Quality Check

The processing of the weather data with CrowdQCplus resulted in over 60% of data loss. This is consistent with previous case studies, in which the data loss was even over 70% [34]—see the comparison in Table 2. The difference may be explained by the fact that in the Oslo case study the initial metadata check was already performed before running the data quality scheme.

3.2 UHIs Spatial Distribution

UHIs intensity was calculated for selected days and mapped in ArcGIS Pro to show its spatial distribution—see Figs. 3 and 4.

Table 2 Percentage of hourly data availability at each level of the quality check in previous case studies in Amsterdam and Toulouse and in the new case study in Oslo

CrowdQC+ step	Amsterdam (2019) (%)	Touluse (2020) (%)	Oslo (2023) (%)
Raw data (number of weather stations)	100 (368)	100 (1214)	100 (2626)
m1	69.4	92.0	84.1
m2	59.9	82.5	74.3
m3	59.4	82.2	74.0
m4	58.2	81.4	73.4
m5	47.1	70.6	65.6
o1	47.8	70.2	–
o2	36.9	56.6	52.5
o3	20.7	29.5	33.7

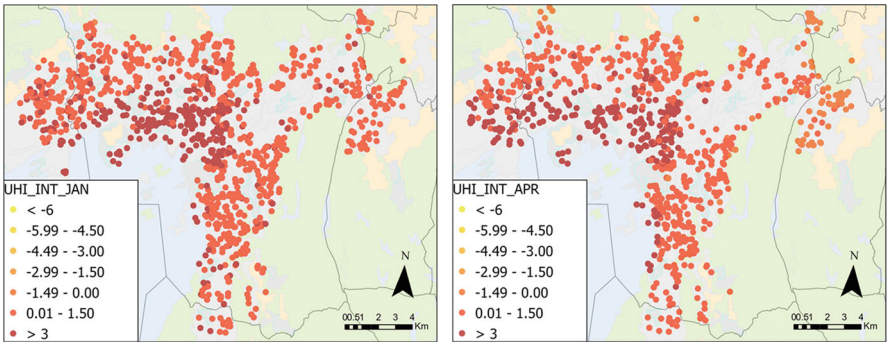

Fig. 3 UHIs intensity in Oslo at 12.00 on 15 January and 15 April 2023

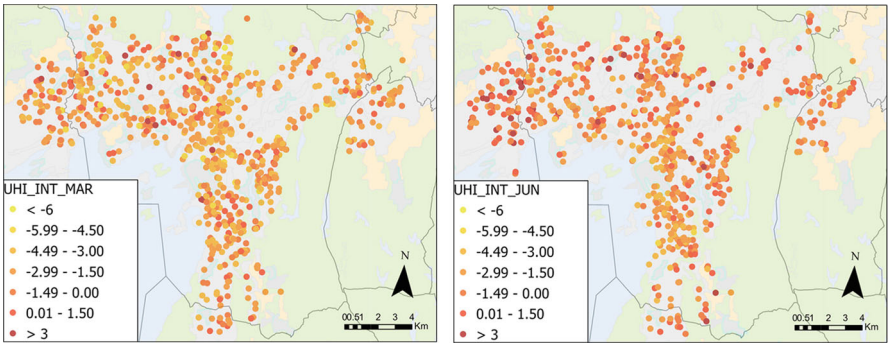

Fig. 4 UHIs intensity in Oslo at 12.00 on 15 March and 15 June 2023

What is interesting when comparing the UHIs intensity maps is that it varies with seasonality. In the first two cases (January and April), it follows a typical gradient with a stronger UHIs effect in downtown areas (even up to 3° higher), while in the other two cases (March and June), the distribution is random or even has an inversed pattern. In some cases, the temperatures captured in downtown areas were lower than at the agricultural monitoring sites (with up to 6.5° of difference). The results are consistent with previous studies, which suggest that UHIs intensity in Oslo is relatively high in selected seasons and marginal in others. However, a previous study identified autumn and winter as seasons with the strongest UHIs effect [23]. Further analysis is still needed, but it seems that in many cases the effect of the topography and larger-scale weather effects may have a stronger influence on the occurrence and spatial distribution of UHIs compared to the urban form characteristics. For example, a strong effect of a thermal inversion in Oslo was observed, when on days with mild or no winds the temperature increases with increasing altitude [43].

4 Discussion and Conclusions

This study has explored the availability and suitability of low-cost Netatmo station weather observations for evaluating the spatial and temporal distribution of UHIs. It proved that the very high spatial resolution of the crowdsourced weather data, coupled with appropriate data management procedures, makes it possible to provide an updated estimate of the distribution of UHIs intensity.

The increasing popularity of these personal weather stations results in high spatial coverage with data points which, even after applying rigorous data quality check schemes, are a substantial dataset very useful for further analysis. This makes it possible to evaluate and address the problem locally in order to design better mitigation strategies. Many previous case studies looking into the drivers of UHIs are available but they are very often case-specific and not easily transferable to other

areas with different climatic, topographic, or spatial conditions. This work showcases the suitability of the emerging weather data collection networks for more climate-intelligent spatial planning.

The next step will be to better understand to what extent UHIs effect in Oslo can be explained by urban form characteristics and how much it is affected by the local weather patterns and topography. It will be also important to better understand the relationship between UHIs intensity and urban form characteristics as this can bring important implications for urban planning and design.

1 Introduction

Whilst urban areas occupy only 4% of land area, they contribute about 80% of greenhouse gas (GHG) emissions and consume 60% of world water resources [1]. This situation is likely to be become more severe by 2050, when around 80% of the global population is expected to be living in urban areas [2, 3] resulting in a number of sustainability pressures including increasing global warming impact, water stress, biodiversity loss and resource scarcity [1]. In addition, the urban heat island (UHI) effect, which occurs in cities due to the replacement of natural land cover with dense concentrations of pavement, buildings, and other surfaces that

absorb and retain heat, will also have a significant heating effect on our urban environment [4]. This effect increases energy costs and associated GHG emissions (e.g. for air conditioning), air pollution levels, and heat-related illness and mortality. These pressures will likely increase exponentially, unless resource consumption is reduced using innovative and efficient technologies and government policies for reducing environmental impact. Developing economies are going to experience significant rural–urban migration [3], and there will also increasingly be higher standards of urban living, which will result in increased consumption and associated GHG emissions [5]. GHG emissions resulting from fossil fuels and excessive resource consumption are directly and indirectly destroying natural resources due to sea level rise, drought, wild/bush fires, and intense flooding. Other indirect benefits are improved human health, livelihoods, water and food security resulting from reduced air pollution, particularly in urban areas [6]. To tackle climate change and resources depletion resulting from urban activities, urban metabolism (UM) approaches have been considered.

UM facilitates the analysis of the flows of materials and energy within cities, based on mass balance or energy and material flow analysis of a city [7] and identifies the ways to promote circular economy resource-efficiency measures to help in the achievement of a carbon neutral city [8]. Using this approach, Li et al. [9] found that there is a negative correlation between population size and carbon emission rates, hence large cities are usually more energy efficient than small cities due to the reduction in per capita resource consumption. In this paper, life cycle assessment (LCA), which is an environmental management assessment tool, has been combined with UM to evaluate environmental impacts and resource efficiency in modern cities [10–12]. In addition to resource efficiency, Seto et al. [13] found that urban and regional landscapes could also help achieve near net zero carbon emission targets by reducing their metabolic emissions through sequestering CO_2 from the atmosphere. This paper is unique in the way that it presents the use of LCA to help determine decarbonisation strategies for the energy-intensive central business districts (CBDs) in our cities using a UM approach. This approach will consider both the CO_2 sequestration of the vegetation coverage of the urban landscape and the integration of a sustainability assessment framework to assess the sustainability of decarbonisation pathways/strategies to assist achieving net zero emission (NZE).

2 Urban Metabolism and Decarbonisation

The UM approach considers cities as living organisms [14] and analyses the flows (inputs, stocks, and outputs) by studying production, distribution, and consumption-related processes and their corresponding outputs: growth, energy production, and waste generation [15]. Increased urban metabolic energy use is directly linked to unsustainable production and consumption, resulting in the gradual increase of carbon dioxide emissions. Urban metabolic carbon, which is directly linked to metabolic energy, has been defined as the amount of GHGs emitted from a particular

urban area, produced through the activities of primary footprint processes (e.g. burning fossil fuels) and secondary footprint processes (e.g. electricity generation). LCA can be used to highlight the areas causing the most emissions so that mitigation strategies can be considered to reduce the metabolic energy and materials used so as to help decarbonise the UM.

3 Sustainable Decarbonisation Model

This model uses a life cycle assessment tool for calculating the GHG emissions from the flows of the materials and energy within cities to find out the end uses and sectors contributing the most to the overall GHG emissions, known as urban GHG hotspots. Accordingly, the decarbonisation pathways or improved technological scenarios are selected to treat these hotspots and further reduce GHG emissions. These emissions can be reduced, but cannot be reduced to zero, so vegetation coverage also needs to be considered to sequester GHG emissions. This framework will thus determine the amount of vegetation coverage needed to sequester the remaining emissions after the implementation of GHG mitigation technologies. The technological options for decarbonisation could have other environmental, social, and economic impacts. Therefore, a life cycle sustainability assessment has been considered for evaluating the sustainability performance or implications of these options. The following section discusses the procedure for decarbonising a city.

3.1 Carbon Footprint Calculation

The ISO14040-44 guideline has been followed to determine the carbon footprint of the model of a 'standardised CBD' as a representation of the NZE efforts required to decarbonise our cities. The LCA guidelines consist of four steps [16]: goal and scope definition, compilation of life cycle inventory (LCI), life cycle impact assessment, and interpretation. The first step of the guideline is to determine the goal and scope of the LCA. The goal of this LCA is to decarbonise a city. The target or the timeframe for achieving the decarbonisation will depend, however, on regional or national policies. The scope defines what inputs, processes, and activities need to be considered in the LCA analysis. The emissions from the production of capital infrastructure, such as buildings, pipe infrastructure and machinery, and transmission and distribution lines, are excluded from the system boundary of the LCA analysis due to their long lifespans [17]. Only the operational inputs used in a typical city-based CBD in terms of its urban metabolism are included, as shown in Table 1. A functional unit then needs to be defined to conduct a mass and energy balance of these inputs. The functional unit in this LCA is the CBD. Table 1 shows that energy, materials, transportation, and water are consumed by end use appliances to perform day-to-day activities in the residential, industrial, public, and service sectors of a CBD.

Table 1 Urban metabolism activities

Key inputs (*I*)	**Systems (sys)**	**Types (*t*)**
Energy	Utility—Decentralised	Renewable
	Utility—Centralised	Non-renewable
		Thermal
		Electricity
	Private transport	Conventional
	Public transport	Alternative
		Heavy vehicle
		Light vehicle
Materials	Virgin	Building
	Recycled	Ferrous
		Non-ferrous
		Composite
		Ceramic/diamond
		Nanomaterials
		Rocks/clay
Water	Centralised	Surface
	Decentralised	Desalinated
		Recycled
Sectors (*s*)	**Activities (*a*)**	**End use appliances (*e*)**
Industry	Food processing	Lamps
	Textiles	Motors
	SMEs	Machinery
	Equipment	Manufacturing technology
Residential	Apartments	Air conditioning
	Houses	Cranes
	Waste management	Treatment technology
	Construction	Cars
Service	Wholesale and retail trade	Trucks/buses
	Accommodation	Electronics
	Food services	Office equipment
	Information/telecom	Traffic system
	Finance/real estate	Harvesters
	Education/training	Elevators/conveyors
	Legal and administrative offices	Information system/server
Public sector	Health	Transmission and distribution
	Road and traffic service	Gas stations
	Waste management	Shower heads/pumps
	Construction	Heaters (water)
	Utilities	Mowers
	Parks and landscaping	Storage

The second step is to develop a life cycle inventory that estimates the amounts of the inputs used in the urban metabolism, including energy, materials, transportation, and water. The inputs consumed by the end use appliances and machinery across different sectors are quantified and then multiplied by the corresponding emission factor (EF) to determine the environmental impact, which is the third step in the ISO LCA guidelines. An emission factor (EF) is the amount of pollutants emitted to the geosphere resulting from the production of the input during all its upstream processes (e.g. mining, processing, and manufacturing of inputs such as cement, caustic soda, and urea). Emission factors are usually expressed as the weight of the pollutant produced divided by a unit weight or volume of the input or service involved (e.g. kilograms of particulate pollutant emitted per MWh of electricity generated). The units of inputs (e.g. MWh) and their corresponding emission factors (e.g. kg/MWh) should be consistent so that they can be simply multiplied together.

Different gases and effluents resulting from the production of an input cause different impacts. The carbon footprint is one of these impacts. In the case of a decarbonisation LCA, only GHG gases (global warming-causing gases; e.g. CO_2, CH_4, N_2O, etc.) are to be considered in estimating the carbon footprint. Different types of GHG are produced from the production of different inputs used in the urban metabolism process. Since global warming impact is represented in terms of CO_2 produced, all GHGs need to be converted to an equivalent amount of CO_2 (i.e. kg or tonne of CO_2 eq). Once all inputs in the urban metabolism have been converted to the equivalent amount of CO_2, they are added up to determine the total CO_2 emissions/global warming impacts resulting from the activities in the CBD.

Careful consideration needs to be made in using or selecting the emission factors as any misrepresentation could affect the reliability of the LCA data outputs. The emission factor for the same input can vary with the processes, location, and inputs used to make them. The same amount of electricity can be generated from both renewable and non-renewable sources, but their EFs are different because the electricity is generated from different types of energy sources using different energy technologies. For example, the average emissions from electricity production in Denmark were 185 g CO_2 eq/kWh in 2023, where 81% of the energy was produced from renewable sources (with 58.7% generated from wind alone) and only 9.9% was produced from coal [18]. If the same 1 kWh of electricity were produced in the USA, 296 g of CO_2 will be produced due to having a different energy mix (i.e. 41% coal, 17% natural gas, 42% petroleum, and other sources) [19]. Therefore, the same amount of a material produced in two different locations using different electricity mixes will have different emission factors. Similarly, different construction materials with varied specifications can provide the same structural strength, but their EFs will be different due to having different manufacturing processes and using different raw materials. The EF of the same input produced in the same location could vary depending on the way it was produced. For example, the equivalent of 3894 tonnes of CO_2 would be emitted from the production of 1 GL of desalinated water from a seawater desalination plant if the electricity were produced from a fossil fuel-powered electricity grid [20]. This emission can be reduced to 367 tonnes of CO_2 if 100% renewable energy were used to run the desalination plant. If recycled

water is used instead of desalinated water, the emission factor will be 1300 tonnes of CO_2 eq/GL of water produced, which is 933 tonnes of CO_2 eq higher than the desalination plant at Binningup in Western Australia powered by 100% renewable electricity [21]. Therefore, the EFs should be carefully selected for the inputs used in the CBD metabolism for the LCA analysis. It is also worth mentioning that both the inputs in the inventory as well as their EFs need to be updated every 5 years to account for future technological changes [22]. The emission factor EF for an input I of type t, which is produced within a system sys is expressed as

$$\mathrm{EF}_{\mathrm{sys},t} = \frac{\text{kilograms or tonnes of } CO_2 \text{ eq}}{I_{\mathrm{sys},t}} \tag{1}$$

For clarification, t could be the type of energy or materials or water produced in a certain system (e.g. conventional, decentralised, recycling). The emissions of the same input could potentially vary with the systems, locations, production strategies, processes, regulations, chemicals, energy mix, sources of raw materials, usage pattern, etc. Therefore, in the decarbonisation process, the inputs need to be sourced in a way that has a low emission factor.

The carbon footprint of inputs used in the CBD metabolism, which is expressed in terms of kilograms or tonnes of CO_2 eq, is obtained by converting all GHGs to an equivalent amount of CO_2 by multiplying by the equivalent emission factors (e.g. 1 kg of CH_4 = 28 kg of CO_2, 1 kg of N_2O = 265 kg of CO_2). So, EF is measured in kilograms or tonnes of CO_2 equivalent.

The carbon footprint of the CBD can be calculated as follows:

$$\mathrm{CBD}_{\mathrm{CO2}} = \sum_{s=1}^{S} \sum_{a_s=1}^{A} \sum_{e_a=1}^{E} I_{\mathrm{sys},t,e_a} \cdot \mathrm{EF}_{\mathrm{sys},t} \tag{2}$$

where $e_a = 1, 2, \ldots, E$ is the number of end use appliances used for an activity a, $a_s = 1, 2, \ldots, A$ is the number of activities performed in a sector s, and $s = 1, 2, \ldots, S$ is the number of sectors in the CBD.

Equation (2) gives the breakdown of GHG emissions to help find the sector contributing most to the emissions. Secondly, the GHG breakdown in terms of inputs for significantly contributing sectors can be presented to identify the hotspot (s). Once the hotspot(s), or carbon-intensive inputs or processes, have been identified, a range of mitigation strategies or improvement scenarios can be considered to further reduce CO_2 emissions.

3.2 *Hotspot Analysis for Determining Mitigation Strategies*

Hotspot identification is important to help develop a decarbonisation pathway for the city. Accordingly, measures are taken to improve the technology and processes to further reduce GHG emissions. The sector contributing the most will be investigated,

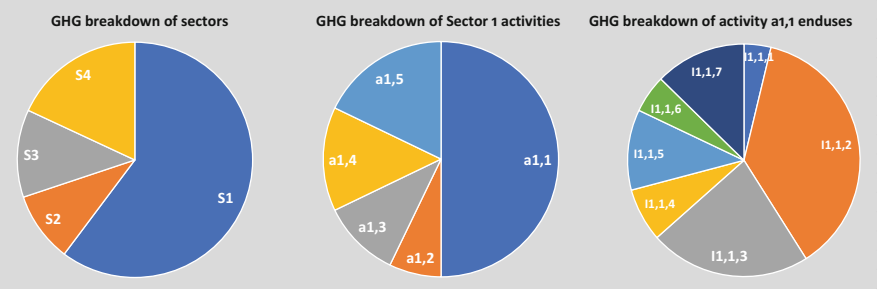

Fig. 1 Hypothetical example for hotspot analysis

Table 2 Decarbonisation strategies

Set_1	Set_2	⋯	Set_n
O11	O21		On1
O12	O22		On2
⋮	⋮		⋮
O1*N*	O2*N*		On*N*
10 million tonnes	15 million tonnes	⋯	16 million tonnes

support provided and the logistics offered to deploy appropriate mitigation measures.

Figure 1 shows the type of hotspot analysis that can be carried out on the CBD to identify the end use appliances in a sector contributing to the highest GHG emissions. This approach is aligned with Eq. (2) in the previous section. Figure 1 shows that sector S1 contributes most to the GHG emissions, then within sector S1, activity a1,1 accounts for the most significant portion of the emissions. Finally, end use appliances I1,1,2 and I1,1,3 account for the greatest fraction of the total emissions of activity a1,1 in sector S1.

A number of sets of mitigation options for reducing the emissions from these end use appliances (I1,1,2 and I1,1,3) need to be considered to determine the set(s) with the highest mitigation potential (Table 2). It is worth mentioning that it may not always be the case that only one sector or only one activity is the hotspot. In terms of mitigation options, this framework is using the CBD model as representative of urban metabolism and carbon emissions of a city as a way to facilitate reader understanding of the decarbonisation strategies needed in urban development.

The sets contributing most to the mitigation of GHG or CO_2 equivalent emissions are chosen as the decarbonising pathways for the city.

3.3 Net Zero Emission

It is not possible to reduce CBD CO_2 emissions to zero, unless we are able to utilise carbon sequestration within urban green space landscapes. It is suggested that this

sequestration by green space can at least remove the balance of CO_2 emissions that were unable to be removed through the use of improved options. For example, Set_2 and Set_n have the highest mitigation potentials for reducing greenhouse gas emissions and decarbonising the city, but their use alone may not achieve NZE. As another important decarbonisation strategy, the area of urban green space that is sufficient to offset these reduced emissions needs to be estimated. The green space landscape could help achieve a balance between anthropogenic emissions by sources (UM) and removal by sinks (green spaces) of greenhouse gases. Net emissions (NE) are expressed as follows:

$$\text{Net emissions} = CO_2 \text{ sequestration} - \text{reduced emissions from end uses} \quad (3)$$

When CO_2 sequestration = reduced GHG emissions, NE = 0 (net zero emissions).

3.4 Mapping of Urban Green Space

In order to evaluate Eq. (2) or to determine NZE, the amount of CO_2 that can be sequestered by urban green spaces needs to be estimated. Geographical Information System (GIS) software can effectively integrate, represent, and communicate carbon sequestration data to guide the planning process for urban green space (UGS) [22]. Remotely sensed data are also widely used for Land Use Cover Change (LUCC) studies. Alternatively, drones with machine learning software can fly above green spaces to provide accurate reporting of the potential carbon capture by the landscape [23].

The urban green space ecosystem could play a crucial role in carbon sequestration and providing carbon sinks. It could also provide an important role in countering the heat impacts associated with the materials we typically use in urban construction (e.g. concrete, bitumen) [4]. Although the urban green space area accounts for only a part of the urban ecosystem, it plays a very positive role in the carbon balance of urban and global ecosystems in terms of carbon sequestration and urban cooling. This research suggests that it should be increasingly noted as a carbon sequestration mechanism in urban development and, in particular, as a means of offsetting difficult-to-mitigate emissions from CBD city development like cement and construction material use, non-renewable energy use and LUCC that removes vegetation cover [24].

3.5 Sustainability of Decarbonisation Pathways

Improvement scenarios will be developed for reducing GHG emissions. These scenarios have environmental, economic, and social consequences. Therefore, a sustainability framework for decarbonisation needs to be developed to determine

the decarbonisation scenarios with the best sustainability outcomes. This is based on a framework developed for palm oil and building industries in 2017 and 2020 by Biswas et al. [25, 26]. This framework was based on the 'strong' definition of sustainability as it integrates three pillars of sustainability (environmental, social, and economic) helping to support technologically focused development. A multi-criteria hierarchal analysis and bottom-up approach (i.e., commencing from lower measuring units of sustainability and focusing on micro-aspects like job losses) have been adopted. The process of the development of the life cycle sustainability assessment (LCSA) framework for this research started with a literature review of existing case studies on sustainability performance, building materials, and the service life of buildings to identify the research gaps in existing LCSA frameworks.

The steps for conducting the LCSA framework are as follows:

1. Development of triple bottom line (TBL) indicators
2. Calculation of the TBL indicators
3. Determination of the sustainability gap for further improvements

Development of Triple Bottom Line Indicators A participatory approach was carried out to select and develop the TBL sustainability indicators for cities of a region because these indicators could vary across regions due to the variation in socio-economic situation, geography, and lifestyle. Local experts were involved in the selection of these region-specific TBL indicators for improved decarbonisation scenarios. The methodology involved four main steps.

A. Preliminary Selection of TBL Sustainability KPIs A careful review of existing national and international literature for best practice guidelines on life cycle impact assessment is needed for selecting the indicators pertaining to the city's sustainability.

B. Final Selection of TBL Sustainability KPIs Once the preliminary list of indicators has been selected, a questionnaire was designed to collect data from the area experts regarding the relevancy and importance of these KPIs. The questionnaire also had the provision for participants to provide feedback and suggest additional KPIs. Potential participants need to be approached through emails to gauge their interest to participate in an online survey. The respondents agreeing to participate will be emailed a link for the online questionnaire to gather their responses. It would be preferable to gather responses from an equal number of respondents from each stakeholder category. The responses are of two types. Firstly, to uncover their agreement with the relevance of the indicator for assessing the sustainability performance of the city. If an indicator receives 50% or more votes, then this indicator is selected. Secondly is the rank of the indicator given by the experts, which is then converted to a weight. The value of the weight represents the significance of the indicator.

C. Weighting of Selected KPIs The weight of each KPI was determined based on the level of importance provided by respondents. The responses with no comments were excluded from weighting calculations and when the response for a KPI was

'irrelevant', it was excluded from further consideration. The scores for responses, including somewhat important, moderately important, important, and most important, were presented on a Likert scale and were assigned as 1, 2, 3, and 4, respectively. The weights of all KPIs under one impact category were then aggregated to the determine the weight of the respective impact category. The weights of the impact categories were aggregated to calculate the weight of the sustainability objectives.

The scores for the level of importance of each of these KPIs given by the area experts in a consensus survey were converted to corresponding weights using Eq. (4) [26].

$$w_i = \frac{\sum_{r=1}^{N} S_{ri}}{N \cdot \sum_{i=I_1}^{I_n} S_i} \tag{4}$$

where w_i = weight of KPI i; N = number of respondents $r = 1, 2, \ldots, N$; S_{ri} = score given by respondent r for indicator $i = 1, 2, \ldots, I_n$, the number of KPIs; and S_i = value of each score.

D. Threshold Values of KPIs The threshold values of the KPIs will be determined by reviewing existing case studies, sustainability guidelines and standards, national and international agreements, and government statistics and reports. The values considered to be optimal or the best value for the regional context will be selected as the threshold values and were given a maximum score of five on a five-point Likert scale.

Calculation of TBL Indicators Environmental LCA (ELCA), social life cycle assessment (SLCA), and life cycle costing (LCC) will be used to calculate the environmental, social, and economic KPIs, respectively. Both ELCA and SLCA follow the same ISO guideline. In the case of SLCA, the qualitative values are converted to numerical values. LCC uses the same LCI as ELCA for calculating the economic indicators.

Determination of the Sustainability Gap for Further Improvements The position of a TBL indicator is located on a five-point Likert scale where the gap between its position and the corresponding threshold value can then be determined.

$$P_{\text{low}} = \frac{\text{Threshold value}}{\text{Calculated value}} \times 5 \tag{5}$$

$$P_{\text{high}} = \frac{\text{Calculated value}}{\text{Threshold value}} \times 5 \tag{6}$$

Equation (5) was used to determine the value of the KPI's position on a Likert scale where less is good (e.g., carbon footprint, embodied energy, construction, and demolition waste). Equation (6) was used to determine the position of KPIs when more is good (e.g., net benefit, GDP, income). The difference between the position value of the KPI and its threshold value (i.e., five on the Likert scale) is the gap G,

which was multiplied by the corresponding weight to calculate the performance score PS of the KPI. For example, if the position value of an indicator on a five-point Likert scale is 3, the gap will be $G = 3 - 5 = -2$. Suppose the weight of the indicator determined by using Eq. (4) is 0.21 then the performance score will be $PS = 0.21 \times (-2) = -0.42$. The indicators with the highest gaps need to be identified and appropriate strategies need to be considered to further reduce the gaps. This is an iterative process that keeps going until the gaps are sufficiently reduced. Policy, strategy, and technological changes are considered for reducing the sustainability gaps. That is why the LCSA framework is helpful in determining strategies and policy changes for reducing the gaps associated with the hotspot indicators to help find a sustainable decarbonisation pathway.

4 Deployment Plan

Government Departments of Planning, Land and Heritage, and Environment and Energy can work together using this decarbonisation model by collaborating with different sectors in the city, *including* utilities, suppliers, researchers, urban planners, architects, and industries to deploy this decarbonisation framework.

The biggest challenge is in gathering data from all the stakeholders in the city, including the industrial, service, residential, and government components of the CBD, to complete online questionnaires to help provide energy, water, material, transport and waste management data, which can then be converted into a carbon footprint of the CBD using the above assessment framework.

Urban planners and architects will assist in the landscape and green space design with the intention of increasing green coverage in a cost-effective manner, while designing sufficient green space for effective CO_2 sequestration and urban heat island impact reduction [4]. Industry, academia, and stakeholders should all be consulted through stakeholder workshops to help determine the technological options that can help achieve a more sustainable NZE decarbonisation pathway for a CBD environment. A range of options, such as rebates, feed-in-tariffs, and capacity building programs, can be established, enabling the various participant sectors in the CBD to switch to decarbonised options. The stakeholders also need to be aware of the economic benefits of the decarbonising operational changes, which could reduce operational costs and avoid carbon taxes.

5 Conclusions

This LCA framework was developed to review the potential for decarbonising a city through the increased usage of GHG mitigation options. A step-by-step process has been discussed, including the type of tools that will be used and the categories of stakeholders who should participate in achieving the decarbonisation pathways for

important urban planning areas like major central business districts. Resource efficiency through technological improvement and the existence of a sufficient green space were found to be the key variables in the NZE target achieving pathway. This is undoubtedly a data-intensive process as it requires the collection of information on energy and materials for activities in different sectors of the CBD, and interviewing experts and stakeholders who could be directly or indirectly be affected by the decarbonisation activities. In addition, such a planning framework can assist in managing the increasing pressures of urban heat island impacts in our central business districts.

1 Introduction

The COVID-19 pandemic provided an unanticipated motivation for the transition towards digital pedagogy. This shift, while necessitated by the global health crisis, opened up new avenues in the realm of education. It is a testament to the resilience of educational systems in the face of unprecedented challenges and may pave the way for future advancements in digital learning environments. The utilization of various digital tools fosters a transition towards the flipped classroom model. This pedagogical approach can enhance students' comprehension of the subject matter and optimize lecturers' time by eliminating the need for repetitive instruction each time the topic is presented. This shift not only promotes effective learning but also contributes to the efficient use of educational resources.

This study investigates the possibilities and challenges of student active learning in a flipped classroom in a "concrete technology" course, a specialization course

presented in the fourth semester of bachelor's study in civil engineering at Norwegian University of Science and Technology (NTNU). During the course of this study, 30 students were enrolled in the course. The curriculum primarily encompasses the understanding of concrete properties, the effects of its components, factors influencing its service life, and environmental impacts.

Remote teaching due to the pandemic has made the motivation to shift to flipped classroom method by uploading the course materials and prerecorded videos for the students and using the exercise session to guide the students to perform the expected assignments. Online course materials and affordable hardware and software have also given this opportunity to accelerate this shift [1–5]. Furthermore, measures are planned during the exercise session to keep the students active. While evaluation criteria based on performance and skills are the dominating methods in various educational domains, this evaluation method was also found to fit the given course [6].

The main objective of this study is to help students gain the learning outcome of the course in the flipped classroom teaching system in an active learning environment by improving the learning process. Among different expected learning outcomes, sustainability issues including greenhouse gas emission of the materials have been selected as the learning outcomes to be investigated in this course.

2 Method

To systematically conduct the research and achieve expected results, possible actions were selected based on the literature review, own experience, communication with colleagues, and interaction with students.

Initially, the overall learning methods that would increase student motivation, including acquisition, inquiry, practice, production, discussion, and collaboration, were considered based on the existing literature [7–10], and potentially relevant activities were listed.

Moreover, the methods were selected according to the capacity and experience of the lecturer and the nature of the course, which naturally demands being familiar with the theory and applying it in practice preferably in the laboratory as well as feedback from students and colleagues.

The students were expected to go through the course materials and prerecorded videos and be prepared for the physical classroom. To facilitate the learning environment, the students were encouraged to deliver an assignment before the physical classroom in the form of multiple-choice questions to evaluate their own competence in the theory. In the initial 3 weeks of the course, students experienced a traditional classroom setting, in order to prepare the students and the environment for the flipped classroom. During this time, quizzes and discussions in the physical classroom were solely based on the lecture delivered on the same day. However, after 3 weeks, the classroom approach was flipped, and the students were asked to be prepared and go through the multiple-choice questions before the physical classroom.

In order to ensure that the students have understood the necessary concepts in each lecture, the relevant concepts were reviewed shortly at the beginning of the physical classroom session by going through game-based individual quizzes using a digital learning platform (Kahoot!). This allowed the lecturer to observe the performance of students and the level of acquired knowledge and modify the focus area of the physical session based on the student performance and getting the opportunity to check with the students if there is any topic that needs more explanation. Furthermore, as it is expected that some of the students may not have gone through the course materials and prerecorded videos of the week, activating students' awareness by getting feedback from them as a quiz at the beginning of the physical session would keep them motivated to follow the lectures before attending the physical session. Note that the quizzes were held at the end of the physical classroom in the first 3 weeks that traditional teaching was conducted.

On the other hand, in addition to the multiple-choice questions and quizzes before and during the physical classroom, the learning outcomes were assessed by conducting discussions during the physical classrooms according to the recommendations from the literature [11–13]. Since it is expected that the students show better confidence during and after discussions in groups rather than individually discussing the topic in the classroom, the students were mainly asked to discuss in groups and then present the viewpoint of the group to the classroom. Moreover, the students were given a course project in the form of a laboratory-based group assignment, and they needed to design concrete mixes with different fresh and hardened properties.

The communication with colleagues was conducted through discussions at different stages of the course's progress. Main feedback was collected from the experienced laboratory engineer as well as an associate professor familiar with the subject. The lecturer would then try to implement the outcome of the collegial discussion and observe how it would contribute to achieving the objectives. Furthermore, the students' feedbacks were collected through meetings with the student representatives, which were a group of three volunteer students of the classroom. Figure 1 illustrates the overview of the research methodology conducted in this study.

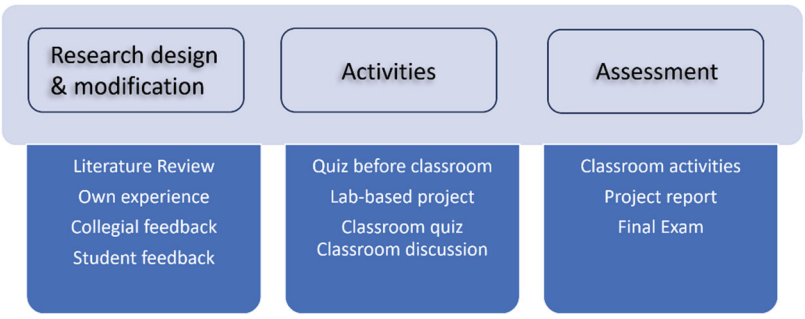

Fig. 1 Overview of the methodology

3 Results and Discussion

Different challenges were observed through performing this investigation according to the above-mentioned method. As it was expected, preparing prerecorded videos with good quality is an extremely time-consuming process that may not be feasible to be conducted during one semester during teaching the course, and it could be considered as a continuously improving process. Furthermore, to keep the quality of the teaching in the prerecorded videos, the potential questions that may arise from students need to be answered in the videos. The feedback from students showed that they were optimistic about the prerecorded videos provided that the videos have an acceptable quality. The lecturer had challenges with the time to prepare the videos and noted that students' feedback and questions could help improve the lectures. Thus, after discussion with the colleagues, it was decided to consider the Microsoft PowerPoint slides for prerecording the lectures and proceed with recording slide by slide to make it feasible to modify them in the next run.

Furthermore, the results showed that the majority of students and colleagues found it beneficial to use Kahoot! to review or discuss the lectures. The student representatives shared feedback from their peers, noting that this process helps keep them engaged and better prepared for in-person classroom sessions. Padlet and Mentimeter were also the other tools suggested by the colleagues, which were tested to a limited extent to compare with Kahoot! It's worth noting that among these digital tools, each has its unique strengths and features. Users can strike a balance in their usage by considering factors such as demand, availability, and feasibility. A noticeable improvement in student performance was observed when transitioning from traditional classroom teaching to the flipped classroom approach. Figure 2 illustrates the overall quiz performance during the initial 3 weeks of both teaching methods: traditional teaching and the flipped classroom. Notably, students performed significantly better in the flipped classroom system, likely due to their preparation before attending the physical classroom sessions.

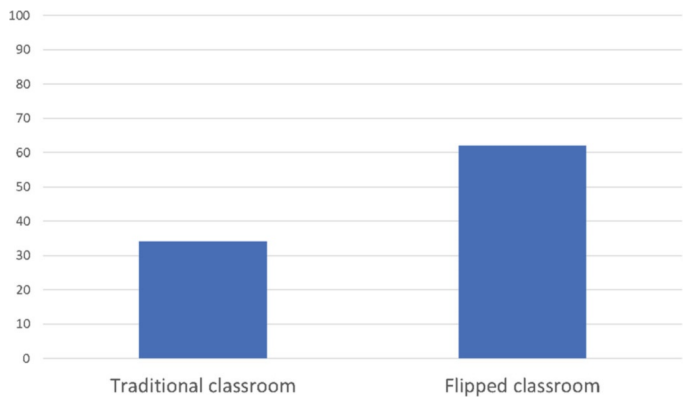

Fig. 2 Average score of the students in the quizzes (percentage) conducted in the physical classroom

On the other hand, both colleagues and the lecturer agreed that too much focus on the review of the lectures at the beginning of the physical session would take considerable time and reduce the motivation of the students to go through the uploaded lecture notes and prerecorded videos. There were different opinions concerning this issue between students and some found more focus on the review process helpful, while some others meant that there was no need for the review as they had gone through the lecture before the physical session. Thus, it was found that a more in-depth review of the lecture, which summarizes the topic, could preferably be done as a separate prerecorded video or podcast and the focus of physical sessions would be on hands-on exercises and in-depth discussions for practical application of the theory.

Furthermore, making the students to discuss practical topics and project-related tasks in groups, could facilitate a student active learning process, and the colleagues agreed with this method as well. However, some students also came with the comment that this method can be inefficient in some cases where no discussion happens in the group or if the time dedicated for the discussion is limited and hinders reaching a suitable outcome. Thus, the engagement and supervision of the lecturer in the group discussions, presenting a proper discussion plan for the students, and considering the suitable time for discussion are suggested as some measures to contribute to overcoming the challenges mentioned by the students, which is in alignment with the literature used in the method section. In addition, using some icebreakers, instructing students how to work in groups, expecting group presentations, and some competition between groups can enable communication between students in the classroom. The lecturer experienced that the automation of activities by methods such as prerecorded videos, multiple-choice questions, and group activities (peer-to-peer discussion) was beneficial for both the lecturer and the students, provided that the lecturer had enough time to design and implement these activities properly and consider a plan for improving them after each run.

Evaluation of the course project in the form of laboratory-based group assignments by the lecturer as well as the feedback received from student representatives emphasized the importance of the laboratory work to bring the theory to practice. Asking students to follow a specific template with guidelines on how to proceed with each section as the requirement to be followed in the delivery of the project report was found to be effective in enhancing the quality of learning outcomes. The requirements of the project work would also need continuous improvements over time to make it suitable for achieving the course objectives.

On the other hand, the students' performance in the quizzes and the final exam revealed that their performance in achieving the learning outcomes was enhanced when they were directly asked to discuss on different aspects of the learning outcomes during classroom discussions, as well as in the requirements of the project report. This was apparent in the selected learning outcome for this study, which was the different aspects of reducing environmental impacts of concrete. Different factors such as optimizing the mix design by reducing the matrix volume, using supplementary cementitious materials, blended cement, or the cement with a more environmentally friendly production method, selecting the right type of cement with

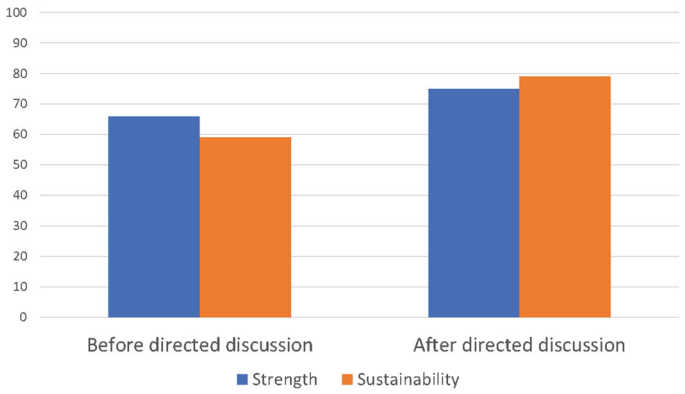

Fig. 3 Average score of the students in the quizzes (percentage) conducted in the physical classroom

minimum transportation demand, proper strength development as demanded, effective consumption of fillers and admixtures, shape and properties of the aggregates, were mentioned to be effective in greenhouse gas emissions of concrete mixes. These factors were relevant to different subjects in the course timeline; however, they were also mentioned as a collection of measures that could be taken to reduce the greenhouse gas emissions. It was found that the students could have a more in-depth reflection on the factors that were directly discussed during the physical classroom or were considered as a requirement to be discussed in the project report meaning that preparing a list of important aspects of learning outcomes and preparing some discussion arena for students to reflect on them during the course timeline can result in a considerable improvement in the students' performance in the course.

Figure 3 shows the students' performance in two distinct learning outcomes within the course: strength development and sustainability issues. Notably, when assessments were conducted after planned discussions, students demonstrated improved performance in questions related to these learning objectives. It's worth mentioning that, in addition to classroom discussions, students were specifically tasked with discussing sustainability issues in their project reports. The higher rate of performance enhancement observed for sustainability issues compared to strength development is likely due to the additional focus on sustainability in the project reports.

4 Conclusion

In this study, the main objective was to help students gain the learning outcome of the course in the flipped classroom teaching system in an active learning environment by improving the learning process. Among different expected learning outcomes, sustainability issues, including greenhouse gas emission of the materials,

were selected as the learning outcome to be investigated in this course. It is expected that increasing student awareness of the environmental impacts associated with material selection for building applications can empower future experts to make informed choices that contribute to sustainability and net-zero construction. While the overall experience of the course responsible, students, and the involved colleagues were in the favor of the proposed teaching method, it was concluded that the following measures can improve the learning process of the designed teaching process:

- Since the prerecorded videos need to be continuously improved over time, recording the lectures in a format with editing feasibility such as slide-by-slide recording is found to be suitable.
- While having a short review of the lecture in the form of a quiz was found to be of students' interest at the beginning of the physical sessions, it was found that more in-depth review of the lecture, which summarizes the topic, could preferably be done as a separate prerecorded video or podcast in order to keep the focus of physical sessions on the hands-on exercises and in-depth discussions for practical application of the theory.
- The engagement and supervision of the lecturer in group discussions, presenting a proper discussion plan for the students with an emphasis on learning outcomes, and considering suitable times for discussion can enhance the quality of students' discussion in the physical classroom. Furthermore, using ice-breaker methods, instructing students on how to work in groups, expecting group presentations, and competition between groups can enable communication between students to improve the discussion performance.
- Preparing a list of important aspects of learning outcomes by the course responsible and enabling a discussion arena for students to reflect on them (such as group discussion in the class, answering to research questions in project report) could make a significant effect on the quality of students' reflections on the learning outcomes.

1 Introduction

Currently, more than 40% of waste generated in Europe is landfilled [1], including residues from incineration processes of urban waste streams like municipal solid waste and sewage sludge, as well as biomass. However, these ashes can undergo valuable metal and mineral recovery, making the residues suitable for recycling as partial replacements for conventional cement, either as supplementary cementitious materials or within alternative binders, e.g., alkali-activated materials [2, 3]. This highlights the potential for urban-industrial metabolism not only in terms of energy recovery but also in waste valorization, where waste originating from the urban environment can be recycled within the construction sector, thereby reducing dependency on raw materials and minimizing GHG emissions associated with conventional cement-based construction material production. Within the European research

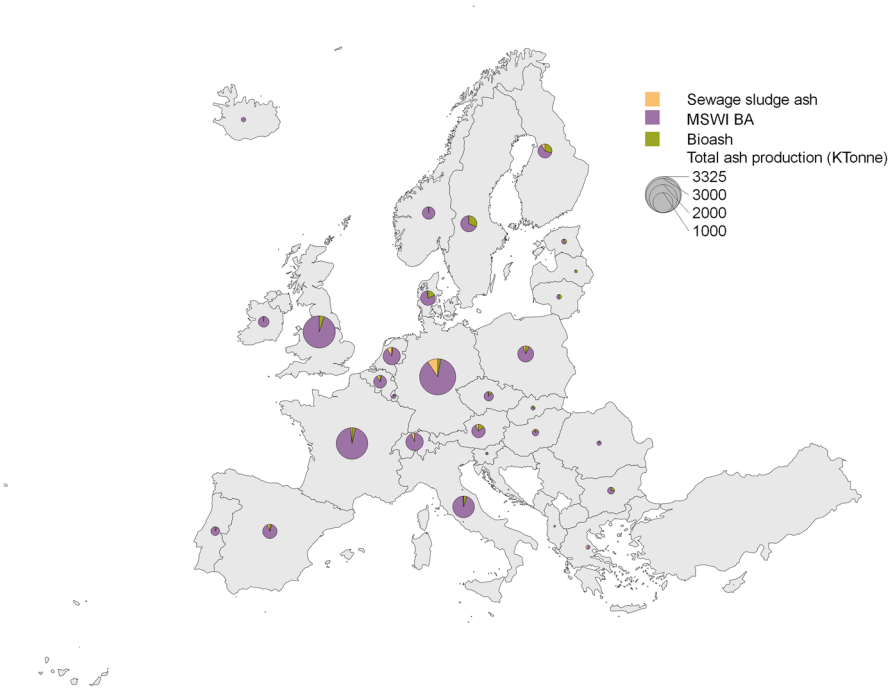

Fig. 1 Production of ashes as residues from urban waste incineration in Europe

project AshCycle [4], several ash pretreatment technologies are being tested for the recovery of valuable metals and minerals, as well as for further pretreatment of ashes for use in alternatives to cement binders, carbstone, and in clay brick production.

In Europe, there are nearly 500 waste-to-energy (WtE) plants [5] that generate almost 19 million tons per year of municipal solid waste incineration bottom ashes (MSWI BA) [6], along with 0.7 Mt/year of sewage sludge ashes (SSA) and 6 Mt/year of biomass ashes (BA). Figure 1 illustrates the amounts of ashes generated in different European countries. This figure reflects the current landscape, with a notable upward trend as more European countries transition to WtE practices, thereby incinerating larger volumes of waste [5]. This underscores the increasing importance of exploring innovative solutions for managing and repurposing these ashes in a sustainable way.

In this study, we apply material flow analysis (MFA) and multi-objective optimization methods to identify optimal supply chain network scenarios for recycling underutilized ashes in construction materials, thereby quantifying associated environmental impacts and costs.

2 Methods

To analyze the environmental and economic impacts associated with urban waste recycling within the construction sector, we focus on the urban-industrial metabolism framework illustrated in Fig. 2.

Within the examined urban-industrial metabolism framework, urban waste streams, including municipal solid waste, sewage sludge, and biomass wastes, are transported to incinerators for energy recovery. The energy generated from waste incineration processes is then used for electricity production and/or district heating [5]. Instead of being landfilled, the ashes, being the residues of incineration processes, undergo recycling where valuable substances, including phosphorus from sewage sludge and ferrous and nonferrous metals from municipal solid wastes, can be recovered. Moreover, ashes can undergo further mechanical and/or chemical pretreatment and be used in the production of alternative construction materials, which are then supplied to the urban built environment.

As a first step, we perform a material flow analysis to identify waste streams that are underutilized, for instance, landfilled or waste streams that can be upcycled. In the next step, we use a combination of geospatial analysis and life cycle assessment (LCA), followed by a multi-objective optimization model to identify optimal supply chain network designs for waste recycling while minimizing environmental impacts and costs associated with transportation, pretreatment, and production of alternative construction materials. Within this paper, we examine urban-industrial metabolism in Denmark.

2.1 Material Flow Analysis

Mass flow analysis is a methodology used to systematically track the flow of materials or substances within a system, such as a city, region, or industrial sector

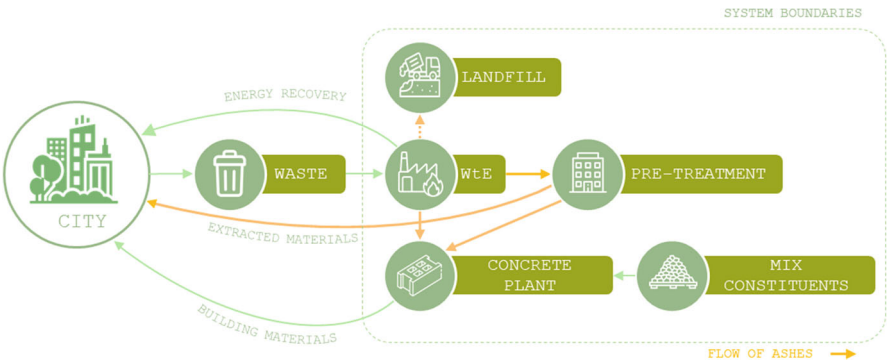

Fig. 2 Urban-industrial metabolism framework

[7]. It offers a comprehensive understanding of material flows, including their sources, destinations, and transformations throughout the system. By quantifying material flows and identifying key hotspots, MFA enables decision-makers to optimize resource management, minimize waste generation, and enhance sustainability [8].

We examine the incineration pathways of municipal solid waste [9], sewage sludge waste [10], and biomass waste [11] in Denmark. The analysis aims to establish the foundation for exploring the potential of extracting valuable materials from the ashes and repurposing the by-products in various construction materials.

2.2 Multi-objective Optimization

To identify optimal supply chain network scenarios for ash recycling, recovery of valuable substances, and the application of ashes in alternative construction materials, we apply a hybrid methodology that involves geospatial analysis and life cycle assessment, followed by a multi-objective optimization model [12, 13].

Geographical information systems (GIS) are used to identify the locations of incinerators, potential recycling facilities, and manufacturers of construction materials, as well as landfills. To determine the shortest transportation distances between the actors within the supply chains, an origin–destination matrix analysis is performed in QGIS software.

As a next step, the environmental impacts associated with transportation and waste recycling are quantified following LCA methodology, where the IPCC 2013 impact assessment method is applied to estimate global warming potential (GWP), using the Ecoinvent database v3.9 for life cycle inventory. The functional unit is defined as the total (potential) quantity of construction materials produced in Denmark using ashes, compared to conventional cement concrete with equivalent mechanical properties. In this case study we examine ash application as supplementary cementitious material and compare it to the conventional CEM III.

To assess the environmental impacts and costs associated with the proposed urban-industrial metabolism, we define a mixed-integer linear programming (MILP) model in GAMS software, building upon previous research [12, 13]. This model allows to identify the optimal locations for ash recycling and the recovery of ferrous and nonferrous metals, as well as valuable substances. Furthermore, the model allows to identify the optimal destinations for ashes to be used in construction material production. The first objective function aims to minimize environmental impacts E associated with the transportation of ashes, recovery and recycling, and concrete production (Eq. 1), and the second objective function aims to minimize corresponding costs C (Eq. 2). Weighted sum method is used to assign weights for each objective function and allows to examine trade-offs between GWP and costs.

$$\min E = \sum_i \sum_j d_{i,j} \times q_{i,j} \times f_t + \sum_i \sum_k d_{i,k} \times q_{i,k} \times f_t + \sum_k \sum_j d_{k,j} \times q_{k,j} \times f_t + \sum e_w \times q_w \times f_w + \sum e_s \times q_s \times f_s + \sum q_m \times f_m \quad (1)$$

$$\min C = \sum_i \sum_j d_{i,j} \times q_{i,j} \times c_t + \sum_i \sum_k d_{i,k} \times q_{i,k} \times c_t + \sum_k \sum_j d_{k,j} \times q_{k,j} \times c_t + \sum e_w \times q_w \times c_w + \sum e_s \times q_s \times c_s + \sum q_m \times c_m \quad (2)$$

$$\text{s.t.} \quad \sum_j q_{i,j} + \sum_k q_{i,k} = a_i \quad (3)$$

$$\sum_i q_{i,j} + \sum_k q_{k,j} \le b_j \quad (4)$$

$$\sum_i q_{i,k} \le b_k \times \partial_k \quad (5)$$

$$\sum_j q_{k,j} \ge b_k \times \partial_k \quad (6)$$

$$\sum_{i,k} q_{i,k} = \sum_{k,j} q_{k,j} \quad (7)$$

where d are transportation distances between actors in supply chains and q are quantities of materials, while the total amount of ashes generated is q_w. The optimization model evaluates options of transporting waste from incinerator i directly to concrete plants j, or to centralized recycling plants k, where valuable substances s are recovered, with subsequent transportation to concrete plants. In this model, m is the vector of other construction material mix constituents, including cement and supplementary cementitious materials.

The emission factor f and cost factor c of transportation t are equal to 0.19 kg CO_2 eq. and 0.09 EUR, respectively, per ton and km traveled. The recovery of valuable substances from ashes is associated with energy consumption e_s and the treatment of ashes for use in construction materials, including milling, grinding, and sieving, is associated with electricity consumption e_w. The emission and cost factors are fixed, being f_w equal to 0.15 kg CO_2 eq. per kWh and c_w equal to 0.13 EUR per kWh, respectively. Different capacities of potential recycling plants are examined, where lower marginal costs are modeled for a bigger centralized facility.

Equations (3)–(7) define constraints to the objective functions on the capacity b of recycling and concrete plants, where ∂_k is a binary variable indicating whether the recycling plant is operating or not. Furthermore, we assume that all ashes produced at the incinerator a_i, will be fully utilized.

The optimized supply chain scenarios are then compared to the baseline scenario where ashes are landfilled and conventional mix constituents are used for the construction material production.

3 Results

In this chapter, we present the results of the material flow analysis that are used to identify waste streams that can be recycled within the construction sector in Denmark. Furthermore, we compare the environmental impacts and costs of optimized supply chain networks for ash recycling in construction materials with the baseline scenario and examine potential implications associated with urban waste stream recycling practices at the European scale.

3.1 MFA in Denmark

Denmark is among the top producers of waste per capita in Europe and has a long history with waste incineration [14]. Its waste-to-energy infrastructure enables the efficient conversion of a significant portion of nonrecyclable waste, including municipal solid waste, sewage sludge and biomass, into energy resources, providing both heat and electricity while minimizing waste volumes.

Figure 3 illustrates the mass flow diagram for Denmark. It encompasses the incineration phase, treatment, material extraction, and end-of-life stages, providing a simple overview of the lifecycle of these ashes. In total, there are approximately 3.8 Mt of MSW being incinerated, which includes 26% imported waste, which results in nearly 0.7 Mt of MSW ashes being generated yearly. While MSW bottom ashes (BA) are used mainly in road construction, fly ashes (FA) pose specific challenges, associated with high concentrations of heavy metals compared to bottom ashes, indicating the need for further improvement of pretreatment technologies [15]. As a result, a considerable portion of MSWI fly ashes are currently being landfilled.

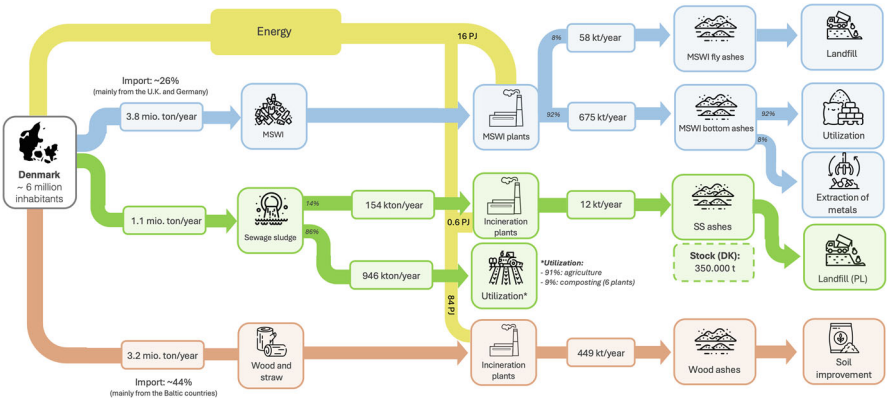

Fig. 3 MFA of incineration ashes generated in Denmark

In the case of raw sewage sludge, nearly 86% is currently utilized directly in agriculture. This approach minimizes emissions associated with pretreatment and transport, thus reducing the overall environmental footprint. However, the increasing pressure from EU directives reflects a growing concern for environmental sustainability and public health [16]. These directives aim to regulate and minimize the presence of contaminants such as microplastics and per- and poly-fluoroalkyl substances in sewage sludge, recognizing the potential risks they pose to ecosystems and human health [17]. The sewage sludge with high contamination levels is therefore incinerated, where technology advancements offer opportunities to extract valuable materials from sewage sludge ashes, particularly phosphorus [18]. If technology can effectively recover the approximately 10% of phosphorus present in sewage sludge ashes, it would represent a highly lucrative business case [19]. Phosphorus is a scarce and valuable resource crucial for agricultural fertilizers and various industrial processes. Considering that all sewage sludge ashes currently generated in Denmark (nearly 12,000 tons) are currently being landfilled, there is substantial potential for both phosphorus extraction and utilizing the ashes in construction materials. Looking ahead, with 86% of raw sewage sludge presently utilized in agriculture, there is a notable opportunity to explore alternative future scenarios, such as increased incineration, particularly if more strict regulations on the direct use of sewage sludge ashes are imminent [20].

Utilizing sewage sludge ashes in construction material presents a promising avenue for *P* resource recovery and waste reduction [21]. Recent studies showed that SSAs can be used as supplementary cementitious materials, replacing up to 20% of cement in mortars, without compromising mechanical properties [22, 23], and exhibiting similar durability properties to conventional cement concretes [24]. SSAs also showed the potential to partially replace clay in fired brick production (by up to 50%) [10] and to be used as co-precursors in alkali-activated materials [25]. SSAs have also proved suitable as sand replacements in mortars and concretes [26, 27]. Further environmental benefits of the application of SSAs in construction materials are associated with the immobilization of heavy metals, thus reducing leaching substantially, depending on application [28, 29]. Furthermore, there is ongoing research on optimization of phosphorous recovery technologies and increasing applications of pretreated ashes in construction materials within the AshCycle project [4].

In Denmark, nearly 0.5 Mt of biomass ashes are produced per year and have been fully incorporated into agricultural practices and are commercially available alongside various products derived from energy use based on biomass [30]. Biomass ashes are used as fertilizers, and biogas residues are used in composting, improving soil [31].

Based on the results of MFA, this study focuses on the optimization of supply chain networks for sewage sludge ashes, acknowledging their significant potential for utilization in various applications.

3.2 *Optimal Supply Chain Networks*

Figure 4 illustrates the main incinerators of municipal solid waste, sewage sludge, and biomass in Denmark. While the MSWI BAs are already widely used in the construction sector (e.g., as road fillers), the MSWI FAs are currently landfilled due to the presence of hazardous contaminants. Currently, there are three sewage sludge incineration plants in Denmark that generate nearly 12,000 tons of ashes per year, which are landfilled. Considering the limited capacity of landfills in Denmark, the ashes are transported to neighboring countries. For instance, MSWI fly ashes are transported to Norway, and sewage sludge ashes are exported to Poland for landfilling.

As a case study, we focus on exploring the optimal supply chain networks that can stimulate the recycling of sewage sludge ashes in alternative construction materials. We apply a multi-objective optimization model to identify the optimal locations for ash recycling, including recovery of phosphorus and pretreatment for further use at existing concrete plants.

Figure 5 illustrates the environmental impacts and costs associated with the baseline scenario and the optimized scenario. Within the baseline, all annually produced SSA are exported for landfilling, while cement concrete is produced using conventional cementitious materials, and primary fertilizers are used. Within

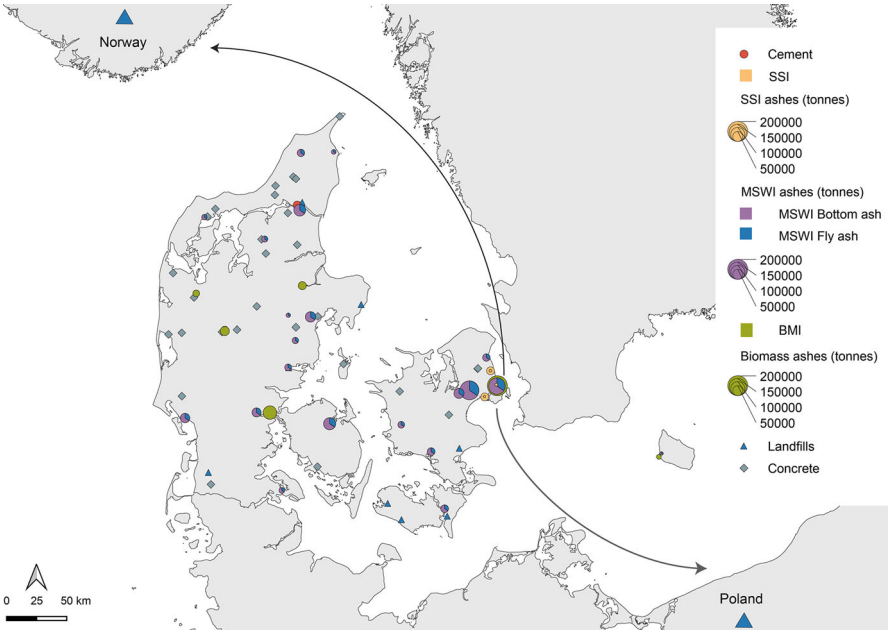

Fig. 4 Baseline scenario. MSWI fly ash and SSA are landfilled outside Denmark

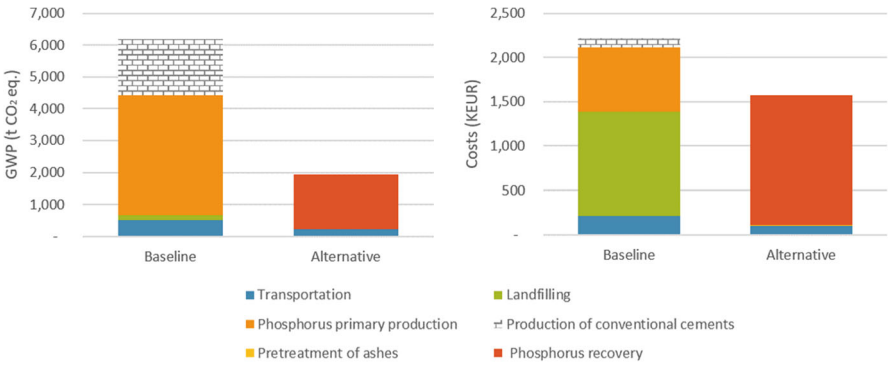

Fig. 5 GWP and costs associated with SSA utilization in Denmark

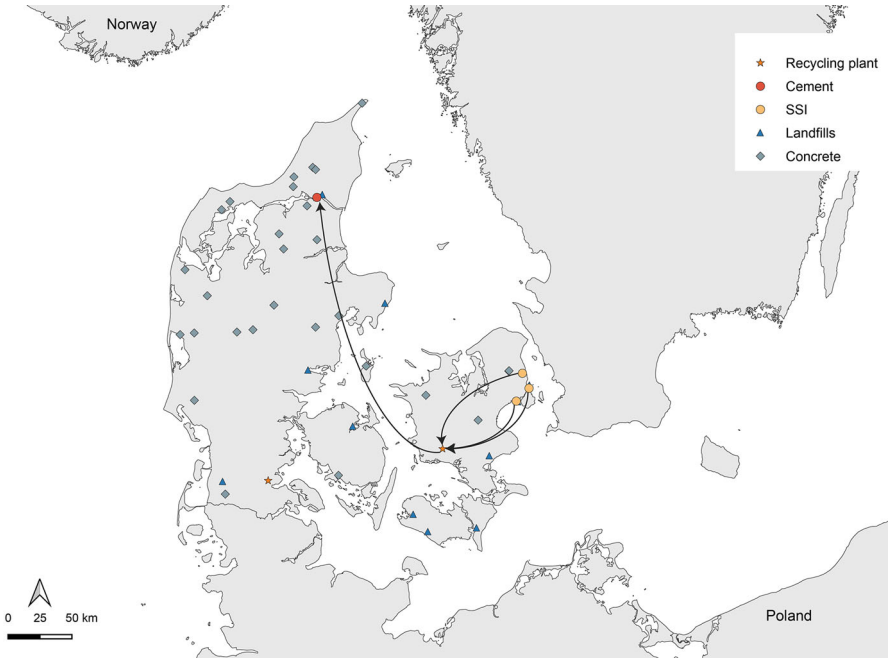

Fig. 6 Alternative scenario. Optimal supply chains for SSA recycling in Denmark

the alternative scenario, these ashes are transported to a single centralized plant (Fig. 6), where 1445 tons of *P* is recovered and residue ashes are pretreated for further use in concrete production.

Within the baseline scenario (Fig. 5), production of primary phosphorous-based fertilizers contributes 61% to the total GWP, production of conventional cement contributes 29%, and transportation to landfills contributes 8%, while within the economic impacts, costs of landfilling are the major contributor of 53%. Within the

proposed ash recycling scenario, the main costs and environmental impacts are associated with phosphorus recovery. Pretreatment of SSAs after recovery of *P* for further use as supplementary cementitious materials has ~1% contribution to both total costs and emissions. Nonetheless, emissions associated with *P* recovery are approximately 40% lower compared to the phosphorus primary production. Overall, it can be observed that the alternative scenario, where *P* is recovered from ashes and residue ashes are used as cement substitutes, results in 69% lower GWP, and 29% lower costs, compared to the baseline.

We further compare the costs of phosphorus recovery technology estimated within the current study with the costs of two existing phosphorus recovery technologies examined in [32]. The PASCH technology involves the recovery of calcium phosphate from SSA using a wet-chemical leaching approach and is associated with the installation of a new recycling plant. The EcoPhos technology involves the recovery of *P* in the form of phosphoric acid at an existing plant: therefore, the investments in the recycling facility are omitted. The investment and operational costs of these two recycling technologies are estimated based on data provided in [32].

Figure 7 illustrates that operational costs vary significantly across examined technologies. Recovery of *P* using available technologies requires higher operational costs than the costs of primarily produced fertilizers. As observed from Fig. 7, investments in the new recycling facility would potentially constitute a substantial barrier, considering the example of existing PASCH technology. In the current study, we assume that ash recovery will be performed at an existing recycling plant. Depending on the total costs of examined scenarios, the economic incentives can be applied to nudge recovery of phosphorus and subsequent recycling of ashes in

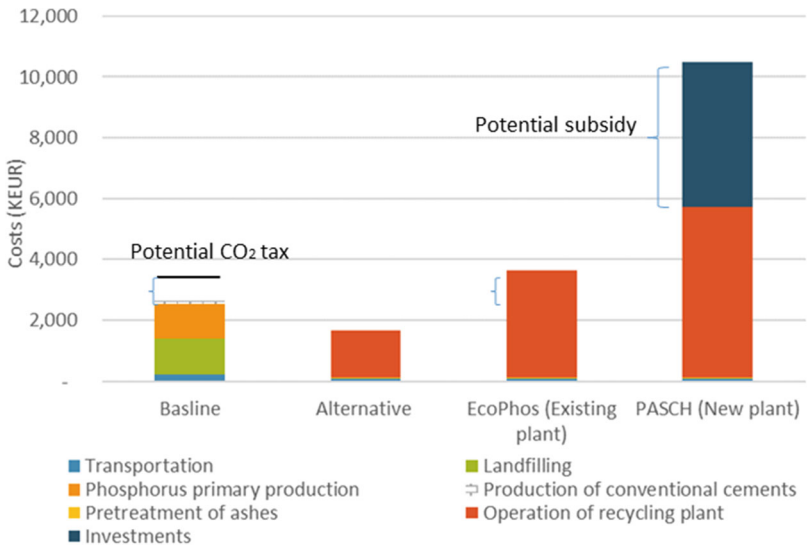

Fig. 7 Costs of SSA utilization in Denmark, considering different recycling technologies

the construction sector. For instance, the CO_2 taxes could increase the costs of the baseline scenario, while policymakers could subsidize the establishment of recycling plants.

3.3 Impacts at European Scale

Within this paper, we examined the potential case of urban-industrial symbiosis in the recycling of sewage sludge incineration ashes within construction materials, as well as quantified potential environmental and economic impacts. While transboundary waste management involving exports of waste can lead to disputes on emission allocations between countries, recycling waste streams within domestic settings can not only bring benefits in terms of recovery of phosphorus but also stimulate recycling of ashes in construction materials, thereby decreasing the demand for conventional cement-based materials and minimizing associated emissions.

In Europe, almost 1.1 Mt of phosphorus fertilizers were used in the year 2021 [33]. As global production of phosphorus takes place outside of Europe, including Russia and Belarus, European countries to a high extent depend on the imports, which not only involves long transportation distances but also due to the current geopolitical situation makes the international supply chain vulnerable and leads to higher costs [33]. The price of phosphorus used in agriculture has been fluctuating between 500 and 600 EUR per ton over the past years [34]. Assuming that the full potential for phosphorus recovery from bottom ashes will be exploited, a considerable share of EU consumption of phosphorus can be covered, and the phosphorous cycle can be partly re-established. As illustrated in Fig. 1, high amounts of bottom ashes are currently produced in central Europe. At the same time, sewage sludge is currently landfilled in multiple European regions, including South and Eastern Europe: Croatia, Slovenia, Spain, Italy, and Greece, where waste-to-energy potentials shall be examined [35]. Moreover, recovery of phosphorus can nudge domestic application of ashes in construction materials, thus minimizing dependency on primary resources or on conventional supplementary cementitious materials, such as blast furnace slag and coal fly ash. The optimization of supply chain networks is therefore an important step that can help to identify optimal locations for waste recycling and recovery of valuable elements, thus providing indication to the policymakers on nudging industrial symbiosis.

4 Conclusions

In this study, we apply a methodology that allows us to evaluate environmental and economic impacts associated with the recycling of waste incineration ashes in construction materials and the recovery of valuable minerals. We focus our analysis on ashes produced at WtE plants in Denmark, while further analysis will focus on

examining patterns across European regions. The MFA enables us to identify waste streams that can be further upcycled in construction materials, including sewage sludge ashes and municipal solid waste fly ashes that are currently landfilled. An analysis of SSAs shows that the recovery of valuable substances is an important step in the urban-industrial metabolism framework that can reduce CO_2 eq. emissions associated with phosphorus production by almost 40%, and encourage further pretreatment of ashes for use in alternative construction materials, overall bringing a 69% reduction in GWP compared to business-as-usual ash landfilling and production of conventional construction materials and fertilizers. Given the high prices of primary fertilizers and the landfilling costs of ashes, recycling of ashes in alternative concrete is associated with 29% lower costs compared to the business-as-usual scenario. The optimization of supply chain networks, therefore, allows to identify optimal locations for the recycling and pretreatment of ashes, thereby minimizing environmental impacts and costs. Improvement of ash recycling technologies can further decrease associated emissions, and it is important to consider the investment and operational costs of new recycling facilities.

Acknowledgments This project has received funding from the European Union's Horizon Europe research and innovation program No. 101058162 AshCycle.

1 Introduction

Collaborative project delivery models (CDMs) are considered integral for building construction to contribute to reaching the United Nations sustainability goals [4]. For a project to reach its goals, it must successfully manage uncertainty [8]. The relationship between CDM elements, uncertainty and sustainability in construction projects remains insufficiently understood [1, 13]. Through a literature review and a

comparative multiple case study of five large European collaborative projects, this chapter seeks to fill these research gaps by answering the following research questions:

1. How are the main elements of CDMs in large projects?
2. How does uncertainty impact the implementation of CDMs in large projects?
3. What are the main lessons learned on the relationship between CDM elements, the management of uncertainty and sustainability in large projects?

2 Theoretical Background

Building construction has a profound impact on the economic, social and environmental dimensions of sustainability. These dimensions encompass several sustainability indicators. Motives and competency of human resources has been identified as the most significant barrier and enabler for the advancement of sustainability in building construction. The sustainable transformation of building construction will necessarily transform the way construction projects are being delivered [3, 10, 13]. A project delivery model (PDM) is a system of elements for organizing and financing the delivery of a project in accordance with the goals of the client. It includes the organization form, the project structure, the form of specification, the procurement route and the agreement format, with the latter encompassing the contract format, conflict resolution mechanisms, risk allocation and the compensation format. PDM elements must be well adapted to one another, the project and the context in which the project is carried out [9].

Sustainable transformation of building construction delivery is accompanied by increased complexity and need for innovation [1]. Complex, innovative, large and uncertain projects are growing in size, frequency and importance and have a relatively high tendency to be unsuccessful in achieving their goals [6]. Uncertainty encompasses both opportunity and risk, which has to be managed successfully if a project is to reach its goals [8]. Uncertainty will change throughout the life cycle of a project and is particularly high in the front-end. Uncertainty emanating from external stakeholders is especially high in the front-end of large projects [15]. Collaborative project delivery models (CDMs) have been found to be particularly suitable for projects with high levels of uncertainty, complexity, risk, size, environmental challenges and number of stakeholders [16]. CDMs are characterized by the integration of inter-organizational participants towards collaboration on common goals [2]. The three most common variants of CDMs are partnering, integrated project delivery (IPD) and alliancing, with the latter being considered the most collaborative [1].

CDM elements are categorized by Engebø et al. [2] into contractual, organizational and cultural elements. Contractual elements, also called hard elements, are directly regulated by the contract or have their basis in the procurement process. Key contractual elements include early contractor involvement (ECI), value-based procurement, target costing with shared risk/reward and open book. Organizational

elements are mechanisms that affect the organization and the process surrounding the project, but are not directly regulated in the contract. Key organizational elements include an integrated project organization, co-location, integrated project controls and workshops. Cultural elements, also called soft or behavioral elements, are designated towards the project culture and contribute to the relationship between the people in the project. Cultural elements frequently mentioned in literature include mutual goals, respect, equality, trust, commitment and openness [2–5, 7, 11, 12].

There is a need for more research on CDMs. No general definition or framework for CDMs has yet to become established. Engebø et al. [1] call for more research on the cause-effect relationship between CDMs, uncertainty and performance. Moradi et al. [13] request further studies on the contribution of CDMs towards the advancement of sustainability in construction.

3 Research Methods

The research design for the paper was based on the framework of Yin [20]. To gain an understanding of the relationship between CDM elements, sustainability and uncertainty in large projects, it was decided to conduct a multiple case study based on qualitative and quantitative data gathered through a triangulation of data-gathering methods.

A literature study was conducted. The literature search was carried out at Scopus, Oria and Google Scholar, with the search terms being "collaborative project delivery", "partnering", "IPD", or "Alliancing", combined with either the term "sustainability", "uncertainty" or "risk".

Five case projects described in Table 1 were selected for in-depth study due to their relevance and willingness to share experiences.

Cases 1 and 2 were studied as part of a specialization report written in collaboration with one of Norway's leading developers of public buildings, while Cases 3, 4, 5 were studied as part of a master's thesis written in collaboration with one of Norway's leading developers of public infrastructure. The projects are anonymized per request of the contact persons from the client.

Table 1 Case information

Case	Type	Status	Cost (mill. USD)	Construction time (months)
1	School	Operation	40	20
2	Swimming facility	Operation	75	29
3	Road tunnel	Operation	210	37
4	Oil and gas	Operation	7500	52
5	Railway	Construction	3100	69

Document studies were carried out for all case projects. Through collaboration with the client leadership, students and researchers gained access to relevant project documents, including contracts, project plans and lessons learned reports.

Semi-structured interviews with clients constitute the main source of data for the study. The primary interviewees were the project managers, who in all cases were engineers with decades of industrial experience. Senior managers, construction managers and assistant project managers were also interviewed, with the latter including non-engineers with only a few years of experience. The number of interviews ranged from eight interviews with seven individuals in Case 1, to three interviews with three individuals in Cases 3 and 4. Interviews for Cases 1 and 2 and Cases 3, 4 and 5 were carried out with different interview guides, which nevertheless covered similar PDM elements. Several of the interviews were carried out with the active participation of both researchers and industrial partners.

Document studies and interviews were in Cases 2 and 5 supplemented with observations. In Case 2, daily observations during the construction period were made over the course of several months, while observations in Case 5 were carried out through a physical visit by researchers and industrial partners to the construction site and a day-long workshop together with client management.

4 Results

4.1 Case 1

In Case 1, which encompassed the refurbishment of a historic school building of national significance, the contractor was involved upon startup of the pre-project. Procurement was carried out with prequalification, value-based award criteria emphasizing collaborative ability and a bidding competition. The CDM was to be carried out in two stages, with stage 1 consisting of the pre-project, and stage 2 consisting of detailed design and construction. The contractor was compensated on a reimbursable basis with open book. The contract included a target cost agreement with a shared bonus/scheme and an equal share of risk. The project had an integrated steering committee with the participation of senior management and project management from the client and contractor. The project organization was led by the project manager from the client, who was located onsite with the contractor and actively involved in all aspects of the project. The designers had been procured upon conceptual selection, and their contract was transferred to the contractor upon the start of the pre-project. Subcontractors were involved early, with the client actively participating in their selection. Project controls were strongly integrated and highly focused on hunting for opportunities, with active use of BIM for design and Last Planner for schedule management. Workshops were actively used both for both problem-solving and team building. Trust, openness and mutual goals were highlighted in the contract as key components of the project culture.

One of the main challenges during stage 1 was the task of developing a design which would both meet modern requirements and preserve the original characteristics of the school. Active dialogue between the project manager and the municipality and early involvement and good collaboration between subcontractors and the rest of the project organization through BIM contributed to the successful management of this uncertainty. Through Last Planner, the project organization developed an optimized schedule that enabled the school to open one year earlier than planned. Joint sharing of risk and opportunity, and an active hunt for opportunities, enabled the project to improve on sustainability throughout construction. Early subcontractor involvement facilitated innovative reuse of historic construction material, which was beneficial from both economic, social and environmental perspectives. Active use of BIM in collaboration with subcontractors contributed to a design which minimized the need for changes during stage 2, enabling the project to be sustainably delivered on time for the upcoming semester. Upon completion, the project was on schedule and about 20 percent below budget, with the client and contractor sharing a substantial bonus.

4.2 Case 2

The CDM of Case 2, which encompassed the construction of a swimming facility in an urban neighborhood, was based on learnings from Case 1. The contractor was involved after the completion of the pre-project, with the relatively late involvement being due to disagreements between senior management and the project organization on the choice of delivery model. Procurement was carried out with value-based award criteria emphasizing collaborative ability and a bidding competition, with a single bid being received. The CDM was to be carried out in two stages, with stage 1 consisting of detailed engineering, and stage 2 consisting of construction. The contractor was compensated on a reimbursable basis with open book. The contract included a target cost agreement with a shared bonus/scheme and a planned equal sharing of risk. The project had an integrated steering committee with the participation of senior management and project management from the client, contractor and designer. The project organization was led by the project manager from the client, who was located on-site with the contractor on a daily basis and actively involved in all aspects of the project. The designers had been procured by the client at the start of conceptual development and there was an option for them to have their contract transferred to the contractor upon completion of detailed engineering. Subcontractors were involved together with the contractor at the onset of detailed engineering. Project controls were integrated and highly focused on hunting for opportunities, with active use of BIM for design, Last Planner for schedule management and a shared digital platform for information management. Workshops were actively used for both for both problem-solving and team building, with a signed collaborative charter being developed at a startup workshop. Trust, openness and mutual goals

were highlighted in the contract as key components in the project culture, with the collaborative charter also emphasizing mutual respect.

At the beginning of stage 1, the contractor and the designer disagreed on several conceptual solutions. Active client involvement was crucial to developing a mutually agreed concept and a collaborative culture. Stage 1 was extended for several months, during which the energy efficiency, life cycle cost and user-friendliness of the facility was significantly improved. Interviewees believe earlier involvement of the contractor and subcontracting of the designers to the contractor could have prevented the initial disagreements. Cost estimates for the new concept turned out to be substantially higher than the estimates for the initial concept with a reduced scope, and this cost difference made the municipal authorities hesitate to give the project permission to proceed to stage 2. Interviewees believe a more thorough conceptual review and realistic cost estimation in the front-end would have prevented the municipal hesitation. To keep the project organization together and ensure schedule performance, the client encouraged the suppliers to finalize the detailed design. As a result of concerns about cost, it was agreed to separate several elements from the target cost and make them fully reimbursable, resulting in a lower cost estimate but less equal risk sharing than planned. The design drawings were shared on the digital platform relatively late, which gave the subcontractors little time to review risk before signing their contracts. Construction start was postponed because of delayed voting in the municipal assembly, but once the cost estimates had been subjected to external review, the client secured municipal permission for an early start-up of preparatory works. During construction, changes were required both for the technical installations and the reimbursable elements separated from the target cost. Client-organized workshops were important to ensure constructive collaboration on the work for the technical installations, while the interviewees believe earlier involvement of the subcontractors and sharing of drawings on the digital platform could have reduced the need for changes. For the changes connected to the reimbursable elements, the client and the contractor disagreed on whether they should be handled through the contingency or not, but through active involvement of the steering committee it was agreed to use of the contingency. Interviewees believe the project would have required less senior management involvement if the risk allocation in the target cost had been clearer and more equal. Uncertainty emanating from global events ensured that the project received additional municipal funding and a three-month extension to stage 2. Upon completion, the project was on budget, built in accordance with the planned construction time and relatively high-performing compared to contemporary swimming facility projects. The reaching of a final settlement required renewed involvement of the steering committee, and none of the contractual parties received a bonus. Reflecting on experiences from Case 2, one interviewee interestingly stated: “A CDM should be contractually structured so that every participant emphasizes what’s best for the project rather than what’s best for themselves. That means that what’s best for the project must be what’s best for everyone. This will give you the best effect of a CDM.”

4.3 Case 3

Case 3 was a road tunnel delivered through project alliancing. Contractor involvement was initiated 5 years after project startup, when the project had already received governmental and municipal planning permission. Procurement was carried out in several stages with prequalification, value-based award criteria emphasizing collaborative ability and technical and commercial negotiations, during which the collaborative ability of the bidders was tested. The CDM was to be carried out in two stages, with stage 1 consisting of project development, and stage 2 consisting of project implementation. The Alliance was compensated on a reimbursable basis with open book. The contract included a target cost agreement with a shared bonus/scheme connected to several KPIs for economic, social and environmental sustainability, while risks were carefully allocated to either the Alliance or the clients, or shared between them. The highest decision-maker in the Alliance was an integrated steering committee chaired by the senior manager from the main client. The Alliance was led by a project manager from the contractor, who worked in close cooperation with the deputy project manager from the client. The designers were part of the Alliance, while the suppliers of technical installations were subcontracted yet tightly integrated into the organization. The project organization was co-located onsite. Project controls such as risk management, cost management and schedule management were strongly integrated, with a strong emphasis on fostering innovation. Workshops were actively used both for team building and joint problem-solving. Openness, mutual trust and respect were highlighted in the project plan as key components of the project culture.

At the startup of the development stage, a political party strongly opposed to the tunnel won local elections, putting the project at risk of not being delivered. Reimbursable payment and a collaborative culture encouraged the suppliers to contribute resources to the project despite the political uncertainty. Early involvement of the suppliers, and a joint focus on innovation, enabled an economic, social and environmental optimization of the design, which combined with joint stakeholder management helped win over enough political support for the project to proceed to the implementation stage. Key activities in the implementation stage included tunneling, construction of technical installations and commissioning. The biggest risks impacting tunneling were rock quality and groundwater conditions. Sharing of these risks between the clients and the Alliance enabled efficient management, with excavated rock being innovatively utilized for local land development, and groundwater being successfully handled in a way that minimized negative consequences for residents and a neighboring lake. Joint schedule management and good collaboration contributed to efficient tunneling. Early involvement and tight integration of suppliers of technical installations in the project organization enabled early construction of technical installations and commissioning, which was critical to ensure timely delivery. At completion, the project was 6 months ahead of schedule and on budget, with all members of the Alliance allocated a substantial bonus.

4.4 Case 4

Case 4 was an oil and gas project consisting of dozens of contracts, of which the largest and most complex were delivered with active use of collaborative elements. For these contracts, contractors were involved early in the pre-project as subcontractors of the main consultant. Procurement was carried out with prequalification, value-based award criteria emphasizing collaborative ability and technical and commercial negotiations, during which the collaborative ability of the bidders was tested. The collaborative contracts were to be carried out in two stages, with stage 1 consisting of detailed engineering, and stage 2 consisting of construction. They included target cost agreements with a shared bonus/scheme connected to several KPIs, including quality of collaboration. A substantial amount of risk was allocated to the client. Integrated steering committees were established for all major contracts. The project organization was led by the client, who closely involved themselves in collaboration with the suppliers. Integrated and co-located teams were established for all major contracts, with the participation of the client, the consultant, the contractors and subcontractors. Suppliers of heavy equipment were involved early as subcontractors of the main consultant. Project controls, in particular schedule and safety management, were strongly integrated, with a heavy focus on continuous improvement. Workshops were actively used, particularly for the purpose of managing interfaces and building teams. The project aspired to create a "One Team" project culture characterized by mutual goals, openness and trust.

At the startup of the pre-project, the parliamentary majority pressured the minority government and the client to adopt a conceptual solution with high cost and schedule risk, but the client was reluctant to accept this. Integrated involvement of key external stakeholders was crucial for the project at this time. Amidst a sharp market downturn, the government permitted the client to award conditional contracts to the contractors and move ahead with detailed engineering and construction, which saved several local companies and workers from respective bankruptcy and unemployment. The market downturn enabled the client to negotiate contracts on favorable terms and helped the project win over the parliamentary majority to the original concept. Familiarization processes with regular workshops for interface management and team building ensured good collaboration and smooth handover of the pre-project design for detailed engineering, while integrated schedule management enabled the development of an aggressive and optimized schedule. Integrated on-site teams and project controls enhanced quality, efficiency and worker safety during fabrication. Target costing with incentives encouraged close collaboration, which contributed to efficient marine operations and innovations in pipelaying, which in turn reduced emissions, material consumption and disturbances to marine biodiversity. Early involvement and tight integration of the project organization enabled the project to capitalize on innovative technology for the hook-up and commissioning, which significantly reduced eco-nomic, social and environmental risk. Upon completion, the project was 2 months ahead of schedule, 30 percent below budget, and one of world's highest-performing oil and gas megaprojects in terms of worker safety and CO_2 emissions.

4.5 Case 5

In Case 5, which is an ongoing railway project, the contractor was involved several years after project startup, after the project had received governmental planning permission, but before necessary municipal permissions had been secured. Procurement was carried out in several stages, with prequalification, value-based award criteria emphasizing collaborative ability and technical and commercial negotiations, during which the collaborative ability of the bidders was tested. The CDM was to be carried out in two stages, with stage 1 consisting of front-end design and stage 2 of detailed design and construction. The contractor is compensated on a reimbursable basis with open book. The contract includes a target cost agreement with incentives, while much risk was intended to be shared. The highest decision-maker in the project is an integrated management committee with representatives from the client, contractor and designer. The project organization is led by a project manager from the contractor, who works in close cooperation with client management. The designers and suppliers of many key works are subcontracted yet tightly involved. The project organization is co-located onsite. Project controls such as risk management and cost management are strongly integrated. Mutual trust is highlighted in the contract as a key component of the project culture.

Developing a design that would accommodate the needs of municipal authorities and residents was a major challenge during stage 1. Early contractor involvement, active joint stakeholder management and sharing of planning risk helped the project face the challenge. Rising cost estimates during stage 1 made the government hesitate to permit the project to proceed to stage 2, causing delays and uncertainty. Reimbursable payment encouraged the suppliers to contribute resources to the project despite the uncertainty. The assumption by the client of almost all project risk helped reduce the cost estimates to a level acceptable to the government, which gave the project permission to proceed to stage 2. Design immaturity upon procession to stage 2 caused changes during contractor-led detailed engineering, requiring active client oversight. Ground conditions, rising costs of materials and concerns of local authorities and residents were major uncertainties during construction. Much risk was borne by the client, leading to cost increases for the project, while the schedule and quality of collaboration were largely preserved. Early involvement with a co-located and integrated project organization helped build a collaborative project culture, which contributed to efficiency and innovations in land reclamation, stakeholder management and localized sustainable concrete production. Target costing with incentives helped encourage the contractor to perform sustainably, but the interviewees believe the allocation of more risk to the contractor would have incentivized them to perform even better. As the project was reaching completion, it was one year delayed and had a cost overrun of about 100%.

5 Discussion

Early contractor involvement (ECI) was characteristic of all case projects. Case 1 and Case 4 are characterized by particularly early involvement and had the highest performance on economic sustainability. This is in line with past identification of ECI as the most important CDM element and sufficiently early involvement as the most important ECI success factor [7, 17]. While the procurement method in all case projects emphasized the collaborative ability of bidders, this ability was more vigorously tested in Cases 1, 3 and 4, which had the highest performance on all sustainability indicators. The method of contractor involvement appears to be significant to succeed with ECI, which is in line with prior research [17–19]. While all the case projects were delivered through a two-stage CDM, the level of detail on the design on the transition between the stages differed between the projects, and a relationship between this level of detail and sustainability cannot be observed. Nevertheless, it can be observed from Case 2 that sufficient investment of time and effort in the first stage can contribute to a more sustainable design and collaborative culture. Reimbursable compensation with open book was characteristic of all projects and appears to be particularly important to maintain schedule and mutual commitments when collaborative projects are facing external uncertainty. While target costing with shared bonus/malus was characteristic of all case projects, Cases 1, 3 and 4 were characterized by a higher degree of risk sharing, better collaboration on the management of risk and higher performance on all sustainability indicators. This is in line with past studies that have found equitable sharing of risk as important to succeed with target costing in collaborative projects [14]. Social, political and market uncertainty was high in the front-end of most of the cases, and in Case 2 and Case 5, these uncertainties were closely connected to low front-end cost estimates and limited market capacity. These are also the two cases with the highest client risk, most challenging collaboration and lowest performance on economic sustainability. Successful engagement of social and political groups, realistic front-end estimates and the securing of sufficient market interest during procurement appear to be crucial to ensure a target cost risk allocation that encourages collaboration towards advancing sustainability.

Integrated steering committees and active client involvement were important organizational elements in all the studied cases. This was particularly the case in projects where the risk allocation was unclear or where collaboration between stakeholders constituted a major uncertainty. In such situations, a client manager supported by the steering committee can bring stakeholders together, encourage the development of joint solutions and make swift and mutually understood decisions for the best of project. The way of involvement of the designers differs among the projects, but the competence and quality of collaboration between the designers and the rest of the project organization appears to be important for performance. Early and tight involvement of subcontractors of technical installations and heavy equipment was a crucial success factor for the advancement of both economic, social and environ-mental sustainability in Cases 1, 3 and 4. In Case 2, insufficient involvement

of sub-contractors resulted in changes and collaborative challenges, which required active client involvement. Integrated and continuous schedule management with early engagement of stakeholders and active focus on opportunities was a key feature of the projects with the highest performance on schedule, which was beneficial from both economic, social and environmental perspectives. Co-location was characteristic of all projects and is reported to have contributed to improved team building and higher efficiency, quality and safety of work, which is in line with theory [2, 5]. Workshops were actively used in the majority of the studied case projects, and in several cases crucial for project success. For Case 4 in particular, client-organized startup workshops enabled the development of joint understanding between stakeholders, while continuous workshops facilitated good interface management, which was critical for performance. In Case 2, active referencing to a collaborative charter from the startup workshop, and continuous client-organized workshops, helped get collaboration back on track when challenges occurred during construction.

The identification of mutual trust as a cultural element in all the studied case projects is in line with previous literature on the subject [3]. Mutual goals and openness were cultural elements of importance in four of the five cases, and the observed significance of these elements corresponds well with literature [11, 12]. While mutual respect was identified as a cultural element in just two cases, this element was considered fundamental for the maintenance of trust, which is necessary for a team to efficiently collaborate towards common goals [2]. The identification of mutual respect as a cultural element of fundamental importance in CDMs corresponds with recent findings [11, 12].

6 Conclusions and Further Research

This study demonstrates the interrelatedness between CDM elements, uncertainty and sustainability in large projects. CDM elements contribute to enhanced management of opportunities and risks in ways that can advance both economic, social and environmental sustainability. Through the contractual elements, the client can recruit suppliers with motives and competence to collaborate on the goal of advancing sustainability, and establish mechanisms that further incentivize them to achieve this goal. Social, political and market uncertainty greatly impacts the flexibility of the client to select and implement contractual elements that advance sustainability. Successful implementation of the organizational and cultural elements benefits from active client involvement in their implementation. Organizational elements contribute to the recruitment of personnel with the right motives and competence and the sustenance and enhancement of the ability of the team to collaborate towards common goals, while cultural elements help formalize the goals of the team and the way they are to collaborate in achieving them.

This chapter has documented similar experiences with CDMs in localized medium-sized construction projects and transcontinental industrial megaprojects, which supports the view that its conclusions can be generalized irrespective of size, industry and geography. In future research, it is recommended to study in detail how collaboration towards sustainability can be integrated into CDM elements and to carry out comparative quantitative studies on how projects with various forms of such integration perform economically, socially and environmentally.

1 Introduction

Uninterrupted power supply through robust power generation, transmission, and distribution in electric power networks (EPNs) is crucial to keep society functioning today. However, local power grids are prone to whims of weather events with undeniable impacts, such as hurricanes, strong winds, tornados, wildfires, floods, blizzards, or extreme cold. The profound impact of strong winds on power grids often leads to widespread disruptions in the electricity supply caused by breaking power lines, toppling utility poles, and damage to transmission towers [1, 2]; these threats, coupled with flying debris, pose a significant threat to the structural integrity of the grid. Extreme high or low temperatures are usually associated with higher electricity demand that can potentially overload the grid, leading to equipment failures and blackouts. For colder climates, extreme winter weather events such as ice storms and heavy wet snowfall can build up on power lines, weighing them down

and potentially causing them to snap. Heavy rainfall accompanying hurricanes and organized thunderstorm systems, including derechos, can lead to riverine flood events or more local flash flooding, impacting substations and underground grids and weakening the foundation of poles and towers.

As climate change accelerates, its impact exacerbates the challenges faced by power grids in the burden of extreme weather events. Rising global temperatures may contribute to the intensification of hurricanes, increased frequency, and changes in the timing and location of wildfires and tornadoes. Additionally, shifting climate patterns may impact severe weather phenomena such as destructive winds brought by derechos. The warming climate also contributes to the instability of polar vortexes, escalating the likelihood of extreme cold spells. These climate-related shifts can change the frequency and severity of weather events, underscore the urgency of power grid infrastructure adaptation to the evolving challenges posed by a changing climate, and integrate more reliable power resources in the long run through effective climate change adaptation actions [3]. In the United States, 96% of power outages in 2020 were caused by severe weather events [4]. The increased intensity and frequency of natural hazards subsequently increased the consequences of such events on electric power networks. The adverse economic, social, and environmental impacts of power supply disruptions are significant. Preparing for the effects of these weather-related events is paramount to ensuring the resilience of power grids. Pre-emptive measures, such as reinforcing power lines and implementing smart grid technologies, can be strategically employed based on the insights provided by risk assessment. Moreover, the energy sector is essential to climate change vulnerability and adaptation analyses. It is responsible for almost two-thirds of greenhouse gas emissions and most power supply disruptions, causing adverse economic, social, and environmental impacts. Figure 1 shows weather events and their associated impacts on energy infrastructures [5].

Worldwide, the burden of global climate change and increasingly frequent associated events have started to affect various infrastructures, as highlighted by the UK Institution of Civil Engineers [6]. Much of climate change vulnerability, risk, and adaptation efforts are devoted to better understanding and quantifying global climate change impacts on the regional level, given the possibility of increasing the intensity and frequency of extreme environmental events, including intense wind events [7]. The investigation of the reliability of power networks is already challenging due to the numerous involved variables and their inherited uncertainties [8]; the estimation of climate change projections adds to the complexity of the process, especially the regional variability of climate, climate change, and infrastructure properties. Climate scientists use historical data and complex models to estimate and predict future environmental conditions. This process is usually region-dependent, as generalizing or adapting climate change adaptation strategies of other locations might not be feasible or possible due to the different and complex nature of climate change impacts and the critical infrastructure performance in each region [9], such as The North American Regional Climate Change Assessment Program (NARCCAP) [10], High-resolution regional climate change projections

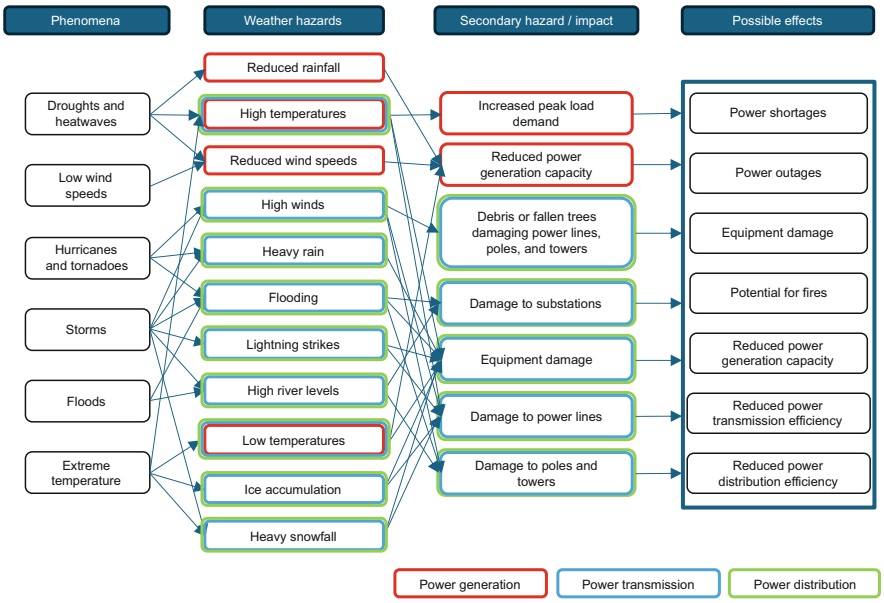

Fig. 1 Weather hazards and possible associated impacts on energy infrastructures

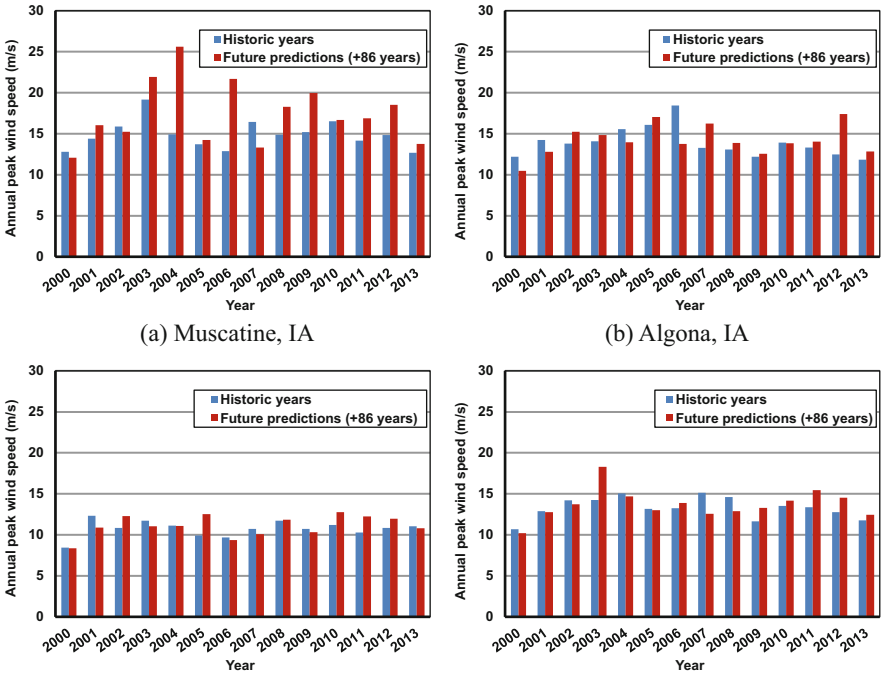
for the northeast USA developed using IPCC SRES emission scenarios by Hayhoe et al. [11], and for the Midwest area by Wuebbles et al. [12]. Additionally, regional projections have been developed in the UK (UK Climate Projection 2009 (UKCP09)) and KNMI climate change scenarios for the Netherlands 2006 following the fourth International Panel on Climate Change (IPCC) [13].

Numerous researchers have studied the future temperature, precipitation, and wind speed trends. Mideksa and Kallbekken investigated thermal power plants' supply sensitivity to temperature changes due to the large geographical variability [14]. Bloomfield et al. investigated the effects of the shifting climate on renewable energy resources and the supply-demand balance in future power systems [15]. Dobson et al. [16] addressed the power system blackouts and outages driven by extreme weather events and their future projections. The increasing ambient temperature associated with climate change and global warming compromises the efficiency and maximum capacity lifetime of power transformers and power lines, as they are vulnerable to high ambient air temperatures [17]. Global warming and, subsequently, ocean warming impact the complex process of wind formation, leading to changes in wind patterns and currents that can promote distribution network failure by rupturing the poles and wire lines, damaging pole-mounted equipment, or causing cascading outages [18]. Increasing participation intensity, storm surge events, and rising sea levels at some locations jeopardize the power transmission and distribution lines and substations to risk flooding [19–21].

2 Climatic Parameters

Based on the region, climate change can increase the imposed hazard on power distribution networks through increasing extreme wind speeds each year, hence making the grid assets more prone to failure, increasing temperature that expedites the decay rate of wooden poles and increases their vulnerability with time. However, annual rainfall reduction can slow the decay rate of wooden poles [22]. Therefore, assessing the impact of climate change on power distribution networks requires detailed modeling to capture the contrasting region-dependent effects of climatic changes and their differing extents. To visibly measure the effect of projected regional climate change on EPNs' performance, the baseline vulnerability status of a network needs to be established first. Hence, a case study of four cities in Iowa in the USA, namely, Muscatine, Algona, Pella, and Cedar Falls, is presented.



The WRF 3.4.1 model is a numerical weather prediction system designed to serve atmospheric research and operational forecasting needs, therefore assessing the infrastructure resilience from multiple aspects [23]. This study uses a higher resolution 4 km cell grid than is typically used operationally to give a more accurate projection for frequency and intensity of wind speed, precipitation (flooding), and freezing rain over the 13-year simulation period considering climate change. The resolution used herein is much finer compared to the 18 km resolution used in earlier models, including the UK flooding model (UKCP 18), global reanalysis (ERA5), Global-to-Regional Integrated Forecast System (GRIST), China Merged Precipitation Analysis (CMPA), and Integrated Multi-Satellite Retrievals for the Global Precipitation Measurement (IMERG) [24, 25]. The simulation period is based on a reference control period spanning from October 1, 2000, to September 30, 2013, with 6 hours and 0.7 °C and a sensitivity model considering the effects of climate change using the PWG approach ("Physics-WGNE" (Working Group on Numerical Experimentation)), with ten perturbed physical fields to account for uncertainties climate system mechanism. The future climate simulation extends from October 1, 2086, to September 30, 2099.

2.1 Maximum Wind Speed

The behavior of the wind speed shows oscillation around a mean value. Still, given the turbulent characteristic of wind, the maximum wind speed can peak away from the mean value [26]. The wind speed dataset contains maximum wind speeds 10 meters above ground level. Structural analysis showed that poles start to fail near the 15 m/s wind speed threshold, considering that the model values are averaged over the 4×4 km box and peak winds usually are very localized. In addition, models typically are deficient in bringing momentum to the ground. Accordingly, the projections of wind speed over 20 m/s were calculated along with their frequencies in the control and future models.

2.2 Wind Speed Simulation Results

The following Fig. 2 shows the high winds of the four study areas during the reference and projected years. There is a noticeable variety in high wind speeds across the four regions. At the same time, some areas experience higher wind speeds, indicating natural weather pattern fluctuation that can be attributed to terrains and other landscape features. For example, Muscatine generally has higher wind speeds over the years, and occasional years, such as 2090 and 2091, show significant increases in peak wind speeds. Compared to earlier years, Algona shows increased peak wind speeds in certain future years, such as 2087 and 2092, and Pella shows increased peak wind speeds in certain years, such as 2090 and 2093. Cedar Falls has less wind speed fluctuation across the study years. Hence, specific years exhibit extremely high wind speeds compared to the average, indicating the possibility of intermittent extreme weather events, and there seems to be a trend of stronger winds toward the later years of the dataset.

3 Maximum Wind Speeds and Electric Power Network Reliability

3.1 System Fragility Curve Development

The radial configuration of local power distribution networks leads to service outage downstream from any interruption point, i.e., network component failure. Hence, it is crucial to investigate the reliability of the network components in correspondence to various environmental event intensities. In this study, which focuses on the wooden power distribution poles, the capacity of those poles is influenced by their class, geometry, age, and the environmental conditions that expedite their deterioration. After analyzing the wind demand on the poles in the network and their capacity, it is essential to use a limit state function to describe the system's vulnerability by establishing the pole's conditional failure probability in response to increasing wind speed.

3.2 Wind Demand on EPN Components

The poles and wires of EPNs are directly exposed to wind and flying debris. Hence, they are considered highly vulnerable. To evaluate the exerted wind loads, the following relationships provided by ASCE/SEI 7-22 can be used [27]:

$$F = 0.613\, K_z\, K_{zt}\, K_d\ K_e\, G\, \mathrm{Cf}\ A_f\ V^2\ (\mathrm{N}) \tag{1}$$

G is the gust-effect factor, Cf is the force coefficient, A_f is the pole or wire area projected normal to the wind direction. Kz is the velocity pressure exposure coefficient, K_{zt} is a topographic factor, and K_d is the wind directionality. K_e is the ground elevation factor. V is the basic 3-sec gust wind speed. The distributions and coefficient of variations (CoV) of the mentioned random variables related to poles and wires are summarized by Ellingwood and Tekie [28].

3.3 EPN Components Capacity and Case Study

The vast majority of US power distribution poles are wooden due to the availability, serviceability, and lower wood cost than other pole materials [29]. The American National Standards Institute published in (ANSI-O5.1) classified wooden poles into 15 classes designed to have approximately the same load-carrying capacity regardless of their species [30]. In the four locations where the wind speed projections were analyzed, the main wood pole is the Class 3 Southern pine pole. Hence, a fragility function for a 40-year-old Class 3 pole with an average height of 13 meters and an average wire span of 100 meters is chosen as an example.

3.4 Limit State Function

The wind loads acting on the poles and wires of EPNs translate into bending moment in the pole and tensile stress in the wires; hence, the structural demand is directly proportional to wind speed and duration. On the other hand, the EPNs can be structurally analyzed to determine the structural capacity of their components in response to various weather events and external stresses. The following relationship can generally describe the limit state function, $G(x)$:

$$G(x) = C(x_c, d_c) - D(x_d, d_d) \tag{2}$$

Where C is the structural capacity as a function of random and deterministic variables x_c and d_c, respectively. D is the structural demand on the system as a function of random and deterministic variables x_d and d_d, respectively. The system fails whenever the demand exceeds the system capacity and results in the limit state function being negative. The Latin hypercube sampling method (LHS) is used to generate ten thousand random samples for wind speeds, which are used in accordance with the provisions of ASCE/SEI 7-22 to calculate wind load on the poles and connected wires. Subsequently, the failure probability at each wind speed.

3.5 Fragility Function Development

After structurally analyzing the ten thousand realizations and determining their failure or survival based on the limit state function for three modes of failure, i.e., pole rupture, foundation failure, and wires breakage, The pole rupture turned out to be the predominant mode of failure within the range of wind speeds in this study. Afterward, the log-normal distribution was chosen to describe the relationship between wind speed and the fragility of the poles. The distribution parameters can be obtained using the maximum likelihood estimation (MLE) method [31, 32]. The following fragility function shows an increasing failure probability of the pole with increasing wind speeds. Considering the generally projected increase in wind speed in some regions in the coming years, accompanied by the degradation of wooden poles and strength decay, accounting for climate change impacts becomes necessary (Fig. 3).

3.6 The Annual Probability of Failure

The annual probability of failure is obtained by performing a mathematical convolution of the fragility and hazard curve; the last describes the instantaneous probability of failure at a given wind speed. The wind speed occurrence frequency is

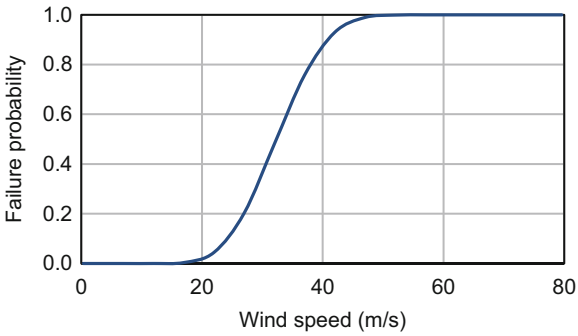

Fig. 3 Fragility function of a 13 m high Class 3 wooden pole

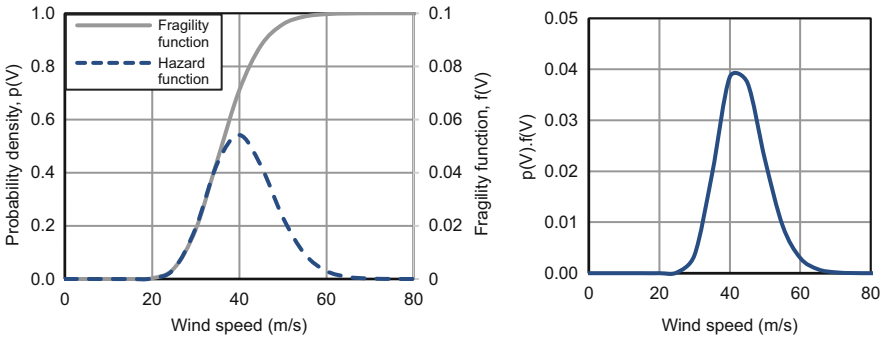

Fig. 4 (**a**) Fragility and hazard curves, (**b**) fragility and hazard functions convolution curve

presented through a probability density function (PDF) that models the available location-related wind data based on the data provided by Vickery et al. [33] in Fig. 4a. Convolution principally combines the fragility and hazard functions to show the overall likelihood of failure at different wind speeds throughout the year. The annual probability of failure, P_f, at maximum wind speed, $V_{\max}$, can be expressed as:

$$P_f = \int_0^{V_{\max}} p(V).f(V).dV \tag{3}$$

where $p(V)$ is the fragility curve, representing the probability of failure at wind speed V, and $f(V)$ represents the PDF of wind speed V, obtained from the hazard curve. Hence, the annual probability of failure, P_f, is the area under the curve in Fig. 4b up to the maximum wind speed, $V_{\max}$.

Considering the prevailing wind conditions, the change in the annual probability of failure of the pole between the reference year and the projected year offers further insight into the changing risk of failure associated with climate change, as depicted in Fig. 5. Despite the shown fluctuations and lack of a clear linear trend between the

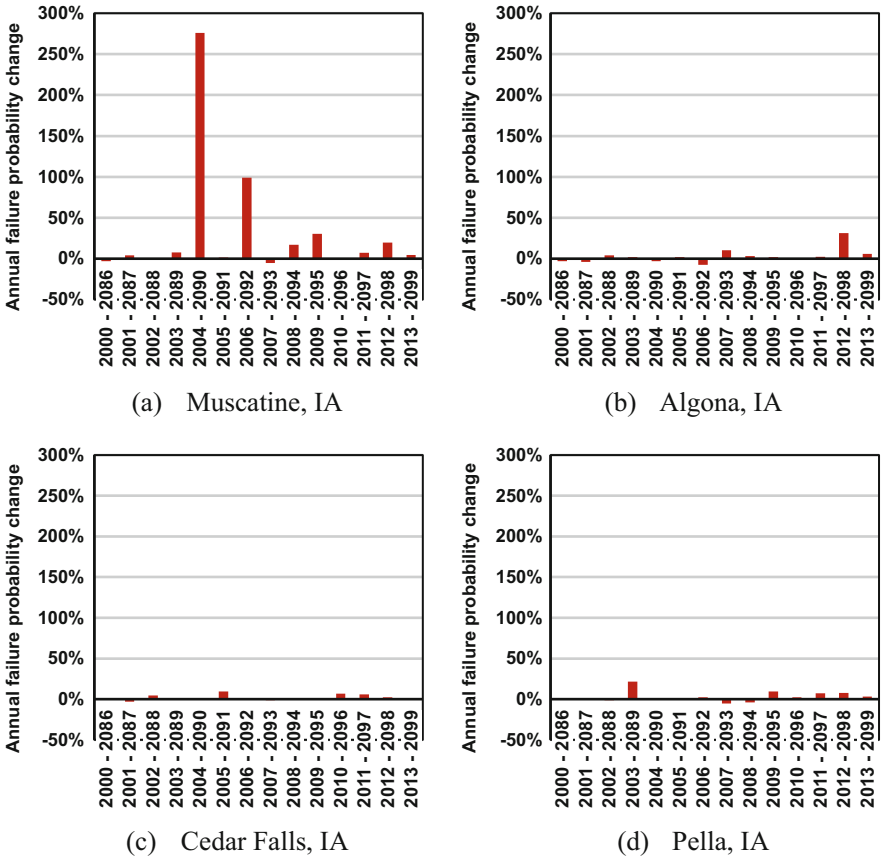

Fig. 5 Percent change of the annual failure probability in the case study areas. (**a**) Muscatine, IA. (**b**) Algona, IA. (**c**) Cedar Falls, IA. (**d**) Pella, IA

change in annual failure probability over the years, there were substantial increases, such as 275% in 2090 for Muscatine, and other decreases, such as −8% in 2092 for Algona. It can be noticed that those percentages correspond to the projected change in maximum wind speed displayed in Fig. 2 as increasing wind speed increases the wind load demand and, subsequently, the component failure probability.

4 Results and Conclusions

As the intensity and frequency of some weather events increase, it further stresses the power supply chain integrity. Distribution networks are the most vulnerable to extreme weather events as they can cause widespread power outages, overload the grid, and potentially lead to equipment failure. Fragility models are essential to

estimate the likelihood of component failure and risk assessment, enabling informed decision-making for predictive maintenance and risk mitigation procedures. This research reviewed the impacts of the ongoing climate change on power distribution networks by estimating the projected maximum wind speeds, evaluating their effect on the components of the power distribution network, and establishing the vulnerability of the EPN as a function of wind speed through statistical analysis. The presented research discusses weather phenomena, their association with climate change, and their projected impacts. The numerical weather prediction model WRF 3.4.1 with a 4 km resolution cell grid gives a more accurate projection of the frequency and intensity of high winds. The percent change in the predicted annual probability of failure is associated with the percent increase or decrease of the high wind speed, therefore calling for adaptive and continuous risk assessment of the network to ensure its reliability.

1 Introduction

In the last decade, the decline of Historical Villages (HVs) has assumed considerable dimensions, resulting in the disappearance of a secular civilization and, with it, the identity linked to both buildings and traces and elements of material and immaterial culture. This negative trend is increasing in several EU countries, and it is especially evident in Italy, which has 4.7% of the world's architectural heritage and where HVs with less than 5000 inhabitants cover a total of 60% of the territory, involves approximately 22% of its population [1].

HVs are settlements that have maintained the recognizability of their structure and the continuity of the historic building fabric, where the original typological and morphological characteristics are clear and denoted by high social, historical, architectural, and/or landscape value, establishing them as an important part of the European Cultural Heritage (CH). HVs constitute fragile environments, often located in marginal areas isolated from main urban centers, frequently abandoned

due to their complex orography, their fragile economy, and high environmental risks, recently exacerbated by the effects of climate change [2].

These features led them to progressively face depopulation phenomena, unemployment, and ageing of the population, which, in turn, caused growing socioeconomic issues and the degradation of buildings and infrastructure. In addition, this significant heritage no longer answers to the new expected building energy standards required to contrast climate change [3]. This gap hinders the fulfillment of objectives advocated by the new EU Green Deal, aiming to establish Europe as the first climate-neutral continent by 2050 [4].

Unfortunately, despite the high cultural riches, the improvement and valorization of this heritage is hindered primarily by economic budget constraints.

In this context, a potential solution that has emerged in Europe, involves the establishment of participatory processes through public–private partnerships. These processes power the local inhabitants to spearhead bottom-up initiatives promoting their crucial role into the building's refurbishment, retrofit, and valorization toward decarbonization aims. The most impactful solution, successfully addressing social, cultural, and economic concerns alongside environmental considerations, is the establishment of Energy Communities (ECs) [5].

Renewable ECs[1] can be regarded as a model of organizational innovation that empowers end customers as protagonists of the energy transition. This approach enables citizens, administrations, and local businesses to collaboratively develop and manage energy projects or services. The governance and ownership structure of these communities often differs from traditional business organizations, emphasizing a more participatory and community-driven approach [6].

Fueled by an ever-evolving national and European legislative framework on the energy transition, as well as initiatives associated with the Next Generation EU plan, Italy has witnessed a notable increase in initiatives dedicated to establishing ECs in recent years. This trend is particularly pronounced in specific contexts, such as HVs [7].

Analyzing the Italian context, the paper provides an overview of the current state of the evolution of ECs, both from a legislative and practical standpoint. Through a detailed description, grounded in reference case studies, the objective is to underscore replicable and inclusive reference models that can encourage interventions such as the reuse, enhancement, and redevelopment of HVs. This includes maintenance and restoration initiatives aimed at integrating energy retrofit interventions preserving the heritage value and enhancing the historical identity of this asset.

To study the innovation potential of the Renewable Energy Communities in Italy, the following methodological steps have been followed:

[1] Energy Communities can be classified in two levels: the Renewable Energy Communities (RECs) can only exploit Renewable Energy Sources (RES) to fulfill different kinds of demand (e.g., electrical and thermal), whereas the Citizens Energy Communities (CEC) can manage only electricity, both from RES and fossil fuels, and can operate in an autonomous microgrid.

- The analysis of the regulation, process and factors that influences the regime and create windows of opportunity for the initiative forming and development in the Italian context.
- The identification of the main goals toward HV shifting to clean energy.
- The descriptive analysis of a best practice example, illustrating the key success factors: community engagement, funding strategies, etc.
- The potentiality of replication for revitalizing HV in Italy.

2 The Energy Communities

Due to the Europe-wide publication of the Clean Energy for all Europeans Package, energy end-users, previously the final link in the decision-making chain regarding the definition and implementation of energy policies, have now been empowered with a potential new role. This newfound role provides them with the opportunity to actively participate, for instance, in the generation of energy from renewable sources. In the short term, this shift has led to a profound transformation of the traditional model of energy system production and management [7].

The European Parliament has issued two directives that lay the foundation for the introduction of ECs: the Renewable Energy Directive 2018/2001 (known as RED II), published in December 2018, and the Directive on common rules for the internal market for electricity 2019/944 (known as the EMI Directive), published in June 2019. The two directives set the legal framework at the European level for individual and community participation, introducing specific definitions for self-consumption (including collective) schemes and ECs [8, 9].

Based on the assumptions contained in the above directives, the basic concept that defines the role of ECs emerges, namely: to promote the generation, transmission and distribution of energy produced from renewable sources, in response to energy, environmental and social needs identified in local realities.

The proliferation of initiatives geared toward establishing ECs is bolstered by specific factors: [10–12].

- Increased adoption of innovative and sustainable energy models: the wider acceptance of innovative and sustainable energy models facilitates the pursuit of objectives set by the energy transition through inclusive, community-based approaches.
- Technological advancements: the maturity of technologies for decentralized energy production on a local scale plays a pivotal role in supporting these initiatives.
- Citizen participation in the energy market: the opportunity for active involvement in the citizens' energy market enables a shift from being solely consumers to becoming prosumers, actively contributing to energy generation.
- Addressing energy poverty: ECs contribute to combating energy poverty, ensuring more equitable access to energy resources.

Finally key success factors for these initiatives lies in the inherent connection between the initiators and the targeted area. Indeed, no one is better positioned to champion the enhancement of their locality than its inhabitants, particularly when the area holds historical and cultural significance. Legislatively, members of an EC can include individuals, SMEs, territorial entities, or local authorities, including municipal governments. However, it's important to note that for private companies, participation in the renewable energy community should not constitute their primary commercial and/or industrial activity.

2.1 Challenges and Opportunities in the Italian Context

The term "Renewable Energy Community" (REC) is adopted to denote a coalition of users who, by establishing a legal entity, choose to collaborate with the objective of meeting the identified needs of the members. This collaboration involves the production, consumption, and management of energy through one or more local plants powered by renewable sources [13].

Main characteristics of the developing models of RECs, responding to different needs site specificity (stakeholder, funding, and sharing model), are summarized in Table 1.

All the assets of the REC must be connected to the same medium voltage (MV)–low voltage (LV) transformation station (i.e., sub-stations or secondary stations). The Shared Energy (SE) is equal to the minimum, at each hourly period, between the electrical energy produced and fed into the grid by RES and the electrical energy absorbed from all the customers. The economic incentives for RECs are guaranteed for 20 years. Afterward, annual tacit renewals apply. The BESS (Battery Energy Storage System) consists of an aggregation of loads connected with a Photovoltaic (PV) plant at the low voltage side of a same transformer, where the loads are

Table 1 Classification of REC models in the Italian context

REC model	Stakeholder/ proponent	Funding	Sharing model
Citizen-driven	Citizens, local private proponents, SMEs	Members' investment, feed-in premium tariffs, bank loans	Equitable redistribution according to the investment participation/amount of shared energy.
PA-driven	Public/local authority, PA, non-profit organizations	Public (national and regional) funding (in the cumulable percentage) and feed-in premium tariffs	Equitable redistribution, establishment of a social funds for disadvantaged members, community services, or energy efficiency measures
Energy/ technical operator-driven	Technical player/energy operator	Developer and members' investments, and feed-in premium tariffs	Divided between energy/technical operator and members

inflexible residential customers. Also, the PV plant could be any RES plant. Recently, the Delibera 727/2022 of ARERA proposed a new policy option to enable the contribution of BESS in standalone configuration [14].

The principles of decentralization and localization form the foundation of an EC. Through citizen involvement and the growth of local businesses and commercial activities, such a community can effectively generate, consume, and exchange energy in a model of self-consumption and collaboration [15]. After the publication of the Clean Energy for all Europeans Package and the accompanying Directives, by 2020 Italy initiated a partial transposition of the Renewable Energy Directive II (REDII)[2]. This transposition aimed to kick start the first experimental applications, albeit subject to two primary constraints: the maximum installable power and the proximity of the plants to the withdrawal points held by consumers.

In addition to national legislation, the institutionalization of ECs in the Italian context has spurred the development of numerous regionally initiated laws. These regional laws aim to locally promote the development of RECs more closely tied to the specific territorial characteristics of each region.

In Italy, the establishment of ECs encountered several challenges, with the main issues including [16]:

1. Individual Power Limits: the imposition of a maximum power limit of 200 kW for individual plants restricted the involvement of third parties. This limitation only allowed for projects that could engage a limited number of households and an even smaller number of small and medium-sized enterprises.
2. Constraints related to MV/LV Transformation Substations: the presence of MV/LV transformation substations posed a significant hurdle to the implementation of large-scale initiatives. This complication also made it more challenging to identify members to participate in these communities.
3. Diverse Regional Laws and Regulations: despite national-level efforts, ECs implementation was impacted by various regional laws and regulations. This occasionally led to uncertainty and created obstacles in standardizing practices.
4. Complexity in identifying members: the difficulty in identifying and engaging Energy Community members presented a problem. There were challenges in educating and incentivizing community participation.
5. Limited Size of Initiatives: regulatory constraints and operational challenges often restricted the size of initiatives, impeding the execution of large-scale projects.

[2] As of 2020, through the combined provisions of Law 8/2020 (which converts Article 42/bis DL 162/19—*Milleproroghe* Decree), the regulatory model identified by ARERA (Resolution 318/2020), and the incentives defined by the Ministry for Economic Development—MiSE (Ministerial Decree September 16, 2020), the establishment of RECs and collective self-consumption schemes became possible. Specifically, these laws predetermined the legislative framework to be followed, outlined incentive mechanisms, and established regulations for tariffs applicable to RECs and collective self-consumption schemes.

6. Limits to Third-Party Involvement: constraints on third-party participation potentially limited the breadth and diversity of actors involved in ECs.

Several limitations observed in the initial experiments have since been addressed with the provisions outlined in the drafts of the Legislative Decrees for the national transposition of the two relevant Directives in 2021. Notable among the key enhancements are:

1. Increased power limit for incentives: the power limit for plants eligible for incentives within the scheme has been raised to below 1 MW per plant. Additionally, the connection of plants and utilities under the same primary substation is now considered, providing greater flexibility.
2. Expanded perimeter: the expansion of the perimeter from MV/LV transformer substations to HV/MV substations serves a dual purpose. It not only overcomes challenges in accessing information but also allows for the construction of larger plants capable of effectively meeting the energy needs of a community.
3. Inclusion of existing plants: the option to include existing plants in the configuration, albeit with a maximum share of 30% of the power held by the community, aligns with the direction of community-based and more integrated management of the generation stock within individual communities.

Following the approval by the European Commission in November, the MASE (Ministry of Sustainable Energy) officially released the RECs decree (DM 414/2023) to actively support the emergence and growth of RECs and collective self-consumption systems. Effective from January 24, 2024, the decree is designed to encourage the proliferation of collective forms of energy production and self-consumption from renewable sources. The decree introduces two primary mechanisms to promote the development of RECs in Italy:

1. Forty percent Non-Repayable Subsidy: financed by the National Recovery and Resilience Plan[3] (PNRR), this provision offers a 40% non-repayable subsidy. The incentive is targeted at communities whose installations are established in municipalities with a population of fewer than five thousand inhabitants.
2. Incentive tariff on renewable energy: the decree also introduces an incentive tariff on renewable energy produced and shared, applicable nationwide. This aims to stimulate the generation and sharing of renewable energy throughout the country.

[3]The PNRR serves as the country's comprehensive recovery program in response to the crisis and socio-economic disruptions induced by the COVID-19 pandemic. Formally accepted by the European Union on June 22, 2021, and ratified through the European Council Decision on July 13, the Plan is an integral component of the Next-Generation EU program. Specifically, the PNRR allocates 2.2 billion euros for the development of Energy Communities in municipalities with a population of fewer than 5000. This substantial financial commitment underscores the strategic focus on fostering sustainable energy initiatives within smaller communities as part of the broader recovery efforts.

3 CommOn Light Energy Community: An Italian Best Practices Case

Despite the predominant administrative, bureaucratic, and economic challenges faced during the initial stages of launching ECs in Italy, there are noteworthy experimental case studies that can be considered as exemplary practices and models for potential replication in other international HVs [17].

The CommOn Light Energy Community serves as a notable exemplar of best practices within the Italian context. This pioneering initiative, situated in the Municipality of Ferla,[4] Sicily, showcases a successful model for sustainable energy development, collaboration, and community engagement.

CommOn Light emerged from a collaborative effort between the Municipality of Ferla, the University of Catania, and the interdepartmental research project TREPESL (Energy Transition and New Models of Participation and Local Development). The collaborative foundation ensured a multifaceted approach, incorporating both academic expertise and local administrative support.

Clear delineation of roles enhanced project efficiency. The Municipality of Ferla assumed responsibility for political, communication, and engagement aspects, as well as the facility's implementation. Simultaneously, the University of Catania took charge of legal-administrative facets, ensuring a seamless integration of skills and expertise (Fig. 1).

The project's commencement capitalized on funding from the Sicily FESR (Fondo Europeo per lo sviluppo regionale) Operational Plan 2014–2020, demonstrating strategic financial planning. Additionally, the integration of resources from municipal funds and the targeted utilization of PNRR funds earmarked for small municipalities underscored a creative and diversified funding strategy.

CommOn Light's primary objective is to curtail dependence on external, nonrenewable energy sources. By implementing on-site energy production and storage, the community strives for sustainability and reduced environmental impact.

An open and inclusive social structure lies at the core of CommOn Light's success. The initiative actively engages the community through cultural awareness programs, training activities, and transparent communication, fostering a sense of ownership and participation.

At the beginning, the EC involved the only installation of a 20-kW photovoltaic system on the roof of the Ferla Municipality building. This solution was made possible through discussions with the Superintendence for Cultural Heritage to identify a design solution that seamlessly integrated with the landscape (Fig. 2).

[4] Ferla is a small municipality situated in southern Italy within the province of Syracuse, boasting a population of just over 2000 inhabitants. It was the first Sicilian municipality to create a renewable energy community. Ferla, in conjunction with the city of Syracuse, has held the designation of a UNESCO Municipality since 2004 and has been a member of the "*Borghi più belli d'Italia*" since 2014.

Fig. 1 View of a segment of the historic village of Ferla

Fig. 2 Installation of photovoltaic panels on the roof of the Ferla city hall to support the ECs

The outcome of the initiative has sparked the creation of a "green village," wherein energy generated from renewable sources is shared through a mutual exchange. This collaborative effort involves private citizens or small and medium-sized enterprises whose users are connected to the same medium/low voltage transformation cabin.

Individuals interested in participating can join the Community by lending their photovoltaic system (thus becoming producers) or by connecting to the grid as end consumers. A portion of the incentives will be allocated to compensate the investments of fellow citizens who opt to be both consumers and energy producers. Another segment will be directed toward providing discounts on energy bills, while the remainder will be reinvested within the community itself, contributing to the expansion of energy capacity through additional systems.

Since 2015, Ferla has initiated a series of administrative and planning activities dedicated to innovative energy. These efforts include the creation of six photovoltaic systems with a total power capacity of 31 kW.

Starting from this experience, the path to establishing the first EC in Sicily begins in January 2021.

The municipal resolutions outlining the creation of the EC materialized through initial acts formulated between March, April, and May 2021. The guideline act was enacted in March 2021, followed by the expression of interest for external users keen on participating in the project.

In May 2021, the association's statute, the incorporation deed of the EC "CommOn Light," and the internal regulations, signed by the members to govern the distribution of incentives, were approved.

Authorization from the Superintendence of CH was crucial for the construction of the photovoltaic system above the Municipality building's roof, given the existing landscape restrictions.

Despite the higher costs and an anticipated lower yield, the Superintendence granted favorable approval for the system's construction, with the condition that the panels be colored in a brown shade to minimize landscape impact.

The management of this system requires the Municipality to make the photovoltaic system available to the community while retaining ownership under an indefinite loan contract. The agreement includes a final term linked to the EC's duration, emphasizing the potential for widespread replicability of this organizational model.

Citizen involvement practices were formulated by the members of the working group and were initiated during the initial meetings dating back to January 2021. The official establishment of the EC was announced to citizens on March 28, 2021. Following this announcement, invitations to participate in a call for interests were disseminated through local social media and the Municipality's official website, resulting in the first wave of participant responses.

As introduced, part of incentives will contribute to the expansion of energy potential of CommOn Light through additional systems. Based on this assumption, new initiatives have already been launched such as:

- the installation of a 30-kW photovoltaic system on the municipal *Carabinieri* barracks, further enhancing the energy potential of CommOn Light;
- additionally, there are plans for the construction of an additional 20-kW system on municipal property, transforming it into "*BorgOstello.*"

Through this initiative, the Municipality of Ferla has showcased its commitment to achieving key objectives outlined in the 2030 Agenda. Notable accomplishments include:

- ensuring access for all to economic, reliable, sustainable, and modern energy systems (Objective 7);
- reducing inequalities within and between countries (Objective 10);
- cultivating inclusive, safe, resilient, and sustainable cities and human settlements (Objective 11);
- promoting models of sustainable production and consumption (Objective 12);
- taking actions at all levels to combat climate change (Objective 13);
- protecting, restoring, and promoting the sustainable use of terrestrial ecosystems (Objective 15);
- strengthening implementation methods and revitalizing the global partnership for sustainable development (Objective 17).

CommOn Light demonstrates a replicable model for other communities across Italy. The project provides a blueprint for how localities can leverage diverse funding sources for sustainable energy projects.

The CommOn Light EC exemplifies best practices in Italy by combining collaboration, innovative funding strategies, environmental consciousness, clearly defined roles, community engagement, and a scalable model for national replication. This case serves as an inspiring reference point for future endeavors in sustainable energy development and community-driven initiatives.

4 Conclusions

The paper aimed at presenting an emerging strategy for the revitalization and decarbonization of Historical Villages.

The decline of HVs in Europe, particularly in Italy, has become a pressing issue due to factors like depopulation, economic challenges, and environmental risks.

In response to this, the establishment of ECs has emerged as a potential solution. ECs empower local communities to spearhead initiatives for building refurbishment, retrofit, and valorization aimed at decarbonization [18, 19].

These ECs are part of a broader trend driven by European legislation promoting renewable energy and community participation in energy production.

Despite facing challenges such as regulatory constraints and limited involvement of third parties, ECs have seen notable developments in Italy. Recent legislative decrees, including the RECs decree (DM 414/2023), offer incentives like non-repayable subsidies and tariff incentives to promote the development of ECs.

In this context, the CommOn Light Energy Community in the Municipality of Ferla, Sicily, stands as a best practice case. The project aims to reduce dependence on nonrenewable energy sources by implementing on-site renewable energy production and storage. Collaborative efforts between the municipality, academic institutions, and research projects have facilitated the establishment of CommOn Light.

Key features contributing to CommOn Light's success include clear delineation of roles, strategic financial planning, and an inclusive social structure. The community actively engages residents through various programs and transparent communication, fostering a sense of ownership and participation.

CommOn Light's achievements align with the objectives outlined in the 2030 Agenda, demonstrating its potential for replication in other Italian communities. By leveraging diverse funding sources and emphasizing community engagement, CommOn Light serves as a model for sustainable energy development and community-driven initiatives nationwide.

Acknowledgments The chapter is the results of a common reflection of the authors, based on their expertise in the specific fields of research.

Specifically, Emanuele Piaia authored the chapter's introduction and Sects. 2 and 3, while Silvia Brunoro wrote Sect. 4. The final revision of the work and the approval of the manuscript version to be published are attributable to all the authors.

This work was possible thanks to the FIRD2023 project "*Renewable energy communities—methodological perspectives and framework models*" funded by the Department of Architecture of the University of Ferrara (local research projects).

The authors also extend their gratitude to Mauro Guerra (Coordinator of *Borghi più Belli d'Italia* for the Emilia Romagna region and the national contact person for initiatives related to Energy Communities) for generously sharing invaluable insights, particularly regarding recent Italian experiences, with a special focus on the Ferla demonstration case.

1 Introduction

According to a report by the United Nations Environment Programme [1], the building and construction industry is responsible for 37% of global carbon emissions, underscoring its significant role in climate change. Further, L. Pérez-Lombard et al. [2] estimate that buildings contribute to 42% of energy consumption in Western countries, highlighting their substantial impact on energy demand. While numerous studies have investigated the relationship between building materials and energy consumption regarding environmental emissions, there has been less focus on real-time energy monitoring and its potential for reducing energy use. I. Knight [3] demonstrated that energy monitoring has significantly reduced energy consumption since 1995. Despite the widespread adoption of EMS, research has predominantly

focused on industrial complexes, leaving a gap in studies that assess EMS in public buildings. Aman, Simmhan, and Prasanna (2013) highlighted that real-time insights from EMS are key for stakeholders to make informed decisions and develop proactive energy management strategies [4].

This chapter investigates a pilot project that implemented EMS in 34 public buildings within the Vestfold and Telemark County municipality in Norway. The objective of the project was to reduce energy usage by closely tracking and analyzing consumption patterns on a weekly basis through EMS. The system provides real-time monitoring, in-depth data analysis, and comprehensive reporting, offering a detailed view of energy consumption trends. This capability allows for a systematic approach to identifying inefficiencies and applying targeted interventions to improve energy performance.

By examining how energy is consumed and identifying patterns through interactive diagrams, the EMS system provides a framework for optimizing energy use. This approach has the potential to inform daily practices and improve the temporal distribution of energy consumption, leading to more efficient and cost-effective energy management.

The structure of this paper is as follows: Sect. 2 provides background information on EMS in Norway. Section 3 details the case study involving 34 public buildings in the Vestfold and Telemark county municipality. Section 4 discusses the findings from the case study, including practical barriers encountered during the implementation of the EMS system, and concludes with implications for future research and policy recommendations.

2 Energy Monitoring Systems (EMS) in Norway

EMS play a critical role in monitoring, analyzing, and optimizing energy costs in mostly commercial and industrial buildings. EMS typically include sensors, meters, and communication software designed to track energy consumption patterns. The software component provides data analytics, visualization, and reporting capabilities, enabling building managers to identify operational inefficiencies and potential opportunities for improvement, leading to enhanced energy efficiency. This approach has been shown to be effective in large public buildings, as demonstrated by Zhao, Zhang, and Liang in their study of EMS in China [5].

The Norwegian government has recognized the strategic value of EMS in energy management and has implemented policies to foster their adoption. Organizations such as Enova offer subsidy programs to encourage the use of EMS, promoting energy efficiency and sustainability across the country [6]. By leveraging EMS, building managers can monitor and optimize energy consumption, contributing to Norway's national sustainability goals and helping to reduce carbon emissions.

In accordance with Norwegian Planning and Building Act of 1997, all buildings are legally required to maintain an energy and power budget, which EMS can help track. To ensure standardization and compliance, EMS systems must be designed

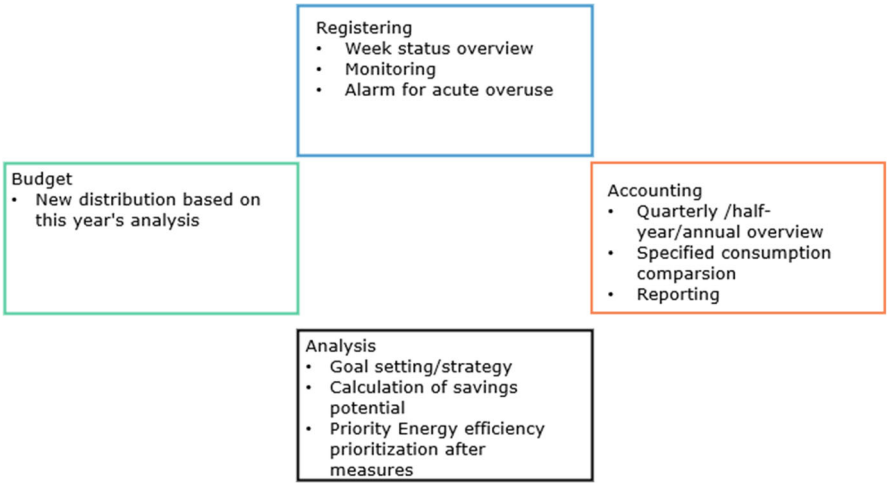

Fig. 1 Energy Monitoring Systems in Norway (Enova handbook 2004:3, page 4) translated in English by the author

according to a specific template, as outlined in "Enova Handbook 2004:3" [7]. This legal requirement also underscores the critical role of EMS in achieving energy efficiency standards in Norway. Fig. 1 suggests how a systematic energy monitoring should be conducted and organized. Experiences in Norway emphasize the importance of organizations systematic approach that is integrated into management and tailored to the routine reporting.

EMS platforms also facilitate transparent energy monitoring, which is essential for identifying consumption patterns, operational inefficiencies, and opportunities for energy optimization. The combination of real-time data collection and advanced analytics empowers building managers to implement targeted energy-saving measures, ultimately leading to cost savings and reduced environmental impact as outlined by Burgess and Nye [8, 9].

3 Case Study: A Pilot Project for Vestfold and Telemark County Municipality

3.1 The Background of a Pilot Project: The Plan for EMS

In 2021, it was decided that all energy usage in the county (Vestfold and Telemark county municipality) needs to be monitored on a regular basis. Energy monitoring was initiated at all county facilities (see the list of buildings in Table 1), as reported by Vestfold and Telemark County Council in a press release. The goal was to reduce energy consumption by 3.4%, but the actual savings amounted to 9.8% compared to normal usage, totaling 9.8 million Norwegian kroner.

The Process for Applying EMS in the Case Study The process of implementing an EMS for the case study involved several key steps. To ensure comprehensive monitoring of energy consumption, energy meters were installed at facilities that lacked existing online energy delivery connections. This approach allowed for the collection of energy usage data from a broader range of sources.

Once installed, all energy meters were integrated into a common energy monitoring platform. This integration provided a unified system for real-time tracking and analysis of energy consumption across the county. The common platform enabled stakeholders to access data from all monitored facilities in a centralized manner, facilitating the identification of energy usage patterns and trends.

The EMS process, as illustrated in Fig. 2, included data collection, integration, and analysis, allowing for more effective energy management. By consolidating energy data into a single platform, the system made it easier to conduct comparative analysis, monitor performance, and implement energy-saving measures based on insights gained from the data.

3.1.1 The Energy Target of the Project

The project established energy targets for each county facility, supported by a follow-up plan. Weekly monitoring of energy consumption and quarterly meetings with facility managers were implemented to ensure adherence to these targets. Any deviations were promptly identified and addressed.

The energy target for 2022 was set at 3.4% below the energy consumption levels of 2021. These energy monitoring efforts continued into 2023, as reported by the county council, with regular tracking and management strategies to maintain and improve energy efficiency across the facilities.

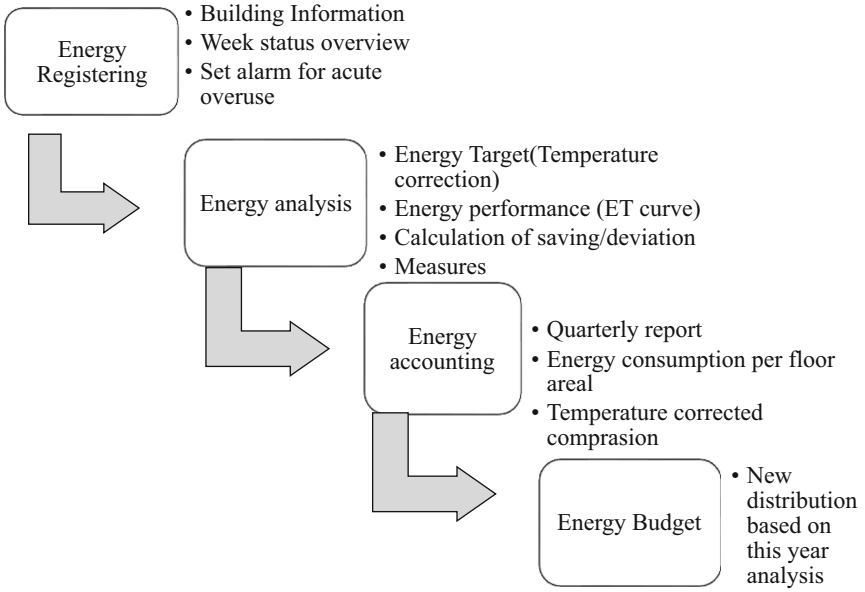

Fig. 2 The process of energy monitoring system of the case study

The assessment of additional metering requirements continued into 2023, focusing on new projects involving solar panels and heat pumps. As a result, more meters were installed throughout 2023, reflecting a proactive approach to energy monitoring. The EMS software or platform, provided by Energinet [10], displayed data from all energy sources, enhancing transparency and enabling comprehensive energy management. Certain buildings operated their own EMS in addition to Energinet, providing localized control over energy consumption.

To ensure precise energy monitoring and response, energy–temperature (ET) curves were adjusted to reduce false alarms caused by excessive energy consumption. This proactive adjustment aligns with the principles outlined in NS-EN 17267:2019, which emphasize the importance of flexible monitoring and the ability to respond to energy data in real time [11].

3.1.2 Energy Analysis: The Interactive ET Curve

The term "ET curve" refers to the energy–temperature curve. The ET curve, a practical tool in Norway, is crucial for energy monitoring, showing how a building's energy usage correlates with outdoor temperature. It is unique to each building according to its energy usage. All deviations from the ET curve exceeding control limits should be documented in terms of total energy consumption and currency. This involves multiplying the deviation in the unit of kWh/m^2 by the floor area to obtain energy usage in kWh. Fig. 3 illustrates an ET diagram with total energy

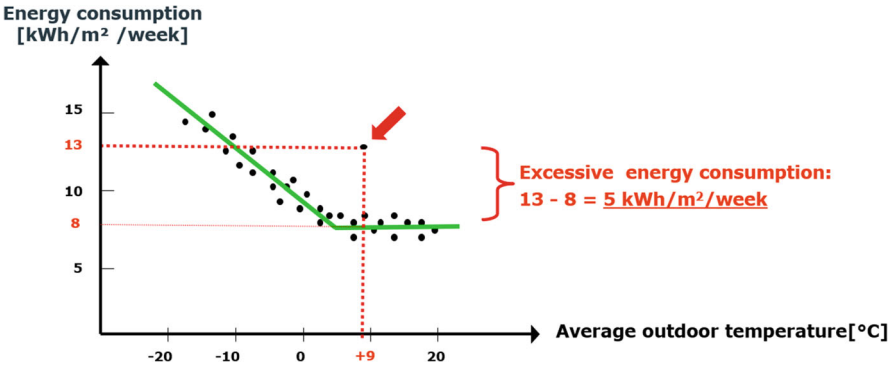

Fig. 3 ET curve example from the case study

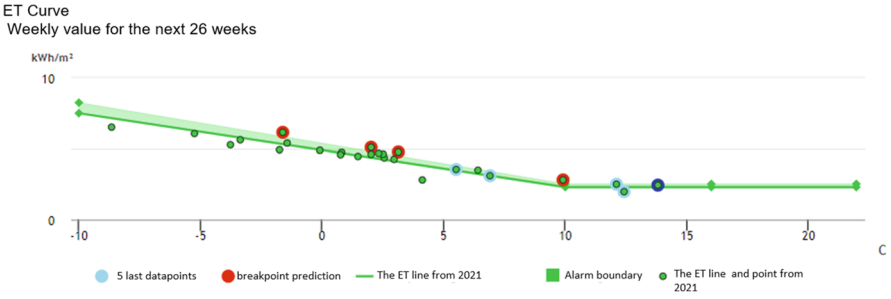

Fig. 4 The ET curve for the weekly value for the next 26 weeks

consumption per week, facilitating communications about energy usage consequences. For instance, a point marked with red point representing 13 kWh/m^2 usage corresponds to approximately a 5 kWh/m^2 deviation from the baseline (8 kWh/m^2).

Figure 4 illustrates how a sudden increase in energy consumption may indicate potential system failure or other operational issues. The cause of the sudden deviation will be identified, and thus specific measures was to be taken to restore the energy performance of the building to the predicted curve as Fig. 4 shows.

3.1.3 Comparing Energy Consumption Across Different Years: Temperature Correction

Even under identical operating conditions, energy usage will vary from one period to another. Energy usage in one period, such as January, cannot be directly compared to the same period in the previous year due to different outdoor temperatures. Therefore, energy usage must be temperature-corrected prior to intercomparison. By reflecting the outdoor temperature fluctuations in calculations, it enables the

comparison of energy use for the same period across different years. This helps the stakeholders spot systematic drifts and errors such as leaks.

In the case study, the "Quarterly report" featured interactive updates on energy consumption, comparisons with previous periods, and strategies for energy saving. This facilitated direct communication with facility managers and decision-makers, promoting actionable solution toward energy efficiency.

Energy Accounting: Quarterly Report One of the buildings within County Hall, Tønsberg, with a heated floor area of 6,400 m^2, is powered by a combination of electricity and district heating. The structure was built in two phases: the first part in 1956 and the latter part in 1994.

The energy target for the first quarter of 2023 (January, February, and March), corrected for temperature variations, was set at 370,706 kWh. However, actual energy consumption during this period totaled 397,038 kWh, exceeding the target by 26,332 kWh. This deviation indicates that the building used 7% more energy than projected, suggesting negative energy performance and reduced efficiency during the first quarter.

The data presented in Table 2 further illustrate these findings:

These values demonstrate that the deviation for January and February contributed significantly to the overall increase in energy consumption for the quarter, while the reduction in March was insufficient to offset the earlier excess. The fluctuations suggest a need for targeted energy-saving strategies in the initial months of the year to meet the desired targets.

Additionally, despite this shortfall against the quarterly target, a year-over-year comparison presents a more favorable outcome. The temperature-corrected energy consumption for the first quarter of 2022 was 404,388 kWh, while the same period in 2023 saw actual energy usage reduced to 397,038 kWh, representing a reduction of 7,350 kWh. This change indicates a 2% reduction in energy consumption from 2022 to 2023, suggesting that overall energy efficiency has improved over the previous year, likely due to effective energy management practices.

Quarterly reports were compiled four times a year, offering a broader analysis of energy consumption patterns and trends. Facility manager meetings were also held on a quarterly basis, promoting collaboration and the sharing of best practices. Additionally, weekly energy follow-up reports were generated, highlighting ongoing energy usage and allowing facility managers to identify areas for improvement. Regular meetings, often held via Microsoft Teams, facilitated communication among facility managers and allowed them to discuss and propose tailored measures

Table 2 The quarterly report on the building of County Hall Tønsberg

Time (month)	Energy consumption	Target	Deviation(kWh)
January 2023	151445	125550	25895
February 2023	124359	119720	4639
March 2023	121234	125436	−4202
Quarter (tot)	**397038**	**370706**	**26332**

to reduce energy consumption. This structured approach to energy management underscores the importance of consistent monitoring and the flexibility to adapt to changing energy requirements.

In summary, the data-driven metrics and outcomes from the first quarter of 2023 indicate significant progress in energy consumption management for the building, exceeding both set targets and reducing energy use compared to the previous year. This progress not only demonstrates the building's trajectory toward greater energy efficiency but also underscores the positive impact on sustainability and reduced environmental footprints.

The achievement of these energy efficiency targets was facilitated by a combination of national support from organizations like Enova, clear energy-saving objectives, and structured, interactive EMS data monitoring through weekly tracking by Energinet. This systematic approach ensures effective communication among stakeholders, early detection of system failures, and a proactive response to optimize energy usage.

Overall, the case study exemplifies how a concerted effort in energy monitoring and management can contribute to national climate goals. The systematic approach detailed in the study serves as a model for other public and commercial buildings seeking to improve energy efficiency and reduce their carbon footprint. By adopting similar practices, buildings can not only meet but exceed energy-saving targets, supporting the broader objectives outlined in the National Climate Policy Action Plan [6].

4 Conclusion

The case study presented in this paper illustrates an effective, systematic approach to implementing an EMS to visualize and promote multidisciplinary collaboration from the national level down to the community level. By leveraging the EMS platform, various stakeholders, including facility managers, engineers, and policymakers, can identify the root causes of energy inefficiencies and develop customized measures to optimize energy use. This collaborative approach helps achieve energy-saving targets through a combination of top-down guidance and bottom-up initiatives.

The study demonstrates how the EMS system serves as an interactive platform that supports both regulatory compliance at the national level and cooperative efforts among local stakeholders. This dual approach fosters collaboration among facility managers, engineers, and local politicians, enabling them to align efforts and achieve common energy-saving goals.

However, several limitations are inherent in EMS systems. Energy consumption is influenced by a range of meteorological factors beyond just outdoor temperature, such as wind, solar radiation, and cloud cover. This variability necessitates setting control limits, typically within $\pm 10\%$, to account for expected deviations. The specific control limits vary for each building, depending on factors like age, design, location, and intended usage.

Another challenge arises when adjusting EMS data for external factors like sunlight exposure, shading, outdoor lighting, and wind conditions. While specialized monitoring systems may consider these variables, the added cost, effort, and complexity can be prohibitive. This can be particularly relevant for buildings aiming to meet rigorous standards, such as energy-efficient passive houses, where even minor fluctuations can impact overall energy performance.

Moreover, not all EMS systems provide features for calculating CO_2 emissions based on different energy sources. Since energy supply types can significantly impact carbon footprints, it is crucial for EMS platforms to address both energy efficiency and CO_2 emissions reduction. This requires sophisticated software capable of integrating energy use data with emissions metrics, allowing users to develop comprehensive strategies for reducing both energy consumption and environmental impact.

In summary, the EMS system provides a valuable framework for addressing energy efficiency through a combination of top-down and bottom-up approaches. The ability to collaborate across different levels of governance and technical expertise is key to achieving sustainable energy use. Despite its limitations, the EMS system serves as a critical tool for driving energy efficiency and reducing carbon emissions in the building sector.

1 Introduction

Grand societal challenges (e.g., climate change, pollution, resource depletion) are complex and multi-dimensional problems that cannot be solved with incremental improvements but require fundamental shifts in sociotechnical systems—including the energy system. These are referred to as sustainability transitions (STs) [1]. Positive Energy Districts (PEDs) have emerged to drive STs in the energy sector. Understanding how STs take place in these complex sociotechnical systems is however a challenge. This is because we lack a thorough understanding on the dynamics and interconnections between the various components of the system [1]. STs in complex systems are hindered by the institutionalization, path dependencies, and lock-ins [2], and enabled in the relational processes between public, private, and non-profit actors [3, 4].

A service ecosystems perspective is selected in this paper to address STs in the energy sector. Focusing on the service ecosystem made of overlapping and nested

ecosystems [5] allows us to tackle the complexity of STs [6]. Service ecosystems are "self-containing, self-adjusting system of resource-integrating actors connected by shared institutional arrangements and mutual value creation through service exchange" [7, p. 161]. By emphasizing the logic of value, the business model (BM) approach allows the study of value co-creation in networked environments [8]. We use the BM as unit of analysis to capture the value creation and capture arising from multiple sources [9]. BMs play an important role in the transitions toward low-carbon energy systems, given they can either hinder or drive change in sociotechnical systems [10]. Understanding their distinct role in the transformation of energy systems is therefore fundamental [11].

EU's project initiatives and the energy and climate targets have had a significant role in the emergence of PEDs as a concept. Originally, the concept was initiated in the EU's Strategic Energy Technology Plan (SET Plan) Action 3.2 in 2018 [12], including a target for establishing 100 PEDs by 2025. Several definitions in the literature and the European research field prevail. All these concepts however highlight the role of energy-efficient districts that produce renewable energy, use energy flexibility to optimize the energy use and flows within the area, and integrate to the external energy systems. In this work, the definition from JPI Urban Europe [13] is used as a starting point, where PEDs are identified as "energy-efficient and energy-flexible urban areas or groups of connected buildings, which produce net-zero greenhouse gas emissions and actively manage an annual local or regional surplus production of renewable energy. They require integration of different systems and infrastructures and interaction between buildings, the users and the regional energy, mobility, and ICT systems, while securing the energy supply and a good life for all in line with social, economic, and environmental sustainability" [13, p. 4]. It is further added that each PED is expected to "find its own optimal balance between energy efficiency, energy flexibility and local/regional energy production on its way towards climate neutrality and energy surplus" [13, p. 8]. Overall, three types of PEDs are identified [14, 15]: (1) PED autonomous (i.e., energy self-sufficient districts within geographical boundaries); (2) PED dynamic (i.e., districts within geographical boundaries that generate renewable energy over their own demands; dynamic exchanges with the hinterland to compensate momentary balance differences), and; (3) PED virtual (i.e., those that use virtual renewable energy systems and storage outside their geographical district boundaries).

Transformations taking place at a micro level may induce broader STs at the macro level [4, 16]. Therefore, we propose a conceptual framework intended to support the transition and renewal of PED service ecosystems at micro- and meso levels and demonstrate its potential by applying it to an illustrative case study on a PED located in Espoo, Finland, that focuses on dynamic exchanges of energy with power grid (PED virtual). Espoo is the second largest city in Finland (300,000 residents) with overarching sustainability objectives to reach carbon neutrality by 2030 and reduce emissions by 80%. The Espoo PED is treated as a service ecosystem made of four overlapping and nested ecosystems, namely: (i) Energy positive buildings and district; (ii) Renewable energy production, distribution, and storage; (iii) Energy management (with Virtual Power Plant); and (iv) Electric mobility.

2 Conceptual Framework

We elaborate a conceptual framework mapping the key elements of PED business models from a service ecosystems perspective. As existing business model blueprints are less suited to examine the interdependency and transformation of actors in ecosystems [17], we conducted a literature review to build a conceptualization grounded in relationships between key concepts (Fig. 1). This framework acts as a micro- and meso-level model, describing how the different actors in PED ecosystems create, deliver, and capture value. It attempts to feature both the service offerings available in the business ecosystems, as well as the ecosystem actors and their interrelatedness. The BM framework we propose serves a dual purpose [18, 19]: it acts as (i) a *static blueprint* to describe how the different actors operate and the activities they employ to generate value in the nested ecosystems (i.e., micro level); and (ii) a *transformational tool* to address changes in energy systems (i.e., meso level). The framework has been further developed into an online tool to foster its scalability on a city level and/or other PEDs.

Our research process followed an abductive approach [20], where we combined empirical and theoretical inputs with emphasis on making interpretations and comparisons to inform both theory and practice [21]. Service design was adopted as method to enable the tackling of a grand societal challenge with systemic and long-term lenses, while supporting the co-creation of knowledge and mindset change in STs [22]. Core partners from the Espoo's PED service ecosystem were interviewed. Due to a small size of data sample ($N = 4$), the interview findings are used for illustrative purpose only. The framework was externally validated with the SPARCS research project partners (funded by EU Horizon 2020 under Grant Agreement No. 864242), including the interviewees. The practice of submitting knowledge

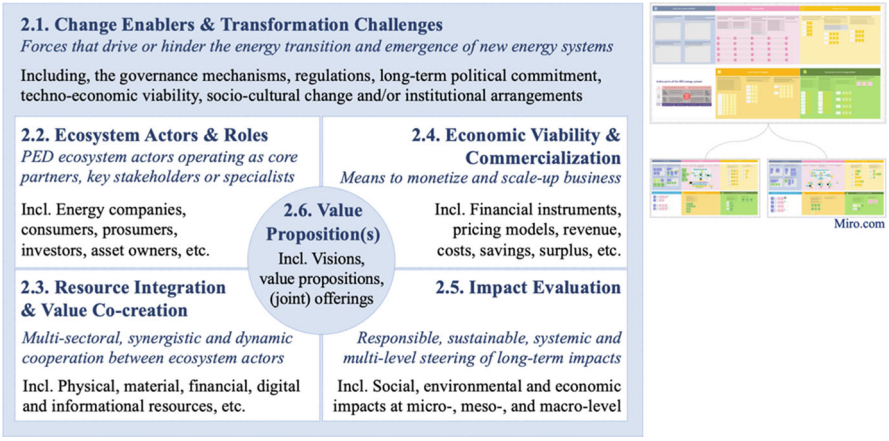

Fig. 1 Conceptual framework elements and online tool (as illustration) to assess and address changes in PED (nested) ecosystem business models

claims for discussion and falsification to members in relevant communities is referred to as communicative validation [23].

In the following sections we discuss the conceptual elements of our framework by first exploring the change enablers and transformation challenges (Sect. 2.1) supplemented with illustrative examples from our case context. Then, we identify the ecosystem actors and their roles (Sect. 2.2), and the mechanisms for resource integration and value co-creation (Sect. 2.3). Thereafter we discuss the economic viability (Sect. 2.4) of PED service ecosystems and the viewpoints for impact evaluation (Sect. 2.5). We end the chapter with discussion on value propositions (Sect. 2.6).

2.1 Change Enablers and Transformation Challenges

Energy transition is a complex challenge, which is why the enablers and challenges are widely studied in the broader context of new energy systems. Overall, they fall into four broad categories. The first category relates to the *governance mechanisms, regulations, and (geo-)political* forces, which emphasize the long-term political commitment, stable regulatory frameworks, clear vision and net-zero targets, as well as incentive mechanisms as key drivers (and challenges thereof in their absence) to enable the alignment of priorities and actor engagement in energy transitions [10, 11]. The second category discusses the *techno-economic* perspectives, for example, external financial support and funding to ensure the economic viability for new energy systems, alignment of public and private profitability and sustainability targets, adoption of emerging technologies, and the interoperability between the physical and digital infrastructures [24–26]. The third category centers around *sociocultural* aspects, with emphasis on the political and regulatory forces to foster social acceptance, skills, behaviors, confidence, and trust toward new energy systems and the energy transitions [27, 28]. The final category discusses the *institutional arrangements* [29] such as a common language, cultures, and values, cross-sectoral partnerships and evaluation targets, and interoperability of institutions and systems as either drivers or hinderers for change.

In Espoo, the regulatory and political mechanisms play a crucial role in the adoption of new solutions and infrastructure that support the city's carbon neutrality objectives. City planning guided by public regulations sets the requirements for integrated energy systems, for example, in buildings. Sanctions will follow from neglecting the directive regulations. The requirements have proliferated in the past couple of years due to increased tensions in the geopolitical environment, setting pressures to speed up the decision-making and preparation processes in organizations characterized by hierarchical and sectoral silos. In the domain of e-mobility, a great deal of effort is going into promoting sociocultural change. For example, shared mobility solutions (e.g., e-scooters) are introduced, to promote attitude shift and the penetration of e-mobility. Yet, the development of the transport system has faced great challenges due to the COVID pandemic, and the price fluctuations of

fossil fuels. Espoo has attempted to solve these issues by placing public transport nodes and mobility hubs strategically to locations that will support private companies and inhabitants to boost electrification.

2.2 Ecosystem Actors in Energy Systems

Generally, the literature classifies distinct roles that actors operating in energy systems can adopt either individually, or as combination [30, 31]. *Producers* represent the energy production companies (e.g., utility companies, district heating) and local energy producers (e.g., operators of solar/wind power plants), energy *service providers* (e.g., energy management, control, demand response, energy saving companies), and *energy distributors*. *Consumers* (e.g., households) form another category. *Prosumers* are typically discussed in the literature on energy communities as the residential (i.e., small-scale households) or large-scale actors (i.e., industrial entities) operating as energy consumers, producers, and flexibility providers. *Investors* are public organizations (e.g., government subsidies, municipalities, NGOs) and private entities (e.g., local businesses, inhabitants). *Asset owners* typically include technology providers (e.g., platform operators, ICT providers). Literature further separates actors into orchestrators and followers [10]. *Orchestrators* are key players or decision-makers that ensure the overall health of the business ecosystem and/or control activities between actors, for example, by creating incentives and setting rules for knowledge sharing and interaction [32]. *Specialists* are followers or niche-players that employ their specialized capabilities in running the system.

By drawing from these disciplines, our framework categorizes three main actor groups for PEDs, namely, core partners, key stakeholders, and specialists. *Core partners* are orchestrators that ensure the overall viability and interoperability of the PED service ecosystem. They also strengthen social acceptance and action. In Espoo, these actors are energy management system providers, network operators, and the city organization at large (i.e., the sectors of traffic management and design, urban planning, etc.). *Key stakeholders* are actors that ensure the operability and functioning of the nested ecosystems (i.e., positive energy buildings, renewable energy, e-mobility, and energy management in the Espoo context). For example, energy and district heating distributors, energy infrastructure providers, energy storage operators, energy market providers, distributed energy asset owners, and land/real-estate owners, among others. The third category is *specialists* that employ specialist capabilities periodically, for example, for the purpose of research, development, and innovation activity. Actors falling in this category in our illustration are consultants, advisors, research institutes, universities, construction, and engineering companies.

2.3 Resource Integration and Value Co-creation

Literature on energy systems generally differentiates between distinct resource types [10, 11]: (1) *physical or material* resources represent grid infrastructure, electricity supply, renewable energy (e.g., groundwater, biomass), or physical equipment (e.g., energy storage, solar panels); (2) *financial* resources are, for example, capital from financial markets, federal or municipal subsidies, loans, or investments from local residents and businesses; (4) *digital* resources, for example, data or digital networks, and; (4) *information* resources, for example, specialist knowledge on local energy potentials. These resources, then, are shared and integrated through different (often technological) means—smart meters, wireless technologies, (open) data platforms, and grid infrastructure, among others. Overall, collaboration between local inhabitants, municipalities, and private companies, as well as the ability to combine different technological solutions are seen crucial to achieve efficiency, flexibility, and profitability in PEDs [33].

The framework presented in this study emphasizes that actors in service ecosystems are dynamic resources that co-create value and co-produce the service as part of their network [34]. The connectivity between ecosystem actors in smart energy systems permits the analysis of these interdependencies, roles, network positions, and power structures that drive continuous innovation and value co-creation [24]. This connectivity also nurtures a complex interaction between the different actors that is a promoter of systemic change and innovation [2]. In specific, the fostering of knowledge, skills, and innovation is effected in iterative processes where the different ecosystem actors integrate both own and stakeholder resources (i.e., effectuation; [35]). Interactions are influenced by the institutional arrangements (e.g., norms, rules, practices, beliefs) that can either drive or hinder value co-creation [7]. In other words, from a sociotechnical transition point-of-view, transformation of complex energy systems take place through value co-creation and resource integration between actors beyond system borders.

In our illustrative case, a centralized energy management system is in place to measure and control the energy use in the PED service ecosystem. By combining the loads available for demand response (e.g., shifting the time of energy demand) from different sources, the system enables the PED service ecosystem to act as Virtual Power Plant (VPP). Integrated energy systems—including distributed renewable energy production, energy storage, and district heating and cooling—provide energy for the smart buildings and e-mobility as needed. Often, however, interoperability and optimization may cause challenges in a multi-stakeholder environment, with each public and private actor influenced by their technological readiness, beliefs about the future developments, and expectations about the impacts.

2.4 Economic Viability and Commercialization

It is emphasized that actors of new energy systems should continuously explore new business opportunities and sources of finance arising from the private and public sectors to ensure their viability in the long-term (e.g., private capital investments, public subsidies, loans, crowd funding; [25, 28]). Commercial organizations are seen to hold an important role in improving the economic viability of decentralized energy systems by creating more appealing business cases, attracting outside funding, and decreasing operating expenses [30]. The lowering of costs is a key area to increase the viability of new energy systems. Here, the discussion centers around measures that increase energy efficiency and sufficiency—for example, smart energy management, self-consumption, and reduction of peak consumption [11]. The monetization mechanisms separate between revenues from energy services (e.g., mobility, heating, electricity and/or energy management services) and revenues from external services (e.g., balancing power, energy aggregation and flexibility, data valorization, and/or market trading; [31]).

Our framework puts emphasis on the bundling of the various means in the nested ecosystems to reach full operational capacity in the long-term. It looks at the roadmap for commercialization. The PED service ecosystem in Espoo interconnects and commercializes local de-centralized and centralized energy production solutions into well-functioning VPP, offering customers energy solutions as-a-service and enabling the flexibility toward the grid. Therefore, a pool of monetization mechanisms is operational (i.e., private funding, service fees, flexibility market income) due to a strong presence of private organizations, without reliance on public funding. Along with the VPP, new operating models in the production, consumption and distribution of energy are/will be introduced, to better manage energy peaks and energy saving efforts.

2.5 Impact Evaluation

Energy transition puts emphasis not only on economic, but also societal and environmental wellbeing. PEDs aim to facilitate the energy system transformation from a holistic perspective, by approaching the socioeconomic, technical, environmental, political, and institutional aspects of change [33]. This type of perceptual change highlights the role of innovation activities in the society, and the way in which we evaluate their impacts [36]. Evaluation of innovations considers their societal value that promote long-term change in STs [37]. The goal of impact evaluation is to reduce uncertainties, improve effectiveness, and support decision- and policymaking [38], while making purposeful measures for the intended outcomes of specified interventions in defined societal contexts [39]. Multiple actors are in the core of a systemic view on innovation: value is created in interactions at multiple levels [40], and guided by the norms, values, and beliefs of the actors (i.e., institutional

arrangements; [41]). The traditional technological and financial evaluation approaches do not fully capture this multiplicity and systemic nature of innovations [42] that take place in energy transitions. For these reasons, our framework adopts a multi-dimensional approach by looking at the societal impacts in parallel with the more traditional techno-economic characteristics of innovations [37, 43], while considering the shared institutional arrangements among actors at the different levels of aggregation (micro-, meso-, and macro levels; [40]).

In Espoo, the goals and performance of the City Council and sectoral divisions are evaluated with key performance indicators (KPIs) derived from the UN's Sustainable Development Goals (SDGs). This indication system codifies the targets set to steer economic, social, and environmental sustainability performance within the energy system ecosystems. On a meso level, they steer the development efforts at the level of PED service ecosystems, and at micro level, align organizational targets to operate as part of nested ecosystems. For example, Espoo's target in electric mobility is to co-create an infrastructure for e-vehicles together with public and private organizations in partner networks. Here, the macro-level impact indicators detect changes in the share of electric and low-emission cars in total vehicle fleet and new-registrations, meso-level indicators enforce increases in municipal e-car infrastructure, and micro-level indicators increase in residents' satisfaction with road networks and transport routes. These targets and indicators, then, drive the research, development, and innovation activity of individual actors who wish to operate in the Espoo PED area.

2.6 Value Proposition(s)

The value proposition points the ways in which ecosystem actors contribute to the value creation of the customer, while also generating new resources and value for themselves [41]. The role of the value proposition in service ecosystems is to offer opportunities for co-creation and resource integration between the different social and economic actors, rather than act as the proposal for a service offering per se [44]. The relationships between ecosystem actors are founded on value propositions [45] suggesting that the design of new value propositions can improve existing offerings, create new offerings, and/or reconfigure the ecosystem [46]. Multi-actor interdependencies connect individual offerings under joint value propositions [47], while each actor holds distinct capacities to innovate the joint value proposition by adding novel offerings that serve different customer needs.

In Espoo, the overall vision is to reach carbon neutrality, reduce emissions, and generate surplus energy to the district energy systems, by using renewable energy sources (e.g., solar power, geothermal wells), appliances (e.g., sensors, smart meters), and by controlling the electric loads (e.g., lighting, HVAC, and elevators). The value propositions of ecosystem actors center around increasing energy efficiency, flexibility, and self-sufficiency through distributed renewable energy production, while reducing the overall energy consumption, and lowering the carbon

footprint. For example, the value proposition for the VPP is the provision of affordable, sustainable, and reliable energy, while managing energy peaks and energy saving efforts by having local energy production solutions under one management system. The vision for e-mobility is to develop an e-mobility hub for large-scale EV charging systems and multiple EV types. The value proposition, then, is a cost-efficient and convenient solution that serves everyone with an e-vehicle. The joint value proposition for all nested ecosystems is however, ultimately, a good customer experience. PEDs are created for *people*. At its core is a pleasant experience of a place where people (and businesses thereof) which to reside and recreate.

3 Discussion

There are fundamental changes in how energy systems will be operated in the future to enable energy transitions and the development of PEDs. Municipalities and local authorities hold a strategic role in the transition toward renewable energy and local energy systems [30]. Transformations are taking place across siloed organizations and beyond traditional organizational boundaries [48]. BMs hold a vital—although complex—role in the ST of sociotechnical systems. Successful transition in the complex energy systems compels alignment in the different BMs, and co-evolvement of ecosystem actors in new partnerships and resource reconfigurations [10]. For example, tailor-made energy systems and individual system elements must be incorporated to function at the local levels. Transformation at the system level is difficult, requiring abilities to depict the path-dependencies and lock-ins in the present sociotechnical systems [2]. Dealings with such complex transitions necessitate increased flexibility, interconnectivity, cooperation, and decentralized governance mechanisms [42].

Our main theoretical contribution is to apply systems thinking that is fundamentally multidisciplinary [40] to the energy sector, by combining the theories on innovation and sustainability transitions. This allows us to examine the synergies between the two fields. By doing so, we acknowledge that the energy markets are shaped via activities of different actors and formed in systemic processes [2]. We apply the BM as a transformational tool to address change [18, 19] in service ecosystems around PEDs. Accordingly, we depict the managerial opportunities to influence value co-creation [8] and drive STs in PED service ecosystems. Taking this perspective is important, as business model innovation (BMI) is highlighted to contribute toward a complex change process in energy transitions [26]. They not only challenge the prevailing institutional arrangements and industry structures [49], but also the interactions between the public and private actors in PED ecosystems. A networked approach in energy transitions depicts the interconnectedness of the different actors in value co-creation. Therefore, our framework adopts a multi-dimensional approach [43] and analyses the interaction in PED service ecosystems at different levels of aggregation (micro- and meso levels; [40]). By doing so, we aim to make visible how the value in PED service ecosystems is co-created in complex long-term processes.

4 Conclusions and Future Research Avenues

Effective business in PEDs requires seamless cooperation between different private and public actors. We find this interoperability and optimization to be challenging in a multi-stakeholder environment, with each public and private actor influenced by their technological readiness, beliefs, and expectations. PEDs however offer a mean to combine the core elements in energy transitions. They enhance energy efficiency, minimize the energy demand, maximize the energy production locally from renewable energy sources, and balance the demand and production through energy flexibility. These core elements together necessitate the adoption of a holistic view to the provision of sustainable energy when needed. Interoperability of both energy and ICT systems is central. Implementing such complex systems requires understanding of the bigger picture and looking beyond individual business models of specific organizations.

The goal of this paper is to concretize what makes sustainable energy systems commercially successful and offer a comprehensive tool for private and public organizations—including cities—to assess and drive transformation in PED service ecosystems. A framework is created to assess the PED service ecosystem business models: (i) transformation enablers and challenges; (ii) roles of focal actors operating in PEDs; (iii) opportunities for value co-creation and resources integration; (iv) elements of viable business; (v) long-term impacts that unfold; and (vi) value propositions that increase the actors' innovation capacity. We apply a transformational approach and value-based view to the BM framework [19] in the context of STs. BMs are seen to hold a fundamental role in the transition toward low-carbon energy systems [10, 11], but existing BM blueprints are less suited to examine the interdependency and transformation of actors in ecosystems [17]. Therefore, we have built a conceptualization based on key concepts drawn from literature, to allow the analysis of (sub-)ecosystems in energy transitions. As managerial implications, the framework helps public and private organizations to evaluate how to get involved in PED service ecosystems, or alternatively, expand their ongoing operations within PEDs. The framework can also be used as a tool to scale solutions on a city level or to other PEDs. We hope that the framework will be tested and applied in other PEDs and cities to strengthen the construct validity and generalizability of the results.

Acknowledgment The research was funded by the European Union's Horizon 2020 research and innovation program LC-SC3-SCC-1-2018-2019-2020-Smart Cities and Communities under the project name SPARCS, grant number 864242. The funding body was not involved in preparing the manuscript, methods, and results.

1 Introduction

Railway transport is an efficient and one of the greenest means of transportation of passengers and goods in large quantities over long distances. This mode of travel is reliable, punctual, convenient, cost-effective and sustainable, and thus has remained popular among different travel options. For places where the land is separated by wide and deep water bodies, however, the railway connections become challenging. Under such circumstances, railway lines usually have to be terminated on both sides of the water body with ferry connections. This often leads to a longer commuting time and the societal demand for more efficient ways of transportation.

Over wide and deep water bodies such as fjords and sea channels, the construction of conventional bridges can be very challenging and even inappropriate owing to the complex environmental and seabed conditions. A submerged floating tunnel (SFT), on the other hand, may prove to be an appealing option for the connection of railway lines across water bodies owing to its numerical advantages over other types

M. Kioumarsi, B. Shafei (eds.), *The 1st International Conference on Net-Zero Built Environment*, Lecture Notes in Civil Engineering 237,
https://doi.org/10.1007/978-3-031-69626-8_98

of fjord- and sea-crossing options. For instance, SFTs make use of the natural buoyancy to support their weight and imposed loads in the gravitational direction, which eliminates the need for conventional pile supports and thus can cope with complex seabed conditions. Besides, they are submerged at a distance below the water surface where most of the wave energy is concentrated. Therefore, they are subjected to substantially reduced wave loads and no wind loads as compared to their surface bridge counterparts. Besides, such structures are virtually immune to climate changes and thus the water surface elevation due to global warming. The submergence also provides navigation clearance for areas with vessels passing through. Furthermore, as they do not protrude above the water surface, their visual impact on the surrounding environment is minimized. For these reasons, SFTs are perceived as novel engineering structures contributing to a net-zero society and are becoming a hot topic among researchers and engineers for the consideration of fjord- and sea-crossing solutions.

The design concept of SFTs can date back to the early twentieth century [1]. Even though no SFTs have been constructed in reality, numerous feasibility studies and research works have been conducted for various locations in the world. As SFTs are often designed to have a much longer length as compared to their cross-sectional dimensions, they are commonly considered as slender systems interacting with the fluid where the semi-empirical Morison equation is applicable to account for the hydrodynamic loads induced by the waves and current on the SFT structure [2–4]. Alternatively, the hydrodynamic actions can also be evaluated by employing the diffraction theory [5, 6]. A comparative study revealed that both approaches are able to give accurate hydrodynamic calculations under normal conditions [7].

Besides the environmental loads, the main function of SFTs is to serve as a transportation infrastructure to provide safe and comfortable passage of vehicles across water bodies. When they are designed for railway line extensions, the performance of SFT-train systems is studied by various researchers using different models. In a computational analysis, the SFT is typically modeled as Euler–Bernoulli beam segments resting on a Winkler-type foundation representing the hydrostatic stiffness. The train loads are modeled as either moving loads [8, 9] or moving sprung mass systems that account for the inertia effect of the vehicle [10, 11]. To represent more realistic scenarios, the inclusion of the railway track systems leads to a coupled vehicle-track-SFT system [12].

While a coupled SFT-train system considers the interaction between the traversing train and the sustaining SFT structure, such a complex model often hinders its applications in engineering design practice. The development of a simplified, decoupled approach is thus highly desirable. This is possible in view of the fact that the train mass is much lower than that of the SFT and that the effect of a moving train on the dynamic responses of the sustaining SFT is expected to be limited [12].

In this paper, an uncoupled approach is proposed and put forward to investigate the performance of a train travelling inside an SFT under various wave conditions. The SFT is modeled as Euler–Bernoulli beam elements subjected to wave loads modeled according to Morison's equation. The dynamic displacement of the SFT is

then used as input to a train model to study the dynamic responses of the vehicle. Parametric studies are carried out to examine the effect of different wave conditions and train speeds on the vertical motions of the train.

2 Methodology

2.1 Problem Definition

Consider an SFT segment with a length of 700 m and an external diameter of 23 m, as shown in Fig. 1. Both ends of the segment are restrained by strong fixtures/towers which makes it reasonable to assume fixed boundary conditions. The SFT segment is also vertically restrained by mooring tethers equally spaced apart. The water depth is 100 m and the tunnel centerline is submerged 61.5 m below the water free surface. In view that the vertical motion of a train travelling inside an SFT is usually dominating, this study considers the vertical responses of the SFT and the train only. Table 1 lists the key parameters of the SFT. Note that these parameters are taken from the study reported in [13].

2.2 SFT Model

In this study, the SFT is modeled according to the Euler–Bernoulli beam theory, which is justifiable in view of its slenderness. The finite element method is employed by discretizing the SFT segment into a number of beam elements. The mooring

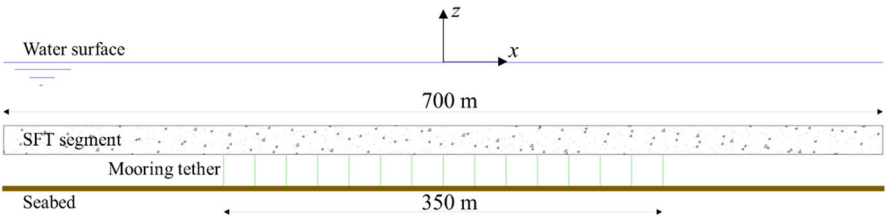

Fig. 1 Illustration of SFT segment

Table 1 Parameters of SFT

Parameter	Value
Young's modulus E	30 GPa
Sectional area A	142 m^2
Second moment of area I	7800 m^4
Mass per unit length m	3.7×10^5 kg/m
Tether stiffness	1.17×10^5 N/m

tethers are modeled as linear vertical springs. According to Newton's second law of motion, the governing equation of the SFT can be written as

$$\mathbf{M}_S\ddot{\mathbf{U}}_S + \mathbf{C}_S\dot{\mathbf{U}}_S + \mathbf{K}_S\mathbf{U}_S = \mathbf{F}_S \tag{1}$$

where $\mathbf{M}_S$, $\mathbf{C}_S$, and $\mathbf{K}_S$ are the structural mass, damping and stiffness matrices of the SFT, respectively. $\ddot{\mathbf{U}}_S$, $\dot{\mathbf{U}}_S$, and $\mathbf{U}_S$ are the acceleration, velocity and displacement vectors of the SFT, respectively. $\mathbf{F}_S$ is the external force vector including the wave loads and the train loads.

According to Morison's equation, the wave load per unit length, f_W, exerted on the SFT can be written as [14]

$$f_W = \frac{1}{4}\pi D^2\rho_w\dot{u}(t) + \frac{1}{4}C_a\pi D^2\rho_w\left(\dot{u}(t) - \frac{\partial^2 w(x,t)}{\partial t^2}\right) + \frac{1}{2}C_d\rho_w D\left|u(t) - \frac{\partial w(x,t)}{\partial t}\right|\left(u(t) - \frac{\partial w(x,t)}{\partial t}\right) \tag{2}$$

where u and w denote the fluid velocity and the displacement of the SFT in the vertical direction, respectively. C_a and C_d are the added mass and drag coefficients, respectively. D is the diameter of the SFT. ρ_w refers to the seawater density.

2.3 Train Model

A quarter train model based on the multi-body system, as shown in Fig. 2, is employed to investigate the performance of the train travel inside the SFT. A quarter of the car body, half of a bogie and one wheelset are modeled as rigid bodies interconnected via spring-dashpot units representing the system systems. Again, according to Newton's second law of motion, the governing equation of the train model can be written as

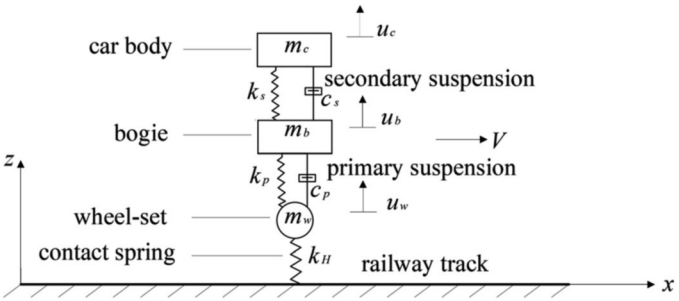

Fig. 2 Quarter train model

$$\mathbf{M}_T\ddot{\mathbf{U}}_T + \mathbf{C}_T\dot{\mathbf{U}}_T + \mathbf{K}_T\mathbf{U}_T = \mathbf{F}_T \tag{3}$$

where $\mathbf{M}_T$, $\mathbf{C}_T$, and $\mathbf{K}_T$ are the mass, damping and stiffness matrices of the train, respectively. $\ddot{\mathbf{U}}_T$, $\dot{\mathbf{U}}_T$, and $\mathbf{U}_T$ are the acceleration, velocity and displacement vectors of the train, respectively. $\mathbf{F}_T$ is the external force vector.

Table 2 lists the parameters of the train model [12].

2.4 Wave Model

Short-term beam sea conditions are considered in this study. The waves are assumed to be long-crested and can be described by the JONSWAP spectrum as

$$S_\zeta(\omega) = \frac{5}{16}A_\gamma H_s^2 \frac{\omega_p^4}{\omega^5} e^{-\frac{5}{4}\left(\frac{\omega}{\omega_p}\right)^{-4}} \gamma^{e^{-\frac{1}{2}\left(\frac{\omega-\omega_p}{\sigma\omega_p}\right)^2}} \tag{4}$$

where $A_\gamma = 1 - 0.287\ln(\gamma)$, H_s is the significant wave height, ω_p is the peak angular frequency which equals $2\pi/T_p$, T_p is the peak period, γ is the non-dimensional peak shape parameter, and σ is the spectrum width parameter which equals 0.07 for $\omega \leq \omega_p$ and 0.09 for $\omega > \omega_p$.

Three sea states corresponding to the design operational, rough and extreme conditions are considered. Table 3 lists the characteristic values of the three wave conditions.

Table 2 Parameters of quarter train model

Parameter	Value
Mass of car body m_c	10965.6 kg
Mass of bogie m_b	1200 kg
Mass of wheelset m_w	1850 kg
Primary suspension stiffness coefficient k_p	1.26×10^6 N/m
Primary suspension damping coefficient c_p	4×10^4 Ns/m
Secondary suspension stiffness coefficient k_s	1.41×10^5 N/m
Secondary suspension damping coefficient c_s	1.3×10^4 Ns/m

Table 3 Wave conditions

Wave condition	Significant wave height (m)	Peak period (s)
Design operational	3	5
Rough	5	10
Extreme	9	12

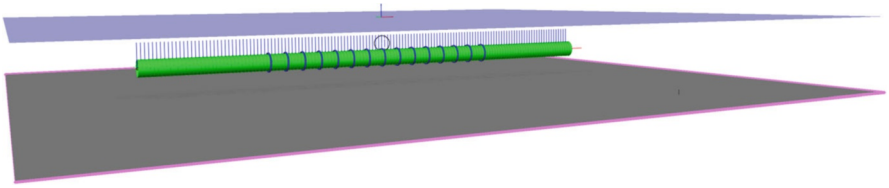

Fig. 3 SFT model

According to the Airy wave theory, the vertical fluid particle velocity associated with a harmonic wave component can be written as

$$u = \sigma a \frac{\sinh k(z+h)}{\sinh kh} \sin(\omega t + \varphi) \tag{5}$$

where $a = H/2$ represents the wave amplitude, $\omega = 2\pi/T$ is the incident wave angular frequency, and k is the wave number. h is the water depth.

2.5 Numerical Procedure

The SFT segment is constructed by using SIMA/RIFLEX [15], as shown in Fig. 3. It is discretized into 140 elements of equal length of 5 m. Rayleigh damping is employed for the structural damping with a ratio of 0.8% [16]. For each of the three wave conditions defined in Sect. 2.4, six independent one-hour wave realizations are used to reduce the statistical uncertainties. In the numerical analysis, the Newmark constant acceleration scheme is employed for the time marching integration. The analysis results of the SFT segment are then processed to remove the initial transient responses before they are used as input to the train model for the vehicle dynamic analysis.

3 Results and Discussion

3.1 Modal Analysis

Figure 4 shows the first three dry modes of the SFT segment. Note that the hydrostatic stiffness is considered in the eigenvalue analysis. However, the hydrodynamic mass is not taken into account. The natural periods of the first three modes are 8, 7.87, and 2.91 s, respectively.

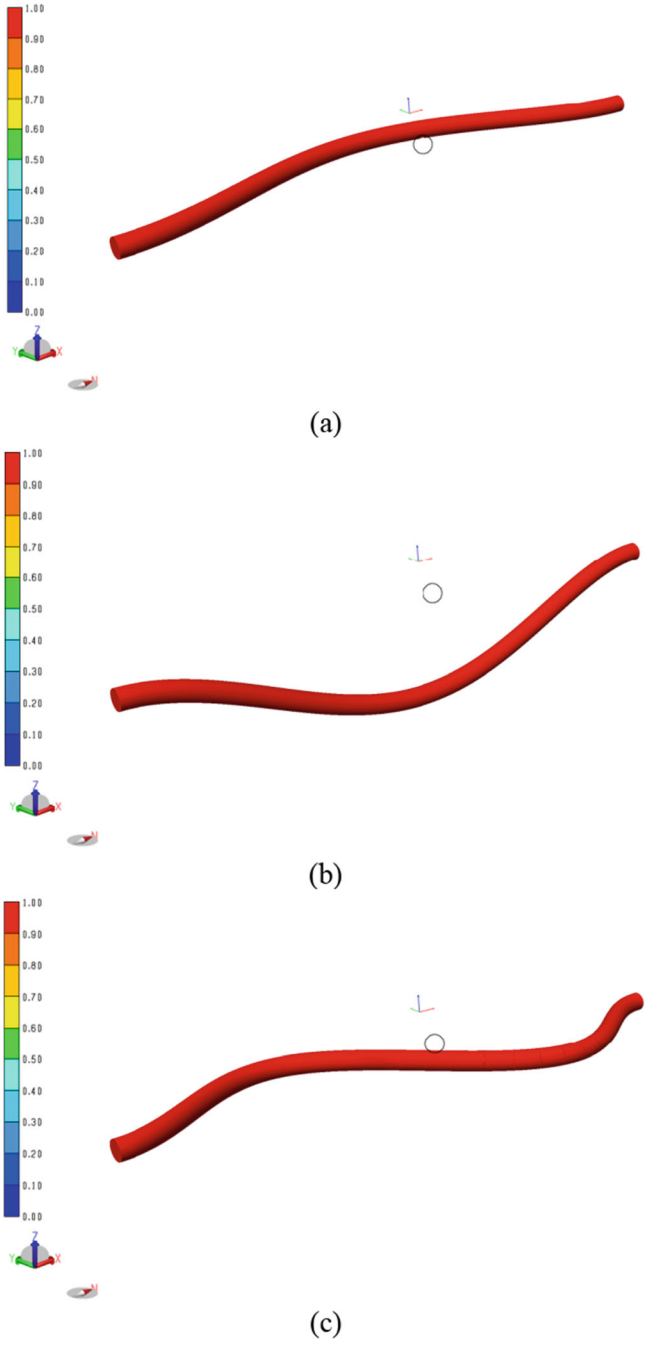

Fig. 4 Mode shapes of SFT segment: (**a**) first mode of 8 s, (**b**) second mode of 7.87 s, and (**c**) third mode of 2.91 s

3.2 SFT Responses

The structural performance of the SFT under different wave conditions is next examined. Figure 5 shows the vertical motion response statistics of the SFT segment at mid-span. Note that the statistical values are obtained by taking the average values of those from each of the six random simulations as explained earlier in Sect. 2.5. As can be seen, the SFT is almost stationary under the design operational wave condition with a maximum vertical displacement below 6 cm at its mid-span. When the wave condition becomes harsher, the vertical motions of the SFT increase substantially. For all the wave conditions considered in this study, the standard deviations of the vertical mid-span displacement, which correspond to the dynamic response components, are below 0.5 m. This can be considered as reasonably low in view of the fact that the SFT segment is 700 m long, and it is expected to vibrate slowly with a fundamental period of around 8 s.

Figure 6 shows the statistical results of the bending moment M_y of the SFT segment at its mid-span. Notably, the contribution due to the performance loads arising from the self-weight, buoyancy, and static component of the mooring tensions has a dominating role in the vertical bending moment. The wave-induced moments are found to be negligible under the design operational wave condition. For rough and extreme wave conditions, the standard deviations of M_y reach 26% and 37% of the magnitude of the mean value, respectively, showcasing a significant increase in the effect of the wave action on the SFT bending moment.

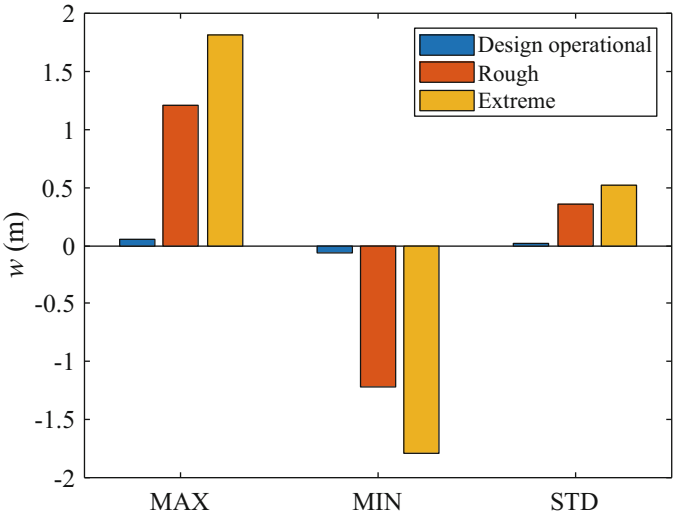

Fig. 5 Vertical displacement of SFT at mid-span

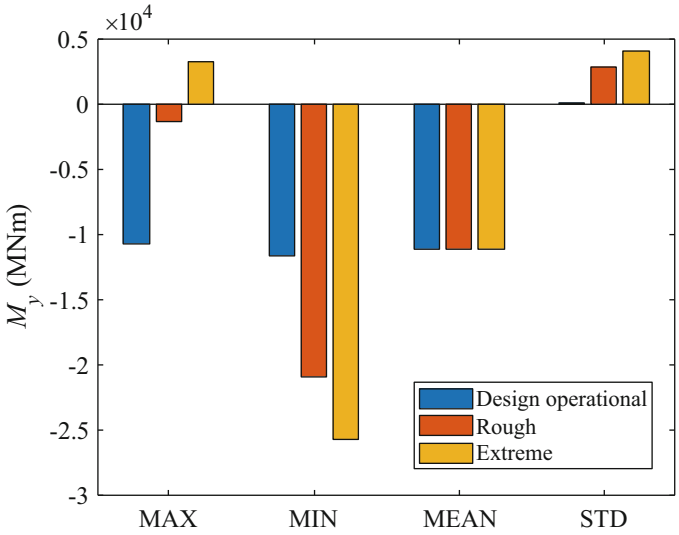

Fig. 6 Bending moment of SFT at mid-span

3.3 Train Responses

The vertical displacement of the SFT segment is next used as input in the form of a vibrating foundation to examine the train responses. In this study, the initial transient responses of the SFT are discarded. In the analysis of the train model presented in Sect. 2.3, the train is assumed to start with an unloaded condition. An initial duration of 10 s is taken into account for the train to settle to its equilibrium state before it enters the SFT segment. Again, these initial train responses are discarded in the post-processing of the results. The railway track is assumed to be perfectly smooth without any track irregularities.

Figure 7 shows the maximum vertical acceleration of the car body under different wave conditions and train speeds. Note that these accelerations are the maximum values out of the six independent random simulations. As can be seen, the vertical accelerations of the car body are rather low under the design operational condition. The train speed also has a small effect on the maximum acceleration. This indicates that train travel is generally comfortable when the track is in new or good conditions. As the wave condition becomes rough, the maximum accelerations of the car body increase significantly. Higher train speeds are also found to augment the car body accelerations. Notably, with a speed of 300 km/h, the maximum car body acceleration is close to the safe limit of 0.6 m/s^2. As only a limited number of random simulations were carried out, this limit may be exceeded in reality, therefore posing an alarming concern on train operations with high speeds under rough wave conditions. Under the extreme wave condition, the maximum car body accelerations exceed the safe limit for all train speeds considered in the study, thereby implying that the SFT segment should be closed to traffic under such harsh sea conditions.

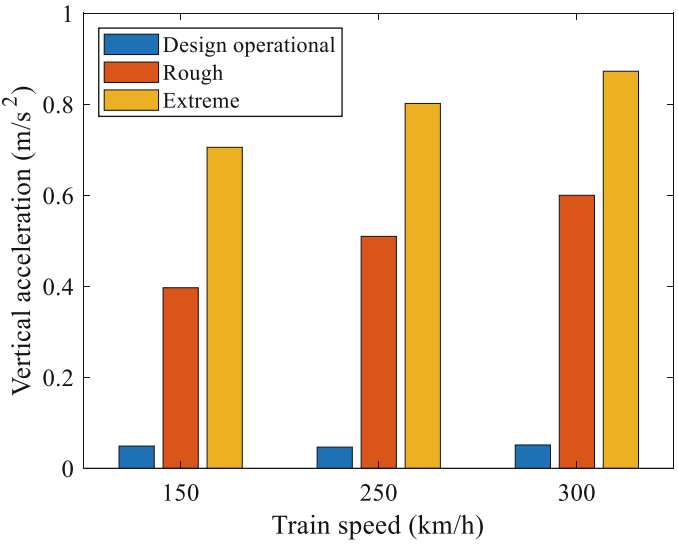

Fig. 7 Vertical acceleration of car body inside SFT

4 Conclusions

This paper is concerned with the evaluation of train travel performance inside a submerged floating tunnel (SFT) subjected to wave excitations. An SFT segment is modeled by using Euler–Bernoulli beam elements with mooring tethers represented by using linear springs. A quarter train model based on the multi-body system is employed to represent the train travelling inside the SFT. In the numerical analysis, the SFT subjected to different wave conditions is first analyzed. The vertical displacements of the SFT are then used as input in the form of a vibration foundation to the train model to examine the vertical vibrations of the train. The analysis results show that trains can travel across the SFT segment safely at a high speed under the normal design operational wave conditions. When the sea state becomes rough, the vertical train accelerations are approaching 0.6 m/s^2. Thus, reducing the train speed may be necessary in order to maintain safe travel. Under extreme or storm conditions, the SFT should be closed to train operations.

1 Introduction

In today's world, urban and global challenges are increasingly being recognized as wicked problems, characterized by their complexity, interconnectivity, and urgency. The need to address these challenges has become more pressing than ever, requiring innovative approaches and collaborative efforts across various levels and sectors. The Sustainable Development Goals (SDGs) call for action by all countries, poor, rich and middle-income, to promote prosperity while protecting the planet earth and its life support system [1]. Europe is striving to become a global leader in energy

transition and carbon footprint reduction, aligning with sustainable development goals. The European Union introduced the concept of Positive Energy Districts (PEDs) to maximize the utilization of local and renewable energy sources while positively contributing to the optimization and security of the broader electricity grid.

Many emerging studies have recognized that the main challenge of implementing PED pertains to suboptimal governance systems and silo thinking [2, 3]. Silo thinking and acting between different levels and sectors, territorial gaps between governments, and lack of interdisciplinary collaboration are among the major obstacles hindering successful outcomes for energy transition [4, 5]. Effective governance networks can be understood as enabling stakeholders to collaboratively address challenges and set priorities, ensuring commitment and ownership of planning outcomes. To achieve successful collaborative governance, a holistic systemic change and paradigm shift are necessary, along with training and education on how collaboration and knowledge exchange across levels and sectors should function [6, 7]. Breaking silo thinking and acting requires exploring governance systems empirically to understand the pitfalls, barriers, challenges, as well as the factors contributing to success and failure of collaborative governance processes [8]. This exploratory chapter aims to delve into the governance structures and functions in the deployment of a PED project.

2 Governance Processes of PED Projects

Moving beyond the building level to the neighborhood scale in PED projects not only enables the implementation and assessment of solutions such as renewable energy sources and decentralized energy production but also necessitates interaction with multiple stakeholders from different sectors [9]. Governance has stood out as crucial for achieving successful PED projects [10]. Above all, effective governance networks enable stakeholders to collaboratively address challenges and set priorities, ensuring commitment and ownership of planning outcomes. According to Potts et al. [11], there is a paucity of practical frameworks for conceptualizing the governance processes and planning processes are often perceived as idealistic, simplistic, and linear models of decision-making, in which issues of representation and the plurality of public interests are overlooked or untouched [11]. This section distills the conceptual framework that can be used to investigate the governance structures and functions in the empirical setting of a PED project.

2.1 Shift to Collaborative Network Governance

In recent years, there has been a change in how governments organize themselves to solve societal problems. Instead of using top-down approaches where the government directs actions and policies, there's a shift toward networked forms of

governance [3, 12]. Unlike traditional hierarchical structures, where one entity has authority over others, network governance relies on collaboration and coordination among various organizations, as they bring together different stakeholders to address common issues. Network governance is about building sustainable relationships between these actors, who come together to solve specific problems or provide services. Thus, network governance is assumed to be better capable of handling complex societal, poorly structured (and even "wicked") problems [13, 14] than more traditional forms of governing that assume hierarchical relationships [15, 16].

In collaborative network governance, actors collectively determine the organization's structure, coordination methods, goals, and strategies to achieve them. To ensure the smooth functionality of such collaborative network, fostering win-win situations, managing actors and resources, reducing interaction costs, ensuring commitment and compliance, coordinating politically and administratively, and maintaining quality and openness of interaction are important factors [17]. This is imaginably an uphill task and actors face barriers such as conflicting political priorities, community complaints, environmental regulations, alterations in funding schemes and participant grievances [18].

To date, few studies have considered the cumulative impact of governance structure and function and their interactions in real-world, multilayered, and complex systems. Many planning theories emphasize the interrelations of structures but overlook the significant influence of functions within the system. In the existing theories, planning theories generally shape the understanding of the governance issue, primarily focusing on its structural components, while decision-making theories offer practical tools for assessing and analyzing the functional aspects of governance processes. Since our research examines the interconnection between governance structure and process, we draw on the "structural-functionalism theory" in the planning context (Potts et al. [11]) to investigate how dynamic, multilayered, and complex governance structures and processes have led to different outcomes (of planning and decision-making) over time.

2.2 Structural-Functionalism Model in Planning

The structural-functionalism model uses the rational planning approach to discuss and analyze the underlying complexities and uncertainties, in which visioning and objective-setting, strategy development, implementation and monitoring/evaluation are the recognizable stages of strategic planning. According to Potts et al. [11], structures are organized or institutionalized in a specific manner and consist of many interrelated, interdependent, but also autonomous, individuals, existing at different levels of society: national, regional and local. They can include government agencies, industry groups, nongovernment organizations, community groups and individuals. Structures run processes and are involved in different planning or policy cycles, such as goal setting, strategy development, implementation and evaluation, and produce different outputs (e.g., formal documents such as legislation, policies, strategies, plans, reports) to guide actions for the achievement of desired outcomes.

The functional dimension of the structural-functionalism approach connects the actors in a system but also represents the relationships between them. The functional components tend to be more dynamic and less robust than structures. Three cornerstone functional components can be used to investigate "governance processes," namely knowledge use, connectivity and capacity. Knowledge use indicates the importance of applying, coordinating and integrating relevant social, economic, environmental, traditional and historical knowledge, rather than one set of knowledge or one method, to solve complex problems and enable better functioning governance systems. Connectivity implies a collaborative approach of stakeholders' engagement and participation, which can develop consensus and build stronger community and institutional networks. Capacity (human, social, financial and physical) refers to the power or capability of institutions to achieve outcomes, depending on the amount and types of capital/resources that they have accrued or access.

In the structural-functionalism model, the levels of capacity, connectivity and knowledge are unequal among different actors. There are therefore different magnitude of the capacity, varying strength of connectivity, and different knowledge disciplines, both explicit and tacit, to be considered.

Structural-functionalism provides a logical, systematic and evidence-based approach to the analysis of strategic planning systems that is complementary to existing theories of planning. It recognizes the inherent complexity and iterative nature of planning systems and allows analysts to consider a plethora of interactions and other factors influencing planning processes and outcomes across scales. While structures exhibit more stability and change at a slower pace, functions are in a constant state of flux and evolution. It is essential to recognize that structures and functions influence each other reciprocally, and any study or analysis should view them not in isolation but in their interconnectedness and interaction.

2.3 Research Question

This chapter therefore poses the following research questions: What are the structural components of governance in the multiactor environment in the development of a sustainable plus energy neighborhood? How do the functional components of its governance system operate in terms of the interaction among actors for exchanging knowledge and resources, utilizing their capacity as well as building connectivity to achieve defined goals?

3 Research Design and Methodology

This section explains why the single case study design is used and outlines the data collection methods before presenting the GNICE SPEN as the empirical setting for investigating governance structures and functions.

3.1 Why Single Case Study

The research design concerns a single case study. It aims to develop in-depth descriptive-analytical perspectives toward the governance system in planning and decision-making processes of the GNICE SPEN in Salzburg. Yin [19] (p. 18) believes that the case study has a distinct advantage when a "how" or "why" question is being asked about a set of events within its real-life context, especially when the boundaries between phenomenon and context are not clearly evident [19]. When there is no pressure on the researcher to impose controls or to change circumstances [20], the best research strategy is the case study that provides the opportunity to obtain an in-depth investigation of a given phenomenon, within its context, by the strategic selection of a case [21]. Since the governance concept focuses on interconnected and interrelated structures and processes, sufficient details are required to unravel the complexities of a given situation. Thus, the case study of GNICE SPEN is specifically and strategically selected for this study, out of the many PED cases that are familiar to the authors.

This research adopts intrinsic case study [22], in which a particular case is explored to describe and analyze the background, development of the idea, interaction of governance components, and internal-external influences in the planning and decision-making processes over time. Our single case will determine whether propositions of governance in structural-functionalism theory are confirmed, challenged, or need to be extended. This single case can represent a significant contribution to knowledge and theory building and can help to refocus future investigations in the entire field.

The justification for selecting this specific case is rooted in our ongoing research and collaboration, aimed at identifying enabling and success factors across various PED cases. Through this collaborative effort, we have observed and interviewed numerous cases, leading us to recognize that the GNICE SPEN stands out for its successful governance practices and outcomes. Consequently, our aim is to delve deeper into this case to explore its success factors, glean valuable insights and clarify its deeper causes and its consequences.

3.2 Data Collection

To comprehensively understand the dynamics of governance networks, given the fluidity of actors, roles, and interactions across multiple projects and contexts, research has called for empirical consideration of contingent factors influencing governance relationships [23]. For the last 5 years, the authors have been actively engaged in governance and stakeholder analyses of neighborhood-scale projects across various contexts, including smart city, energy transition, and PEDs. Their ongoing collaboration and involvement in relevant projects and networks have kept them abreast of the latest governance theories and studies, aligning their research

interests with their practical experiences. The first author's role as work package leader responsible for innovation management, exploitation and market uptake of the H2020 Innovation Action project syn.ikia project has fostered close collaboration and ongoing dialogue (since 2021) with the stakeholders involved in GNICE SPEN. The first step toward network governance is to systematically identify the key actors in the different phases of PED development [24]. Data collection has relied on site visits, in-person discussions, bilateral digital meetings and email correspondence to better understand its governance practices and outcomes. In addition to extensive desk research (project deliverables), document analysis (quality agreement document for GNICE) and literature reviews, the narrative, semistructured interviews with the project responsible of GNICE SPEN in 2022 was conducted and facilitated by the second author. Emphasizing participatory research and observation methods, the authors leveraged their collective expertise and experiences from various projects and initiatives to jointly analyze and comprehend the governance dynamics in the advancement of GNICE SPEN in Salzburg.

3.3 Sustainable Plus Energy Neighborhoods (SPENs)

Many PED projects are being implemented to deliver proofs-of-concept to demonstrate that decarbonization in the built environment is not only possible but that it also has the potential to generate value. One pathway focuses on planning and designing multistory apartment homes on a neighborhood scale than the business-as-usual conventional way of building, embarking on a novel concept called Sustainable Plus Energy Neighborhoods (SPENs), via four real-life demonstration cases in four climatic zones (Spain, Austria, Netherlands and Norway). SPENs are envisioned to be groups of interconnected multistory apartment homes that are highly energy efficient and fitted with renewable energy sources that have the potential to generate a surplus of energy [25].

3.4 GNICE SPEN in Salzburg

GNICE is a new residential development in Salzburg to be developed into a Sustainable Plus Energy Neighborhood. It is a greenfield development located on the city's outskirts in a quiet area with primarily multifamily houses. The 17 buildings on the plot consist of mostly multiresidential dwellings (251 apartments), from which half will be social housing units, and the other half will be sold at a certain fixed price. Passive design includes well insulated and airtight envelope and high-performance glazing. Active systems include heat pumps for space heating and DWH, and efficient mechanical ventilation with heat recovery. PV panels are placed on the roof and on some façade sections. Innovations include smart house technology, user engagement processes, central heat pump system based on ground and

wastewater sources, photovoltaics, energy peak shaving, green roofs, and consideration of climate change adaptation. The neighborhood will have a kindergarten, a doctor, and a base zone (for low threshold neighborhood work) managed by the social aid and service organization, Caritas, and will also include a Silberstreif (for those aged 55 and older) residential group.

4 Governance Processes for the Development of GNICE SPEN

This section presents highlights of the structures and functions that enabled the governance of the multiactor environment in the development of a SPEN.

4.1 Structural Components

Governance structures shape a framework that determines how different actors relate to each other within a network and what outcomes are expected. It includes policies, rules, procedures, and organizational frameworks. By identifying the governance structure in GNICE SPEN, the goal is to identify which structural components will help to establish order, accountability, and efficiency within the project's organizations that defines roles, responsibilities, and decision-making processes. We identified five structural components to understand the governance structure for the development of GNICE SPEN: Smart Cities Network Austria, the competence center for sustainable neighborhoods, Klimaaktiv, Local Multiactor Framework and the Quality Agreement, an informal voluntary instrument.

The Positive Energy District (PED) is increasingly recognized as a vital component in the journey toward achieving climate neutrality and fostering smart cities. Derived from the principles of smart city initiatives, the PED concept serves as a complementary approach aimed at optimizing energy efficiency and sustainability within urban environments. The Austrian Smart Cities Network plays a pivotal role in advancing Austria's urban development strategies toward sustainable and resilient cities. This network consists of pioneering cities committed to the implementation of smart city concepts and proactive climate change adaptation. Among these cities, Salzburg, alongside six others, stands as a prominent member of the Smart Cities Network Austria. Supported by the Federal Ministry for Climate Action, Environment, Energy, Mobility, Innovation, and Technology (BMK) and the Climate and Energy Fund, these initiatives have empowered municipalities to prioritize urban quality of life, innovative technologies, and integrated urban planning. With a holistic vision for decarbonizing existing systems, the Smart Cities Network recognizes the importance of strategic collaboration among diverse stakeholders, including funding agencies, local authorities, decision-makers, and energy suppliers. At its

core, the Smart Cities Network operates as a dynamic partnership between the BMK, cities, and the coordination office, serving as a catalyst for impactful urban transformation and innovation in Austria.

Another key structural component that operates at different levels of the governance system in Austria needs to be emphasized: The Salzburg Institute for Regional Planning and Housing or Salzburger Institut für Raumordnung und Wohnen (SIR). SIR is a competence center for sustainable neighborhoods in the Austrian National network. It is located locally in Salzburg but operates nationally and acts as an intermediary between multiple governance sectors, including the EU, national, and local levels. Through coordinated efforts facilitated by the SIR, the network fosters interdisciplinary collaborations and multilevel governance approaches.

Another significant structural component in the Salzburg case study that operates within multilevel governance systems and warrants recognition is Klimaaktiv. Serving as an initiator of climate-friendly technologies and practices in Austria, Klimaaktiv plays a pivotal role in promoting sustainability and addressing climate change challenges. Established in 2004, Klimaaktiv, under the management of the Austrian Energy Agency, has been instrumental in promoting climate-friendly initiatives in various sectors such as building and renovation, energy conservation, renewable energies, and mobility [26]. Acting as a catalyst for change, Klimaaktiv bridges the gaps between politics, business, and society through its modern governance approach. By providing advice, information, and qualification initiatives, along with transparent standards and quality assurance measures, Klimaaktiv actively engages and integrates relevant stakeholders in its efforts. Understanding Klimaaktiv as a structural component in the Salzburg case study is essential for comprehending the transformative impact it has had on the region's approach to climate protection and sustainability.

As the GNICE SPEN is not only a construction project but also an energy concept, a diversity of actors are involved. As the project progresses, a local multiactor framework was gradually identified as those most relevant for the activities backed by shared goals that may or may not derive from legal or formally prescribed responsibilities [27–30]. GNICE SPEN is being implemented by the social housing provider and project developer, Heimat Österreich. It works through and together with a Steering Committee, which is led by the City of Salzburg. This Steering committee makes the final decisions and is also the interface between the local authority and the political institutions. Energy Consulting Austria is the Energy planning company responsible for the development, planning, implementation, and monitoring of the plus energy concept. Energiewerk Baumgartner e.U. is the external energy consultant for neighborhood, and it manages the energy questions and integration with the neighbors. Raumsinn is the service provider responsible for resident engagement during the planning process as well as resident engagement in the use of the buildings. Raumsinn's sociologists have conducted important analyses of the existing neighborhood. Caritas Foundation Austria, an Austrian nonprofit charity organization, is responsible for the implementation of social concept and represents the voice of future users of the new buildings. It has provided input during the development and planning process. Wohngruppe Silberstreif (meaning silver

lining) is a housing community (+55 year old community) cum residential association have been consulted upon to provide input during the development and planning process. Finally, Österreichischer Verband Gemeinnütziger Bauvereinigungen–Revisionsverband (GBV or Austrian association of nonprofit building associations), an umbrella organization of the nonprofit housing industry acting as a cooperative audit association, provides feedback as it acts as an interest group giving voice to housing associations focused on affordable housing.

Another structural component identified in our research is the Quality Agreement initiated by SIR, which is a nonlegal binding agreement or an informal voluntary instrument. In structural functionalism theory, certain legal and formal outputs such as policies, plans, and regulations are determined as safeguards for collaboration, coordination, accountability, efficiency, and legitimacy. In the case of Salzburg, the Quality Agreement is an agreement between the project developer, the city of Salzburg, the architects, and other relevant planners, that describes the goals/qualities for six topics (management, communication, urban development, buildings, energy, mobility). It consists of documents that are short, easy to understand, and serve as reference points throughout the project. At the outset of the project, various actors convene in a workshop to share their interests, goals, and strategies. If a new actor joins the network later, another workshop is conducted to ensure that the agreement is understandable for new entrants while remaining open and flexible for new ideas and insights. The Quality Agreement is the result of a communication process and expresses the goals that must be fulfilled by the end of the project to ensure that all stakeholders deem it a success. These goals include reaching the requirements of the local building code, complying with the local housing subsidy directive, adhering to the Klimaaktiv standard for the entire neighborhood, achieving the Klimaaktiv gold standard for all buildings, and meeting the Greenpass standard for the blue and green infrastructure.

4.2 Functional Dimension

In understanding the functional components of governance within the GNICE SPEN project, we recognize the significance of four key factors.

Firstly, the unique role, position, experience, functionality, and capacity of SIR within the multilevel governance system stand out prominently. SIR leads the project group, coordinates steering group and working groups to make decisions, keeps all relevant stakeholders informed, both internal and external, and ensures the defined goals are achieved. With extensive years of experience and active involvement in Austrian planning for sustainability and climate, SIR possesses relevant political, practical, and operational knowledge and skills. Familiarity with the dynamics of different actors' interests, strategies, and perspectives enables SIR to effectively function as a moderator and consultant, initiating positive strategies for communication, collaboration, participation, transparency, trust-building, and

enhancing the sense of ownership, commitment, and engagement among diverse stakeholders. Additionally, SIR's role as an "external" expert in the quality assurance process, devoid of municipality or governmental biases, serves as a crucial intermediary. Collaboration among the partners of the EU project helped SIR share ideas on an international level and stay informed about international trends in the planning and construction of neighborhoods.

Secondly, the role of the quality agreement, an informal, voluntary joint agreement, emerges as another success factor for governance functionality. The agreement, which took more than a year to discuss and define during the preplanning phase preceding detailed design, fosters trust, coordination, and collaboration, effectively mediating governance challenges identified in research and practice. It is time-consuming to explain to involved parties that the document is a voluntary instrument and not legally binding. However, incoming new actors are introduced to the quality agreement to ensure that all stakeholders "have the same picture." Whenever questions arise, actors can always refer to the quality agreement.

Thirdly, the engagement of the community and their involvement in the steering group adds significant value to the governance structure. Caritas, in collaboration with the highly motivated +55-year-old community group "Wohngruppe Silberstreif," shapes the neighborhood's community, particularly addressing the needs of the increasing elderly population. The Silberstreif +55 association provides older people with the opportunity to remain independent for longer while living among like-minded individuals.

Lastly, the contribution of sociologists at Raumsinn stands out as pivotal. Their involvement in the governance network and collaboration with experts from various disciplines facilitate the integration of nontechnical and human-centric aspects into the project, establishing a culture of interdisciplinary collaboration. Raumsinn's role as a service provider hired to develop the "social concept" of the district further enhances governance functionality. Raumsinn analyzes the neighborhood infrastructure, develops common areas, organizes community activities, and engages residents in the project. The surrounding community, organized as a citizen association, is also informed and involved in the GNICE construction project and provided with information about energy advisors and consulting programs for renewable heating installations during the design phase of the project. Raumsinn has played a crucial role in gaining acceptance and commitment from the residents in the neighborhood. By involving residents in the process, their concerns were addressed, and trust began to develop. The cooperative planning process helped to minimize objections, which are common in such building projects when solutions cannot satisfy everyone. Strong relationships have been established with surrounding neighbors, future inhabitants, and companies, which are expected to play a vital role in GNICE SPEN as partners meet with external experts to discuss the next steps regarding the energy community and the involvement of neighbors. Raumsinn laid the groundwork in the early stages of the project, starting in 2019, and is expected to build upon this as tenants move in during the operational phase around 2025.

5 Discussion and Concluding Remarks

This chapter contributes to refining the structural-functionalism model for empirical investigations of governance models, particularly in the context of Positive Energy Districts (PEDs). Our findings challenge the adequacy of both total rational planning and incremental planning approaches in addressing the complexities inherent in neighborhood-scale projects like GNICE SPEN in Salzburg. The rational planning approach, characterized by its emphasis on predictability and continuity, falls short in capturing the nuanced dynamics of multilevel governance systems. In the context of Salzburg, where numerous initiatives operate beyond the formal project structure, rational planning fails to account for the temporal and informal influences that significantly impact decision-making processes. Moreover, the uncertain and interconnected nature of complex contexts renders the rigid framework of rational planning inadequate, as it struggles to accommodate dynamic power relations and ambiguous causality.

Conversely, while incremental planning offers flexibility and adaptability, our case demonstrates the necessity for some level of rational planning to provide guidance and maintain focus on overarching goals. The quality agreement established in our study exemplifies this need, serving as a flexible yet binding instrument to ensure alignment with project objectives. Thus, a balanced approach that integrates elements of both rational and incremental planning is essential to navigate the complexities of governance in projects like GNICE SPEN.

By adopting a communicative planning approach, Salzburg's case illustrates the potential for reconciling the tensions between rational and incremental planning. This approach emphasizes dialogue, negotiation, and collaboration among stakeholders, allowing for iterative decision-making processes that accommodate diverse perspectives and uncertainties. However, it also highlights the limitations of the structural-functionalism model in adequately capturing the cross-scale complexity of governance systems. The model's holistic framework fails to distinguish between intrainstitutional and interinstitutional relationships, overlooking the fluidity of power dynamics and the evolving nature of governance processes.

To conclude, our study underscores the importance of recognizing the limitations of traditional planning paradigms and advocating for more adaptive and inclusive approaches to governance. By embracing communicative planning principles and integrating elements of rational and incremental planning, stakeholders can navigate the complexities of multilevel governance systems more effectively, ultimately enhancing the success and sustainability of projects like GNICE SPEN.

Acknowledgments The research conducted in this chapter has received funding from the European Union's Horizon 2020 research and innovation program under grant agreement No 869918, SYN.IKIA Project. This chapter is partially based upon work from COST Action 19126 Positive Energy Districts European Network PED-EU-NET (see https://pedeu.net), supported by COST (European Cooperation in Science and Technology, http://www.cost.eu).

1 Introduction

The transition to a sustainable built environment demands a multidisciplinary approach that involves combining knowledge and techniques from different fields to tackle complex challenges. One such example is the integration of risk management and fault detection techniques in building energy renovation. This approach combines technical expertise and strategic planning to address the diverse challenges related to energy efficiency. [1].

To enhance the energy performance of existing buildings, building energy renovation practices require a nuanced understanding of risk management principles. This understanding ensures that renovation efforts meet the planned energy

performance targets and adhere to the highest reliability, efficiency, and occupant comfort standards. The literature reveals a broad spectrum of risks associated with building energy renovation [2]. These risks range from the delivery and installation of heating, ventilation and air conditioning (HVAC) systems to the optimisation of these systems under uncertainty and the development of innovative business models for energy management in urban districts.

In addition to the risks associated with building energy renovation, there are challenges in the maintenance and operation of building energy systems. Fault detection and diagnosis are critical components of this process, as they can significantly improve operational efficiency and energy savings. The process involves identifying deviations from normal operation and diagnosing the type of problem or its location [3]. Previous studies indicate that operational faults can increase energy costs by up to 30%, highlighting a significant issue for building operators who often lack the resources for effective fault detection and resolution [4]. Fault detection can significantly improve operational efficiency and energy savings, providing a robust foundation for continuous energy management practices such as monitoring-based commissioning. However, despite the potential benefits, implementing fault detection technologies faces several hurdles, including a lack of standardised methodologies and the complexity of building energy systems [5]. The analysis of fault detection and diagnosis in building systems reveals a need for improved algorithms and consistent use of terminology and definitions [6].

The maintenance and operation of building energy systems, particularly HVAC installations, involve significant risks such as project delays and cost overruns. Research by Mosaad et al. [7] highlights the complexities and interdependencies within construction activities, while Sun et al. [8] propose an integrated framework for enhancing HVAC efficiency through uncertainty and sensitivity analysis at the buildings' level. Innovations in business models for energy management at the district level, as explored by Sepponen and Heimonen [9], and smart building energy management strategies, like the conditional value-at-risk model by Feng et al. [10], illustrate the shift towards advanced analytical methods and comprehensive risk assessment to implement energy-efficient solutions effectively.

Furthermore, the integration of smart building technology and HVAC systems in buildings offers a new perspective on managing uncertainties associated with renewable energy and fluctuating conditions, promoting innovative strategies for real-time energy optimisation. Sepponen and Heimonen's work [9] emphasises stakeholder-centric approaches to renewable energy adoption, advocating for flexible and sustainable business models to overcome barriers to energy-efficient urban development. The findings from Sepponen's study, suggest that the field of building energy renovation is moving toward an integrated approach combining technical innovation with strategic risk management and business modelling. The previous aforementioned studies collectively advocate for a shift from traditional, prescriptive methodologies towards more dynamic, analytics-driven approaches that can accommodate the complexities of modern building systems and the uncertainties inherent in their operation.

2 Methods

This study adopted a mixed-methods approach to explore risk management and fault detection methodologies in building energy renovation, focusing on identifying current practices, challenges, and suggestions for improvements. The research was conducted in two primary phases: a comprehensive literature review and targeted Finnish expert interviews.

The literature review of existing academic and industry literature to establish a foundational understanding of the current state of energy efficiency, risk management practices, and fault detection technologies within the realm of building renovations. Sources included peer-reviewed journals, industry reports, and regulatory documents, with the aim of identifying knowledge gaps, inconsistencies in terminology, and variations in methodological approaches. The findings from the review were used to formulate the interview questions by highlighting key areas of interest and concern within the field.

Following the literature review, semi-structured online interviews were conducted with a carefully selected group of professionals, including facility managers and service providers of building services and automation systems in Finland. These participants were chosen based on their extensive experience and expertise in commissioning, maintaining, and monitoring the building's energy performance. Demographic information about the interviews is shown in Fig. 1. The interviews were focused on the insights into the practical challenges of building commissioning, implementation of technologies, effective risk management strategies and fault detection techniques. Questions were open-ended to allow for the exploration of topics not covered in the literature review.

Interviews were video-recorded and subjected to thematic analysis. The responses were analysed to identify recurring themes and patterns related to risk management practices, technical challenges, and areas for improvement. The study

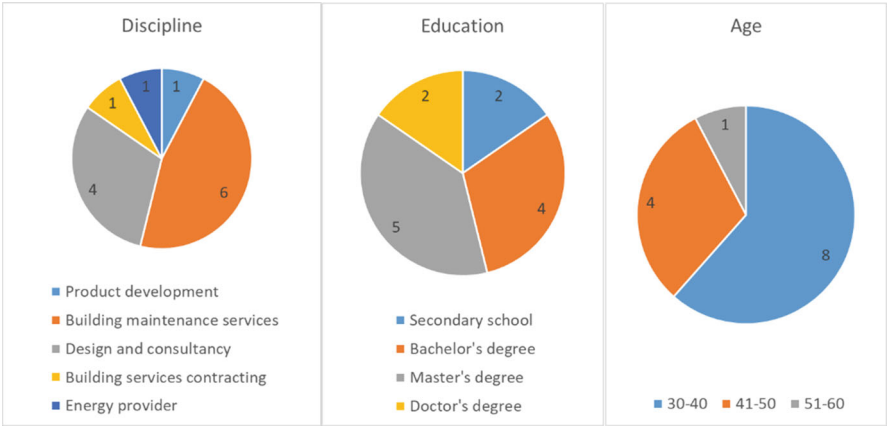

Fig. 1 Demographic information of the interviewees

was conducted in accordance with ethical guidelines for research with human participants. All interviewees provided informed consent, and measures were taken to ensure the confidentiality and anonymity of the participants and their responses.

3 Results

Table 1 organises the collected data from the interviews into three main categories: risk management practices, challenges, and suggestions for improvements. This arrangement allows for a comprehensive understanding of the current state of risk management in building energy systems and offers insights into potential areas of enhancement. The results highlight technical and operational problems that obstruct effective risk management. These issues range from technical difficulties with equipment to the complexities of managing hybrid systems, which require advanced technical knowledge to oversee modern building energy systems. Complex and

Table 1 Practices for risk management, challenges, and improvements

Challenges	Practices for risk management	Suggestions for improvements
Service Providers		
Technical issues with system equipment Navigating the complexity of hybrid systems Issues with sensor placement accuracy Integration of data from different systems and providers Lack of historical data trends or difficulty in accessing building data	Proactive management of component failures Prevention of inter-component interference Early fault detection with multiple sensors and data analysis Data collection at adequate clarity and resolution	Commitment to regular and data-driven system maintenance Enhanced staff training on fault detection and response, including hands-on experience of systems Comprehensive documentation on system operations and failure management Communication with the client on the uses and benefits of building data Sharing of good practices between rival companies
Facility Management		
Adequacy of the electric power connection in the building for use with an electric heating system Adjusting to space usage changes Energy price fluctuations High setup and maintenance costs	Ensuring stability and reliability of heating systems Maintaining a sustainable long-term temperature regime Design and control flexibility for future adjustments	Temperature, flow, and pressure measurements for benchmarking and fault detection Utilising smart building management systems for dynamic adjustments Leveraging data analytics for optimised energy use and forecasting Investment in advanced sensor technology and integration of a unified analytics platform

hybrid systems face operational difficulties, such as inadequate sensor placement and insufficient documentation, which make monitoring and managing them difficult. These challenges reveal the gaps in current practices, particularly in sensor deployment, documentation, and data analysis integration for early fault detection. They suggest a more informed and proactive approach to risk management is necessary.

To properly monitor the energy efficiency in building systems, there should be parallel metering of temperature, flow rate and pressure, which are all connected to the building automation system with appropriate alarm setup. These meters should be placed before and after heat exchangers to identify leaks, fouling, stuck valves and general suboptimal operation. Room condition monitoring is also essential to confirm system operation. Parallel metering of different variables enables the separation of sensor issues from actual system malfunctions. Data-based benchmarking can also be utilised for pre-emptive and demand-based maintenance. Integration of different systems must be done carefully to avoid conflicting operations, such as simultaneous heating and cooling from centralised and local units. It is important to collect dynamic data for long periods to establish historical trends and expected operation levels. A common problem is a too-short storage period of data, which prevents identification of the origins of observed malfunctions.

Figure 2 outlines the four phases of risk management: Risk Identification, Risk Analysis, Risk Response Planning, and Implementation and Monitoring. The figure is designed to guide stakeholders through a structured approach to managing risks in building energy renovation projects.

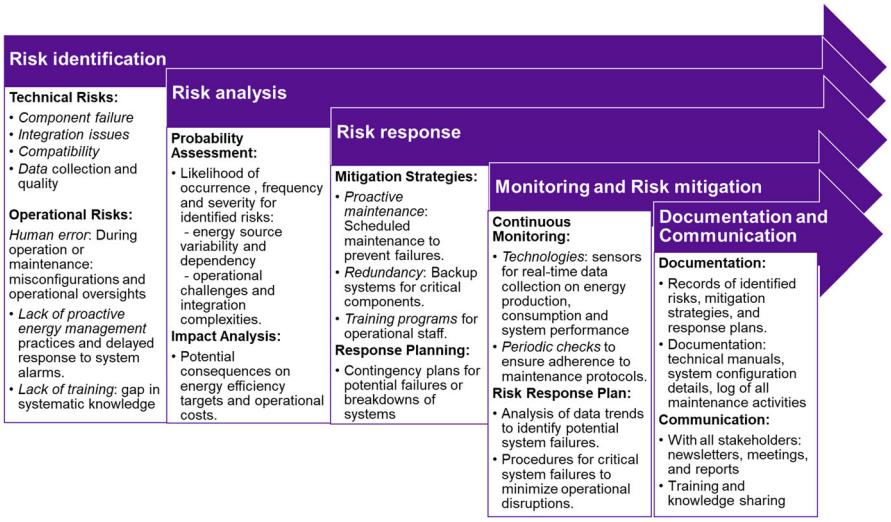

Fig. 2 Proposed process of risk management in building energy projects

The figure shows the first step of Risk Identification, where potential risks associated with building energy systems are identified. Potential issues are anticipated by analysing historical data and performing predictive analytics. A risk analysis evaluates identified risks according to their severity and probability, prioritising them for effective resource allocation and threat preparation. The Risk Response Planning process develops strategies for mitigating, transferring, or accepting prioritised risks when necessary. Implementation and Monitoring involve implementing risk response strategies, adjusting them in real time, and detecting new risks as early as possible. Continually review and adjust the risk management approach to stay aligned with objectives and external realities.

The results underscore the complexities involved in managing risks in building energy systems, highlighting significant challenges and proposing a structured approach to improvement. Table 1 reveals a gap in current practices, particularly in the areas of sensor placement, documentation, and the integration of data analysis for early fault detection. Figure 2 complements these findings by proposing a comprehensive risk management process that emphasises the need for ongoing monitoring and adaptation. Together, these elements contribute to a deeper understanding of the challenges and potential pathways for enhancing energy efficiency and operational reliability in building renovations.

4 Discussion

This research ventured into the complex terrain of risk management and fault detection in the context of building energy renovations, revealing significant insights while also encountering limitations that pave the way for future studies. The reliance on expert interviews and literature reviews, while robust, underscored the need for more empirical data to validate the proposed process of risk management. The generalisability of the findings could be enhanced through quantitative research, incorporating larger datasets from a wider array of buildings and systems.

Future research directions emanating from these limitations include the need for empirical studies that test the proposed risk management model in diverse real-world settings. The integration of quantitative data would allow for a more robust validation of the findings and could help in the development of predictive models for risk management and fault detection. Another avenue for future studies is the exploration of the impact of emerging technologies, such as artificial intelligence and machine learning, on the efficiency and effectiveness of fault detection systems. These technologies hold the potential to transform current practices but require thorough investigation to understand their practical applications and limitations.

5 Conclusions

This research focused on investigating the intricate process of managing risks and detecting faults in building energy systems. The main goal was to develop a risk management protocol to enhance energy efficiency and improve operational reliability. The research methodology involved gathering insights from experts and conducting a comprehensive review of existing literature in order to identify practical strategies for improving risk management practices in this field. As a result of the interview analysis, existing risk management practices were mapped out, prevailing challenges were identified, and a series of targeted improvements were articulated. The preliminary suggestion for the risk management model, as derived from the synthesis of expert interviews and a comprehensive literature review, emphasises an integrated, adaptive approach tailored to the unique challenges of building energy systems. This model advocates for a four-phased methodology: identification, analysis, response, and monitoring of risks, underscored by a continuous feedback loop for dynamic adaptation. These approaches are essential for addressing the intricate nature of modern building systems and the array of uncertainties they encounter. The findings revealed the necessity for a holistic strategy that combines technical innovation, strategic risk management, and flexible business modelling. Such an approach not only aims to mitigate immediate operational risks but also aligns with broader goals of sustainability and energy conservation.

1 Introduction

By 2030, urban areas are expected to have gradually concentrated over 70% of the world's population [1], leading to a growing demand for thermal energy [2]. In the European Union (EU), buildings consume approximately 40% of EU energy for heating, cooling, and domestic hot water usage [3], of which around 35% exceed 50 years of age and demonstrate nearly 75% energy inefficiency. Simultaneously, the average annual energy renovation rate remains relatively low at approximately 1% [4].

EU wants to change this situation by aiming for a more sustainable future and urging building owners and managers to minimise their energy consumption [5]. The public bodies are trying to set in motion plans to renovate buildings owned by them to meet the annual target of renovating at least 3% of their total floor area and reducing their annual energy consumption reduction by 1.9% [6]. This raised the need to invest in energy conservation measures (ECMs), energy efficiency measures (EEMs), or interventions. These measures consist of potential replacements or upgrades of existing systems that enhance efficiency in a cost-effective manner and are recommended to save or reduce utility costs, e.g. energy and gas.

When implementing an intervention in a building or a set of buildings, the actual energy savings cannot be directly quantified. Alternately, savings are calculated by comparing the energy consumption before (baseline period) and after (reporting period) the implementation of interventions while adjusting to condition changes. Based on the literature, systematic approaches for determining the true impact of an investment in energy efficiency are collectively referred to as measurement and verification (M&V) methods, supported by a well-established set of guidelines, directives, and protocols, e.g. International Performance Measurement and Verification Protocol (IPMVP) [7, 8].

M&V is the process of planning, measuring, collecting, and analysing data resulting from ECMs implementation [8]. This methodology is used as a "means of verification" for energy savings achieved by a system capable of adjusting to the user's needs and empowering building occupants by providing precise and relevant information on operational energy consumption and applied interventions [8]. At the same time, it provides a clearer estimation of the actual energy savings achieved by the interventions.

This tool can be helpful for organisations that monitor numerous buildings and are obliged to meet specific energy efficiency measures. Relying on recent advances in M&V, the paper proposes a methodology for applying M&V with large-scale aggregated data during an operational year, making suitable adjustments to the models for changes in the multiple buildings (e.g. environmental, operational changes or renovations).

The proposed methodology is applied to Danish residential buildings in the Municipality of Aalborg [9]. This way, one shared adjusted baseline model is built per cluster of buildings to predict post-intervention energy consumption in the future.

2 M&V Framework with Large-Scale Aggregated Data

The proposed methodology is divided into two phases: (1) the period before applying the interventions (pre-ECM period) and (2) the period after the implementation and activation of the interventions (post-ECM period). The pre-ECM period includes data gathering, data processing, selecting the M&V option, measurement

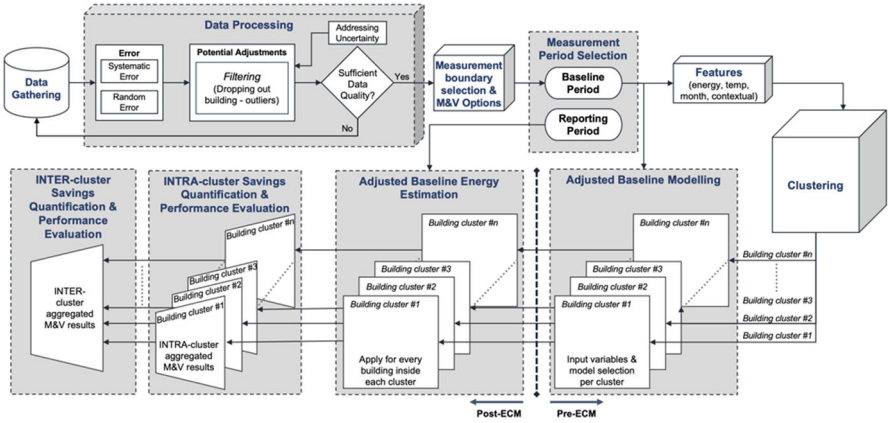

Fig. 1 Methodology for applying M&V on a dataset with multiple buildings

period selection, feature extraction, clustering, variable selection, and finally, baseline model selection for each cluster.

For the post-ECM period, the performance of each intervention is evaluated, and the energy savings are estimated per model and cluster. Multiple-building modelling focusses on a common processing method, model, and set of input variables for all buildings inside each cluster instead of simply summing individual consumptions of each building and modelling them. The proposed methodology formulated to apply M&V on a dataset with multiple buildings is presented in Fig. 1.

2.1 Step 1—Data Preparation and Project Definition

When handling data from multiple buildings, it is essential to (i) understand the functionality and typology of each building and (ii) define the necessary input data variables for adjusted baseline model development. For this step, the relevant information concerns the building's characteristics, data sources, periods with available data, energy types and consumptions, and factors impacting the performance of the intervention and monitoring process (e.g. sensor failure).

2.2 Step 2—Data Processing

The available data are validated for the minimum requirements for clustering and developing the M&V model. Regarding multiple buildings, non-routine adjustments are not easily identified (e.g. facility size, change in occupancy and occupant activities); thus, only the routine adjustments are considered input, and buildings with irregular energy consumption patterns are omitted. So, the available datapoints

are processed to identify potential system failures, random errors, and corrupted data to evaluate the data quality and reduce uncertainty. The minimum datapoints recommended are the total energy, temperature, and relative humidity regarding the outdoor conditions of the buildings.

2.3 Step 3—Measurement Boundary Selection

Per the available information, the measurement boundary and type of energy savings are selected. In the case of multiple buildings, there are two measurement boundaries to be defined: (i) at a macro level, encompassing all the multiple buildings, and (ii) at a micro level, relating to each building. Adhering to the guidelines by IPMVP, option C (whole facility) is the most appropriate [10]. Additionally, several considerations impact the selection process: (i) the period of year in which the intervention occurs, influenced by weather conditions and the type of energy monitored; (ii) the selection of an appropriate statistical model; and (iii) the data frequency, as it is advised to use monthly data to avoid weekly variations [11].

2.4 Step 4—Measurement Period Selection

Two periods are needed to be defined. The period with constant and stable conditions before the ECM is characterised as the baseline, and after the intervention, it is called the reporting period. The selected baseline period should correspond to a normal and full operating cycle of the buildings concerning energy consumption without interventions, representing all operating modes (maximum energy consumption to a minimum) to characterise the savings effectiveness in normal operating conditions. Under real circumstances, such a period may not always be available; therefore, assumptions must be made. For the selection of the reporting period, there are two options: (i) the definition of a common reporting period for all the buildings in the sample or the cluster, which leads to a wider gap between the two periods or (ii) define the reporting period for each building separately.

2.5 Step 5—Explanatory Variables, Features, and Clustering

At first, this pre-processing step focusses on selecting the appropriate explanatory variables and the feature for the clustering. The explanatory variables impact the model creation and the period selection. They can either originate from the dataset to be generated, e.g. quadratic transforms of all the other explanatory variables, or index-derived variables, such as the day of the month. Usually, the most impactful variables are indicators relevant to the weather.

For the feature selection, the methodology proposes a handcrafted feature extraction scheme instead of another due to (i) dimensionality reduction of the feature space is achieved as it is computationally intensive to apply multivariate time series (MTS) clustering, (ii) interpretability of clusters with different patterns (heating vs. cooling) are grouped, and (iii) contextual information integration of buildings' characteristics.

Having the desirable features generated, all buildings are separated into clusters by applying the K-Means clustering algorithm [12, 13], based on the Elbow method [14]. The factors impacting the efficacy of the final clusters formed are [15, 16]: (i) the number of clusters (groups) (K), (ii) the initial cluster centres impact the final cluster formation, as the K-means algorithm is non-deterministic, and (iii) the outliers impact the cluster formation and thus need to be processed. Additionally, the data undergoes scaling using a Minmax scaler, followed by principal component analysis (PCA) to reduce the data dimensionality. The PCA is configured to retain 90% of the variance in the data.

Upon determining the number of clusters, a visualisation check is implemented. Using the raw multivariate time series, the variables per cluster are mapped into a 3-D histogram, with energy, weather, and month on each axis. The histogram is flattened and concatenated with additional binary-encoded contextual features, if available. This step aids in validating the selected number of clusters by revealing shared energy patterns within specific groups of buildings.

2.6 Step 6—Adjusted and Selected Baseline Modelling

Following the assignment of each building to a specific cluster, a testing procedure is conducted to allocate a baseline model and the appropriate transformation for variables within each cluster, utilising a chosen metric evaluated across a predetermined number of representatives.

During the creation of the adjusted baseline modelling, different models are tested in each cluster with different explanatory variables to identify the model with the least test errors in all the indicators [11]. The selected model for different building types or clusters can produce accurate enough adjusted baseline predictions. The baseline model for each cluster is developed by using one of the methods [11, 17, 18]:

1. Linear regression (LR).
2. Theil-Sen regressor (TSR).
3. Random sample consensus (RANSAC) regressor.
4. Huber regressor (HR).
5. Bayesian ridge regressor (BRR).
6. Least-angle regression (LARS).
7. Automatic relevance determination regression (ARD Regression).

2.7 Step 7—Performance Evaluation Per Cluster

A random selection of 10 representatives from each cluster is proposed, with each building trained in all available models and transformations. Subsequently, the model's performance is based on three dimensionless indicators ($e_{m,b}{}^{x}$) specific to the comparison of different heterogeneous datasets [11, 19]: (i) the mean ratio to first (mrtf), averaging the ratio of each model error to the smallest model error obtained for each dataset, without normalising the maximum error; (ii) the mean ranking position (mrp), ranking position obtained by the model on each building; and (iii) the first ration (fr), proportion of times a model ranks first. Eq. 1, Eq. 2, and Eq. 3 calculate the metrics accordingly, with M the number of models and B the number of buildings.

$$e_m^{(\mathrm{mrtf})} = 100\frac{1}{B}\sum\nolimits_{b=1}^{B}\frac{e_{m,b}}{\min_{m\in M(e_{m,b})}} \tag{1}$$

$$e_m^{(\mathrm{mrp})} = \frac{1}{B}\sum\nolimits_{b=1}^{B}\mathrm{rank}_{M(e_{m,b})} \tag{2}$$

$$e_m^{(fr)} = \frac{1}{B}\sum\nolimits_{b=1}^{B}1\left(\mathrm{rank}_{M(e_{m,b})}=1\right) \tag{3}$$

The cumulative errors for each cluster are computed, and the model and transformation yielding the minimum cumulative error are identified. This process facilitates the determination of the optimal model and transformation for each cluster.

Additionally, three metrics are used in conjunction to evaluate the performance and select the most accurate reference model for each cluster [8, 11, 17]: (i) the coefficient of variation of root mean square error (CV-RMSE), depending on the time scale, (ii) the mean absolute scaled error (MASE), and (iii) the normalised mean bias error (NMBE), quantifying the tendency of a model to over or underestimate across a series of values.

The model performs better when the value of CV-RMSE is the lowest, minimising the uncertainty. The metric MASE is independent of the data's scale; therefore, if the forecast is better than the naive forecast computed in-sample, the scaled error is less than one; otherwise, the scaled error is greater than one. The NMBE is more versatile and valuable for globally ranking variables and algorithms, leading to a common baseline model for several buildings. Finally, one model will be selected based on the best evaluation metrics among the algorithms and the selected baseline period.

2.8 Step 8—Intra- and Intercluster and Aggregated Saving Quantification and Performance Evaluation

At this stage, the dataset is M&V-ready and is poised for application to the selected reporting period. Based on the literature, the first results indicate the energy consumption of the buildings in each cluster. They are characterised as INTRA-cluster aggregated M&V results, and the generalised results for the total number of buildings are presented as inter-cluster aggregated M&V results [11].

Following the predictions, the differences between the predicted and actual values are calculated. The cumulative differences across all days are computed to ascertain the predicted savings. This process provides insight into the energy savings achieved after the interventions. The general Eq. (4) to calculate savings is:

$$\text{Savings} = (\text{Adjusted Baseline Energy—Post} - \text{ECM Energy}) \pm \text{Adjustments} \quad (4)$$

3 Integration, Deployment, and Results

3.1 Project Definition and Data Preparation and Processing

The proposed methodology is applied to the Aalborg Municipality, the largest city in the North Denmark region, with a population of 215.328. The dataset comprises 3127 Danish residential buildings (apartments, single-family houses, or terraced houses) equipped with smart commercial heat meters and connected to the district heating network owned and operated by Aalborg Municipality [9]. The analysis focusses on the 2459 single-family houses. Since the dataset was processed before publication, all the data was considered input. At this point, it is essential to mention that the dataset consists of information regarding the construction year, the type of building, and, if available, the energy label and the heat measure for 3021 buildings [9]. Additionally, the selected dataset has only information concerning the energy consumption before an ECM. Therefore, the methodology was applied to build one shared adjusted baseline model for several buildings belonging to a cluster.

3.2 Measurement Boundary and Period Selection

Concerning the measurement boundary, option C (whole facility) is selected for calculating the total thermal heating energy and the corresponding selected baseline period from 02/01/2018 to 31/12/2019 (2 full operational years) and the reporting period 01/01/2020 till 31/12/2020 (1 full operational year). The choice of the reporting period is made to align with the paper's requirements and facilitate the application of the methodology at each stage.

3.3 Features Selection and Cluster Definition

After filtering the available datapoints, three explanatory variables were selected: (i) outdoor temperature, (ii) enthalpy, and (iii) dew point (see Fig. 2). Along with these three variables, two more variables were created and used: (v) quadratic

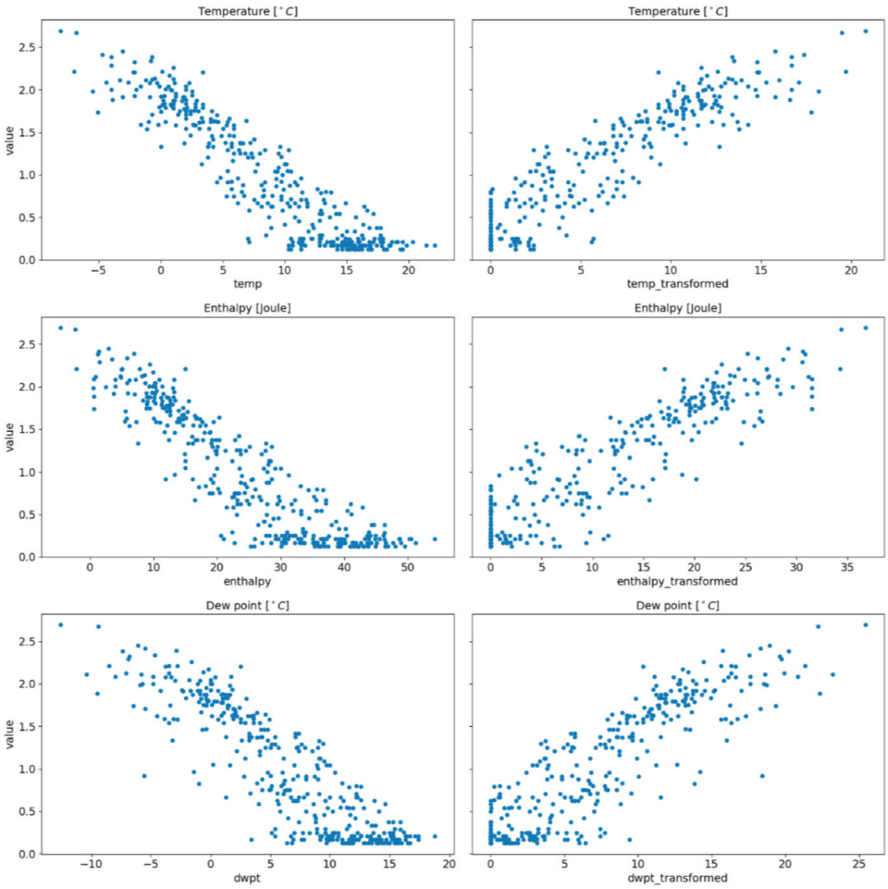

Fig. 2 Graphic representation of temperature, enthalpy, and dew points and their transformations

transforms of all above and (vi) index derived variables, such as day of week and month of the year.

According to the methodology, a series of features were selected for testing, as listed in the documentation by tsfresh Github repo [20]. A removal procedure eliminates features that do not effectively separate the data. This removal process entails discarding binary and constant data and data closely resembling an initial value, subject to a specified threshold. The final concatenated features are used as input for clustering.

For the clustering process, the selected extracted features were used by the K-Means algorithm, based on the Elbow method [21]. Several runs are recommended for sparse high-dimensional problems. Subsequently, the K-means clustering is employed with a predetermined number of clusters. The appropriate number of clusters was $k = 12$ (see Fig. 3), in which all the buildings were visually presented (see Fig. 4). The final distribution of the buildings is presented in Table 1.

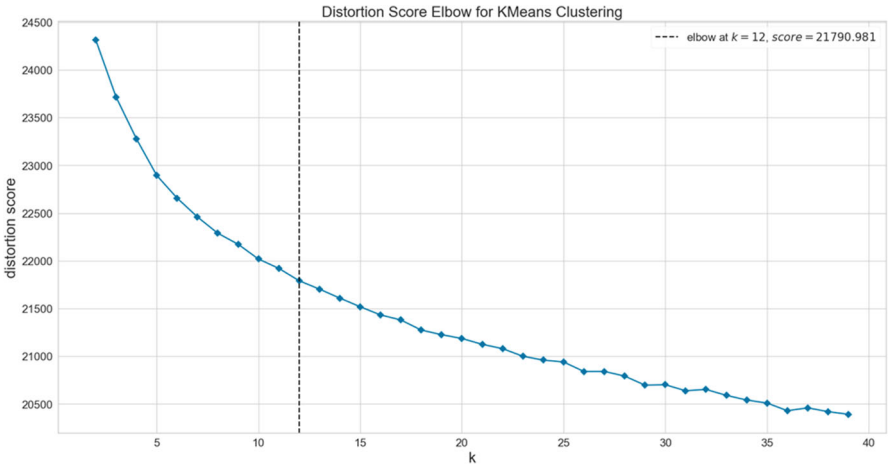

Fig. 3 Distortion score elbow for KMeans clustering

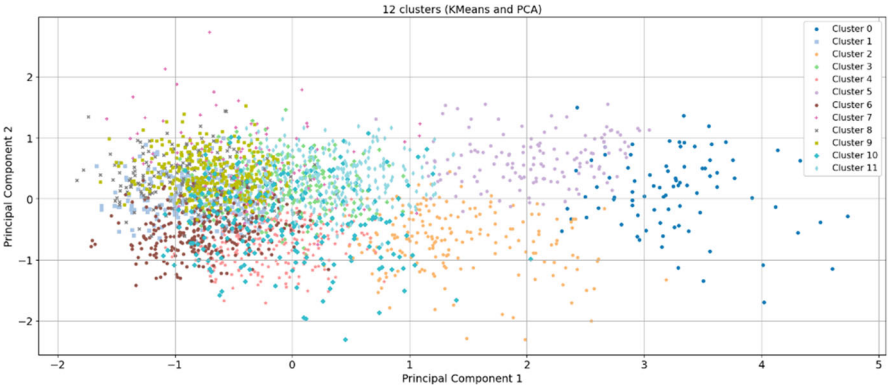

Fig. 4 12 Clusters (KMeans and PCA)

Table 1 The distribution of the single-family buildings in the clusters

Cluster number	0	1	2	3	4	5	6	7	8	9	10	11
Number of buildings	210	181	377	156	315	51	205	195	225	28	262	254

The clustering approach offers the advantage of rapid execution, attributed to the efficient computational characteristics of K-means clustering. In supplementary, the silhouette score was calculated (−0.01386).

So, a time series with measurements for one year each consists of 365 (energy, temp, month) combinations, which are assigned to a bin of the 3-D histogram. After, the 3D histogram is flattened and concatenated with additional binary-encoded contextual features given (unit type and energy label) and the construction year of

the building. From the histogram, we observe the energy signatures of the different building types (clusters) for extended periods (e.g. during summer), while others have zero consumption only for a few months.

3.4 Adjusted Baseline Model Selection and Performance Evaluation

A testing procedure is conducted to allocate a baseline model and the appropriate transformation for variables within each cluster, developing a model evaluated across a predetermined number of 10 representatives.

This was followed by selecting the best combination of variables and models. The primary indicator for comparison inside the cluster was the first ration (fr) equation, and where there was a tie between models, the mrtf equation and mrp equation were applied consecutively. Additionally, three metrics were used, CVRMSE, NMBE, and MASE, to verify that the selected model for each building is appropriate. Thus, by feeding the explanatory variables of the reporting period into the selected model for each cluster, we obtain the most appropriate adjusted baseline model with the relevant transformations (see Table 2).

3.5 Results of M&V Analysis

Through the comparison of the adjusted baseline per building with the monitoring consumption in the reporting period, the final per-cluster (intra) savings are calculated. Then, the savings per cluster are combined to calculate the final (inter) savings. Based on the available dataset, the total savings are estimated to be −1.35%, indicating that the model fits the actual energy consumption closely. As no interventions were recorded, the savings should have been 0%. Consequently, the model demonstrates a well-fitted representation of the observed energy consumption.

4 Discussion

By identifying the different clusters of the buildings, a model per building was deployed based on the cluster to which it belonged. This way, each building had its baseline model, and by aggregating them, the final (inter) savings were close to 0%. This result allows us to assume that the M&V methodology was applied successfully and the adjusted baseline model is ready to be applied once the ECMs occur. In other words, one baseline model is developed per cluster, characterising them as “M&V ready”, meaning that when intervention occurs and the reporting period is sufficient, the developed models can be applied to extract the savings achieved.

Table 2 The performance of the selected baseline model per cluster[a]

Cluster number	0	1	2*	3	4*	5*	6*	7*	8*	9	10	11
Baseline model (estimator)	HR	OLS	OLS	HR	RANSAC	HR	RANSAC	HR	HR	HR	HR	OLS
fr score[b]	4	5	4	5	2	4	3	4	3	5	3	5

[a]The clusters with the asterisk (*) indicate that more than one model with their transformed variable had the same fr score
[b]Number of representatives which selected the model (max: 10)

We concluded that by clustering the meters that show a similar pattern, we can choose a model and transformation for all the houses of the cluster because of their similar nature. This process may incur some inaccuracies compared to studying each building separately, but considering the time and computational power resources needed and the performance indicators, the results are satisfactory overall. The advantage is that we do not have to find each house's regression model and transformation and repeat the same process multiple times.

5 Conclusions and Future Work

The proposed methodology contributes to evaluating the energy savings of multiple buildings during an operational year, covering all the seasons, by comparing the adjusted energy consumption with the energy consumption from the previous phase of the buildings (i.e. without ECMs). This methodology can be extended to all types of energies (i.e. thermal or electrical), including gas, power, and water consumption.

When the M&V is applied in multiple buildings, the optimisation strategy of energy consumption within a set of buildings must be validated without aggregating energy data. This tool can assist public and private organisations that manage multiple buildings in better monitoring the impact and performance of energy-saving initiatives and interventions. This will help them align with the EU energy consumption and efficiency guidelines.

Summarising, the methodology helps develop a generic model per cluster based on the energy type. Therefore, it helps minimise the computational effort of calculating the energy consumption of a series of buildings separately, simultaneously achieving reliable predictions. In general, the modelling process is simplified. However, applying the methodology in a real case is essential to estimate the savings achieved in a wider area of buildings.

1 Introduction

Predicting, evaluating, and measuring the extent of damage in different materials and structures has been a growing research interest where relying on various models such as mathematical, quantitative, material-based, and other models that can assess the damage [1–5]. Recently, implementing unmanned aerial vehicles (UAVs), artificial intelligence (AI), and machine learning (ML) to detect the damage and then incorporate that into the digital twin concept have introduced a transformative potential to various industries by enhancing predictive analytics, simulation, and real-time monitoring capabilities. A digital twin is a virtual representation of a physical object,

system, or process that mirrors its state in the real world. Leveraging UAVs and ML/AI in digital twins for bridges significantly benefits infrastructure management, emphasizing damage detection, timely maintenance, and efficient inspection [6–10].

Building a 3D model of a bridge by using accelerometers, UAVs, and surveillance cameras was the framework proposed by [11, 12] for the inspection and maintenance of bridges. Moreover, A systematic review published by [13] consolidates the latest findings on using bridge information modeling, finite element modeling, and bridge health monitoring for creating digital twins of bridges without AI or ML capabilities. Furthermore, a 3D digital twin model for bridge structures as a part of the next generation of bridge maintenance systems was proposed by [14]. These models are crafted through 3D scanning techniques and alignment-based parametric modeling, incorporating comprehensive geometrical details. Recent studies were published that discussed and assessed the transportation networks and lifetime resilience of the bridges through proposed and developed frameworks for the entire process [15, 16].

This study aims to provide a framework and recommendations for generating a 3D bridge model by utilizing UAVs, photogrammetry software, and AI capabilities in order to have a precise and digital copy of bridges. This innovative approach aims to produce a precise digital replica of the intended bridge structure. Moreover, the study introduces a novel methodology for conducting safe, swift, accurate, and remote inspections, enabling the examination of difficult-to-access areas of the bridge. This methodology enhances the efficiency and effectiveness of bridge inspections and significantly improves decision-making, safety, and accessibility for inspectors, potentially transforming conventional practices in bridge maintenance and monitoring.

2 Digital Twin Framework

Figure 1 represents the structured framework of the present study for bridge inspection and assessment utilizing modern technology. The process begins with data collection, where drones are deployed to gather comprehensive data (2D images) of the bridge. This data is then meticulously filtered to isolate relevant information. Next, defects identified in the data are annotated, a crucial step that feeds into training a specialized AI model. Once the model is trained, it can run a detection algorithm to spot and highlight anomalies within the bridge structure. Following this, by feeding the data into the software with AI capabilities, a 3D bridge model is generated, providing a detailed and manipulable representation of the bridge for further inspection. The inspection process can be initiated using any available device (such as PCs, tablets, and even smartphones) with access to a main server, enabling inspectors to conduct thorough evaluations remotely. Finally, the gathered information and analysis aid in decision-making regarding the bridge's maintenance needs. This high-technology, systematic approach enhances bridge inspection's safety, accuracy, and efficiency.

3 Data Collection

Utilizing drones for image collection has stood out as a transformative technology in bridge assessment. Specifically, drones with high-resolution cameras offer a unique vantage point that facilitates unparalleled data acquisition when applied to bridge mapping. Two types of drones were used in the current study to collect the image datasets, DJI Mavic 2 Pro and DJI Phantom 4 RTK (Fig. 2).

Both drones are widely used in various professional fields. Table 1 present the specifications for Mavic 2 Pro and Phantom 4 RT, respectively.

4 Data Quality and Resolution

Data quality and resolution of images captured by drones hold an essential role in the effectiveness of bridge inspections and 3D modeling. When it comes to structural assessment and maintenance of bridges, detailed and high-resolution imagery is

Present study	177	5472 × 3648

critical for identifying potential issues, such as cracks, corrosion, or other structural defects. Conversely, operating the drone at a greater distance ensures safety and can provide a broader view of the bridge, which is useful for overall structural assessments. However, it may compromise the ability to capture minute details. Therefore, finding the optimal distance is key. This distance is often determined by the drone's camera specifications, the desired resolution, and the need to balance detailed inspection with operational safety. Table 2 compares the current study with the literature on both resolution and the number of images in the datasets.

The first dataset consisting of 177 images was received from the Mavic 2 Pro drone. 111 images were also received from the Phantom drone. The quality for both datasets was 5472 × 3648 pixels. Figure 3 presents an example from the Mavic 2 Pro, while Fig. 4 shows an example from the Phantom 4 RTK. The Mavic drone flew at a distance of 50 feet from the bridge, while the Phantom drone covered the area from a distance of about 180 feet.

Fig. 3 Example for an image captured by Mavic 2 Pro drone from 50 feet distance

Fig. 4 Example for an image captured by Phantom 4 RKT drone from 180 feet distance

The difference in flying distances between Mavic 2 Pro and Phantom 4 RKT from the bridge offers a valuable opportunity for comprehensive data collection. Additionally, it allows for a meaningful comparison of the quality of the 3D models generated by each drone. By examining how much detail the cameras capture at different distances, insights can be gained into the precision and level of information each drone provides. In Fig. 3, the closer proximity of the drone to the bridge allowed for a more detailed capture of the bridge's structural defects, such as cracks. This contrast appears when compared to Fig. 4, where the drone was positioned farther away (180 feet), which resulted in a reduction in capturing the bridge defects. This difference underlines the importance of drone positioning in accurately generating and assessing a 3D model, demonstrating that closer aerial flight can reveal more accurate and critical details that assist with generating an accurate model. Incorporating the optimal drone distance into the inspection strategy significantly enhances drone-based bridge inspection effectiveness and generates precise 3D models. It ensures that the images captured are of high quality and resolution, providing a reliable basis for accurate assessment and informed decision-making in bridge maintenance and safety protocols.

5 Generated 3D Models

In this study, the primary focus is on the 3D modeling of the bridge. By utilizing Bentley Software (with AI capabilities), Pix4D, and Autodesk ReCap Pro, high-quality 3D models have been generated from the images captured by drones for multiple bridges. This integration of photogrammetry software into the digital twin concept not only ensured a more detailed and accurate representation of the bridge's current condition, it also enabled a comprehensive analysis of its structural condition. The 3D models provided a multi-dimensional perspective, allowing a more thorough examination of expected damages and areas requiring maintenance that were missed or there were difficulties in reaching.

In this case, a bridge characterized by its unique construction and current condition was examined. The bridge, built in 1922, stands as a century-old structure, located 19 miles south of Ames, Iowa. It features a robust design with steel beams supported by abutments and topped with a reinforced concrete deck. Figure 5 shows a comparison among the images generated by the three software packages. The difference in the 3D model quality can be noted, where the Bentley software exhibits the highest and most accurate model among the three software packages, while all of them used the same dataset to generate the model. Bentley software has powerful measurement capabilities such as location, distance, area, and volume. Incorporating and utilizing these capabilities with high-quality 3D models offers the safest and fastest inspection and damage detection process. In order to represent the measurement tools in Bentley software, some defects were measured in the generated bridge.

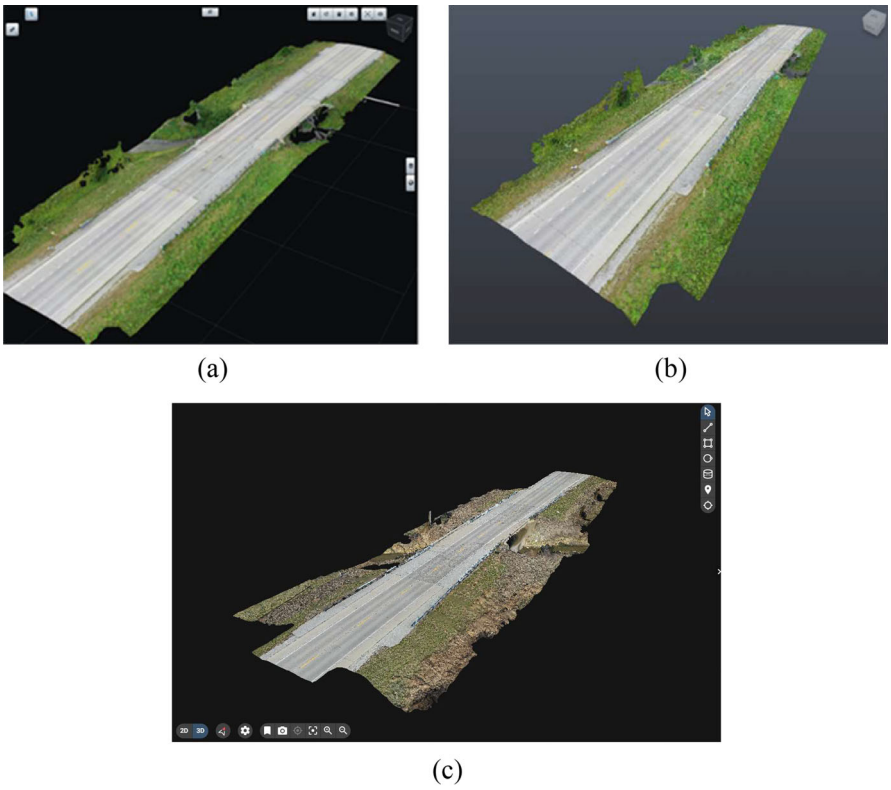

Fig. 5 A comparison among the images generated by (**a**) Bentley software, (**b**) Pix4D, and (**c**) Autodesk ReCap Pro

6 Implementing AI

The integration of AI technology represents a significant advancement in the field of infrastructure management. By preparing and training the AI algorithm, software packages like Bentley can automate and enhance various aspects of its operations. AI can be utilized for more efficient and accurate feature recognition in captured data, improving the identification of defects and anomalies during inspections. In this study, AI capabilities were applied to detect potholes and cracks in the case study bridge. Figure 6 shows the before and after applying the detection model. The software learns from the provided pre-trained weight to detect the cracks (in blue line) and the potholes (green shadow). A high accuracy was obtained because the detection method was trained to detect per pixel in the image, what is often called semantic segmentation.

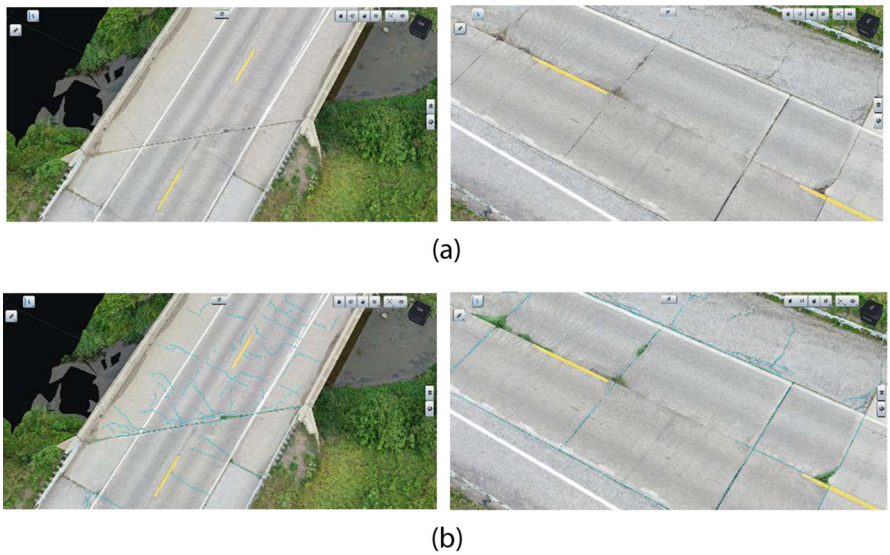

Fig. 6 The 3D model of the bridge (**a**) before and (**b**) after applying the detection algorithm

7 Conclusions

This chapter introduces creating a 3D bridge model using three distinct software packages. In addition, an AI algorithm was implemented into the model to identify defects in the bridge's 3D model. This direct approach leverages the precision of visualization capabilities alongside the analytical power of AI to ensure the integrity and safety of the bridge assessment. Implementing AI capabilities exhibits a powerful combination of measurement tools and detection algorithms. The measurement tools show varsity and accurate scales while comparing them with the actual measurements. Training the detection model on a custom dataset can capture different types of defects directly on the 3D model. This introduces tangible benefits to improve the inspection and maintenance of bridge structures.

1 Introduction

The construction industry is responsible of three fifths of the total UK waste [1], and it generates high resources consumption and greenhouse emissions [2]. The high environmental impacts of the construction industry are linked to the linear economy approach of the sector ('take, make, waste'). To achieve net-zero targets, it is essential for the construction sector to introduce circular economy principles [3]. Circular economy is a framework that is based on three principles: eliminate waste and pollution, reuse and recycle resource, and regenerate nature [4].

Bio-based construction materials are materials that are derived from organic renewable and often fast-growing resources. Agricultural waste (flax, straw, hemp) and other recycled fibres (paper, textile), can be used to produce a variety of construction materials, such as insulation, boards, cladding, etc. [5] Because of the organic composition of bio-based materials, bio-based materials can sequester carbon from the environment, contributing to the reduction of carbon dioxide in the air [6]. Moreover, bio-based materials can be easily recycled or reintroduced in the biosphere as fertilisers and compost.

Although bio-based materials demonstrate circular economy principles [7], there is still scepticism in using them in the construction industry. Lack of confidence in their performance and overall benefits, questions on durability and costs are some of the reasons why bio-based materials have not proliferated in the construction sector [8].

To improve confidence in their performance and sustainability, this research uses bio-based materials in demountable wall panels to assess the feasibility and performances of such innovative wall technology. Three wall panel prototypes were designed to test the applicability and compatibility of different bio-based materials in walls, and to investigate different configurations to make walls demountable.

In this paper, an overview of the three panel prototypes is provided, followed by experimental results on the thermal performances of the wall panels. The wall panels were placed in a large environmental chamber (LEC) at the University of Bath, UK, to investigate the actual thermal transmittance of the walls. A life cycle assessment of the bio-based materials used in the wall panels following the EN15804(2014) is also proposed. The cradle to grave life cycle of the materials was assessed and discussed. This work highlights the benefits and challenges of using bio-based materials in buildings, while, at the same time, giving confidence in the applicability of bio-based materials in buildings.

2 Circular Bio-based Wall Panels

2.1 Design Methodology

Three wall panels were prototyped to inform the design of two living labs built in Ghent (Belgium) and in Kloetinge (Netherlands). The prototypes were designed to be adaptable and demountable. Adaptability is the ability to adapt building elements to different use and purpose, while demountablity refers to the reversibility, accessibility to all elements and reusability of the walls. The metrics for the design of the panels were based on the BS ISO 20887:2020 [9] that provides requirements and guidance for design for disassembly and adaptability in buildings. The following general principles for the wall panel design were applied to all prototypes:

- *Expandability*: design can be expanded.
- *Standardisation*: minimisation of the variations of components.

- *Access to components*: minimal work and no damage to access wall elements.
- *Safety of disassembly*: health and safety aspects considered when dismantling the panels.
- *Simplicity*: construct using the same basic structural element, so that the frame can be built in a factory environment
- *Reversible connections*: screw, gravity connections and other solutions that enable the reuse of materials and components.

2.2 Wall Panels Design

The three prototypes consist in a double timber frame panel (Fig. 1a), stainless steel frame (Fig. 1b) and cross laminated timber (CLT) panels (Fig. 1c).

2.2.1 Timber Frame Panel

The first prototype design (Fig. 1a) is based on a frame of C24 structural timber measuring a finished thickness of 42 mm. Two 1.8 m × 1.2 m frames were joined together, A 'crisscross' framing (the first frame containing horizontal timber bracing members and horizontal bracing in the second frame) was constructed to stiffen the main frame (Fig. 2a). Aluminium removable hook connectors were used to join the

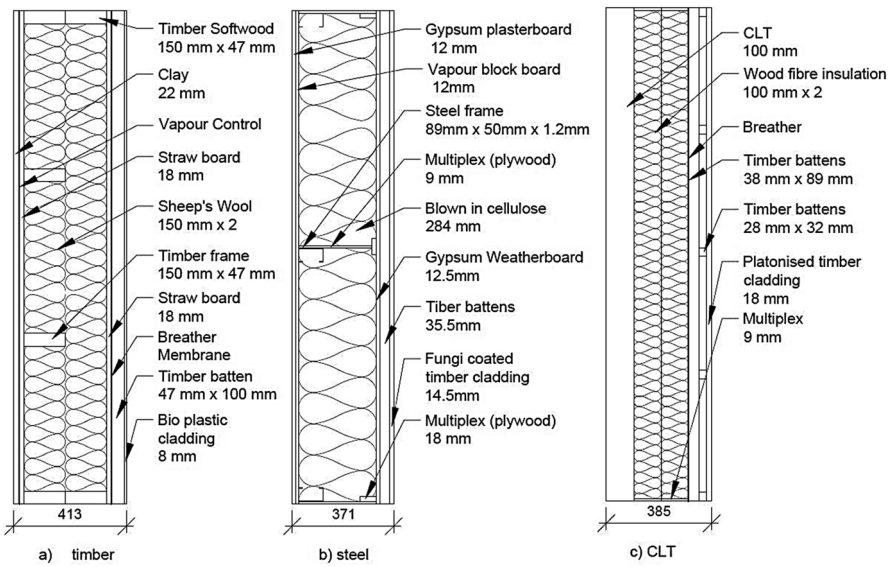

Fig. 1 Section of the three wall panels (mm): (**a**) first iteration timber frame panel, (**b**) steel frame panel, (**c**) CLT panel

Fig. 2 Timber frame panel: (**a**) criss-cross design and (**b**) metal connections

perimetral frame elements together, and the bracing with the perimetral frame (Fig. 2b). These connectors are usually used to connect secondary timber beams to primary. Sheep's wool was selected as insulation material by considering cost, performances, sustainability and availability of the materials in construction-scale quantities [10, 11]. The choice of the façade material was a bio-based polymer composite material manufactured using reed, calcium carbonate precipitated from waste treatment, recovered toilet paper waste [12]. Straw based boards, produced with a soy binding agent were screwed on both sides of the timber frame. As internal finish, a clay board panel reinforced with a textile mesh and wood chips was selected. Commercially available moisture barriers (on the external side) and vapour control layers (on the internal side) were applied.

2.2.2 Stainless Steel Frame Panel

The second panel is a modular light gauge steel frame with blown-in cellulose insulation. Each steel module consists of 900 mm × 600 mm components. Two modules were used to design a 1200 mm × 900 mm wall (Fig. 3a). Internal sheathing boards were affixed to the steel frame, after the drilling of pilot holes into the frame. The internal structural sheathing board consisted of a chipboard with integrated vapour barrier, while the external one is a modified plasterboard with high resistance to fire and weathering. Plasterboard was used as internal finishing. As external façade, a fungi coated timber cladding was used. The cladding was manually coated with the mushroom coating that consists of a layer of linseed oil and a layer of a fungal cells [13].

Fig. 3 Steel frame panel: (**a**) modular light gauge steel frame, (**b**) cladding treated with fungi coating

2.2.3 CLT Panel

The structural element of the third panel was a Cross Laminated Timber (CLT) panel consisting of five laminations joined with a binding agent. Mycelium insulation is used for the prototype. Mycelium is the vegetative part of a fungus, consisting of a network of fine white filaments. 66 mm thick mycelium panels (Fig. 4a) were then joined using a bio-based binding agent. For the façade, a platonised timber cladding was selected (Fig. 4b). The platonisation process consists of a chemical modification of the wood surface through a drying and heating process that increase durability of timber.

3 Hygrothermal Properties

Panels were tested in a Large Environmental Chamber (LEC) at the Building Research Park of the University of Bath under controlled conditions (Fig. 5). The LEC consists of two chambers, with one simulating external environment and indoor conditions, respectively. The prototypes are placed in the central partition wall between the two rooms. The outdoor chamber was set up at 11 °C, while the indoor chamber at 25 °C. Humidity was free to vary. Heat flux, temperature and RH probes

Fig. 4 CLT panel: (**a**) mycelium insulation and (**b**) timber cladding

Fig. 5 On the left, an external view of the LEC; on the right, a view of the partition view with the timber frame wall

were inserted in the walls in correspondence of each layer. Thermal transmittance was observed for 20 days.

From the heat flux and internal and external room temperature sensors, the average thermal transmittance for the 20 days testing was calculated. All the walls comply with the English Building Regulation (Part L) [14] that states that walls in new building should have a U-Value of 0.18 W/m^{2}K or lower. CLT and steel frame

resulted in a U-Value of 0.16 and 0.17 W/m^{2}K, respectively. The timber frame prototype outperformed the others (0.12 W/m^{2}K), but this is due to mainly the significant difference in the thickness of the walls (Fig. 1). Sheep's wool insulation is 300 mm thick, compared to cellulose (284 mm) in the steel frame and mycelium (200 mm) in CLT. There are also some variations on the thermal conductivity of the insulation materials. The declared thermal conductivity for sheep wool and cellulose is 0.039 and 0.40 W/mK, respectively. The declared thermal conductivity is provided by the manufactures. Mycelium thermal conductivity was measure at the University of Bath and it resulted 0.046 W/mK.

4 Life Cycle Assessment of Bio-Based Components Materials

4.1 Life Cycle Inventory and Method

The LCA of the insulation, boards and claddings used in the three panels was performed (Table 1). The aim is to understand whether bio-based materials can help reduce overall Global Warming Potential (GWP100) of the panels. The LCA was conducted to investigate the potential environmental impacts of the circular bio-based building materials by following EN 15804, 2012 + A2, 2019 [15]. The cradle-to-grave impacts were considered by including life cycle stages within Modules A-C. Module D was not included in the study as there are many uncertainties on the loads and benefits of recycling and on the calorific energy produced by bio-based materials when incinerated. The service life of the materials was assumed to be 60 years, which is a standardised reference life span for buildings [16]. A functional unit of 0.15 W/m^{2}K for 1 m^2 of insulation was set up, while for the other materials a declared unit of 1 m^2 was defined, as the thickness of the materials is predefined by the manufacturers. The LCA study was conducted using an attributional framework. LCA was modelled using openLCA version 1.10.3. For background data and, when necessary, for foreground data, ecoinvent 3.6 implemented in EuGeos 15804+A2 IA v4 Unit Processes [17] was used, to enable life cycle impact assessment (LCIA) according to the EN 15804 (2012) + A2 (2019) standard.

Further information on the LCA method can be seen in [18]. The process modelling for insulation, structural, finishing, cladding, sheeting is reported in [18, 19], except for gypsum weather board, vapour block board and platonised timber, for which process modelling is described below (Tables 2, 3, and 4). For

Table 1 Materials assessed using LCA

the end-of-life of the three materials, data can be found in Tables 9 and 10. The Life Cycle Inventory (LCI) was built by collecting data from literature and manufacturers.

4.2 Life Cycle Assessment Results

The results in Table 5 show that materials like sheep wool, cellulose and platonised timber have a low environmental impact, which make the materials suitable to work towards net-zero carbon target. To achieve net-zero it is necessary to improve

Table 5 GWP_{100} of the construction materials ($kgCO_{2e}/m^2$)

Insulation		Finishing		Cladding		Sheeting	
Mycelium	51.2	Clay board	8.6	Bioplastic	46.4	Straw board	6.99
Sheep's wool	10.9	Plasterboard	2.1	Fungi coating	83.9	Vapour block board	7.35
Cellulose	15.7			Platonised	1.4	Gypsum weather board	5.70

recyclability routes for bio-based materials, reduce the amount of chemicals or find more sustainable chemical substitutes to reduce emissions. Chemicals are usually added to bio-based materials to improve durability and performances (especially fire resistance). It is, however, important to notice that not all bio-based materials (Table 5) have low carbon emissions. In this study mycelium produced 215.6 $kgCO_2e/m^2$, which is unusual for a material that is 100% composed of bio-based materials (fungi and plant-based substrate). The reason behind such high value is a combination of high uncertainty around the data collection of mycelium manufacturing and mycelium is not yet widely available on the market. Mycelium, (as well as bioplastic and fungi coating) are relatively new products that did not go through the optimisation process when production is scaled up to industrial scale. Hence, data for LCA are usually collected at laboratory scale or assumption were made [18, 19].

5 Conclusions

Integrating bio-based materials and circular economy principles into wall construction can potentially enhance indoor comfort by providing good thermal insulation and moisture regulations. This paper explored the use of bio-based materials in dismountable wall panel prototypes. The experimental testing showed that the walls have excellent thermal performances with U-Values below 0.18 W/m^2K. Further investigation on the moisture regulation performances in the long term to improve indoor comfort is recommended. The LCA, meanwhile, highlighted some challenges in accurately assessing the carbon footprint of bio-based materials, as some innovative materials are not yet well-established on the market. Some bio-based materials have not yet gone through industrial scale-up and optimisation, and/or data for LCI are not available. Good quality and primary data are necessary to assess the actual environmental impact of bio-based materials, together with life cycle costing analysis. Overall, this paper demonstrated that there is a good potential for bio-based materials to achieve net-zero targets while creating more comfortable living spaces.

1 Introduction

An envelope has a key role in the behaviour of a building since it is its protective system against the outdoor climate. This statement is true for any location in which a building is to be constructed. Hence, it is important to guarantee that the envelope fulfils its role throughout its whole service life. This can be achieved by providing precisely timed building maintenance, which can be determined by having a predic-

tive *building maintenance system* (BMS) [1, 2]. One of the main aims of Staticus Care [3], an EEA and Norway grants financed project, is to develop this kind of tool [4].

The Staticus Care project also aims to develop a novel hybrid unitised façade (HUF) system that replaces part of its aluminium frame by timber [4]. This allows to obtain a more sustainable product [5], given the recent years focus on decarbonizing the built environment sector. It is important to tackle the emissions in this sector because it corresponds to 37% of the total emissions worldwide [6]. It is possible to decrease the carbon footprint of a product if its constituents embodied greenhouse gas (GHG) emissions are precisely quantified. This can be achieved by performing a *life cycle assessment* (LCA) of the product, which is not a novel approach, but has gain a lot of value in the recent years [7]. LCA tracks, throughout a product whole life cycle, the emissions released to nature and the extractions from nature associated to the product [7].

Buildings in the Nordic countries must fulfil even more stringent regulations in terms of heat losses through the envelope compared to other countries [8, 9]. In high-energy efficient buildings, with low energy use, the embodied impacts—production of building materials, construction, maintenance and end of life [7]—become more important than the operation impacts, for example, heating, cooling and lighting [7]. This is also connected to the main message of UN's recent publication [6], in which it is declared that the future decarbonization effort should focus on the building materials.

Buildings are normally designed to have a service life of 50 years. However, it is known that facades have to be, at least partially, retrofitted in the middle of this period, since some of its component's service life is lower than 50 years [10]. The limiting factor is, however, its sealant materials, such as gaskets. They must be replaced due to the wear caused by the environmental impacts, such UV-radiation and moisture [10]. This retrofit has, evidently, financial as well as environmental costs since it will generate waste and consume materials [7].

This study aims to quantify the carbon footprint of a novel hybrid unitized façade (HUF) system by means of developing a cradle-to-grave LCA. Real data for this system, such as material quantities, EPDs and transportation routes, have been used in this study. Ultimately, two hypotheses were tested. This will be achieved by determining the materials used to build one unit of the HUF and respective amounts. Subsequently, the product-specific *environmental product declaration* (EPD) of the used materials was also collected.

The LCA was performed using the tool One Click LCA [11]. The energy consumption was obtained for Oslo, Norway, using a generic office building with the HUF installed. This type of environmental impact studies is scarce in literature for hybrid unitized façade systems [12, 13], but of key importance, if the goals set by the Paris agreement of a more decarbonized built environment are to be met until 2030 [14].

2 Methodology

This study aims to quantify the carbon dioxide footprint of a novel hybrid unitized façade (HUF) unit by carrying out a *cradle-to-grave* LCA based on real data for this specific product. This goal is achieved by applying a multi-set procedure (Fig. 1). Firstly, the materials that compose a unit of HUF were determined as well as their respective quantities. The product-specific environmental product declarations were obtained from each product manufacturer. Secondly, a building energy simulation (BES) model of a specific case-study was run during 60 years for Oslo, Norway. Finally, the performed LCA considers only the HUF unit; no other assemblies, like ceilings or partition walls, are considered.

Climate change (CC) climate files were used, so that the model could account for the expected changes of the climate [15]. The following future RCP (*Representative Concentration Pathway*) climate scenarios were considered: (1) RCP 4.5 (mid-emission scenario) and (2) RCP 8.5 (high-emission scenario), for the period between 2025 and 2084 (60 years). These files were obtained from Meteonorm [16] software. Finally, the carbon footprint of the HUF was determined using the LCA tool, *One Click LCA* [11].

Ultimately, the study explores two strategies for long-term sustainability: (i) examining the impact of retrofitting the façade system elements in accordance with their respective service life and (ii) examining the impact of a complete retrofit of the façade system at 30 years.

The main study limitations are the following: (1) cradle-to-grave LCA is performed without accounting for stage A5, since there is still no information concerning energy spent or the GHGs emissions produced in the installation of the

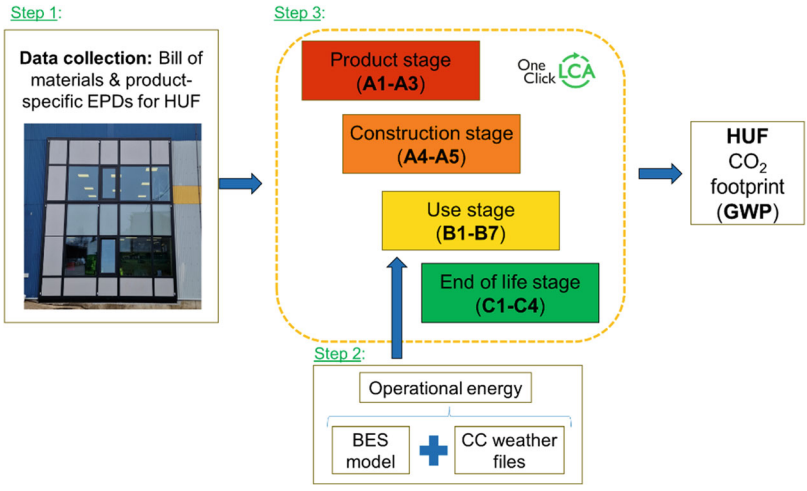

Fig. 1 Step-by-step methodology followed in this study

HUF units in situ; (2) an average energy demand for a span of 60 years is considered due to software; and (3) the influence of the material deterioration in the energy demands is not considered.

2.1 Hybrid Unitized Façade

Staticus Care has developed a HUF system [3] which replaces part of its typical aluminium frame by timber with the aim of reducing the HUF's carbon footprint. This approach is understandable given that while timber is a low-intensive energy material (4.6 MJ/kg [17]), aluminium is a highly intensive energy material (201.0 [17]) and, consequently, has a much higher CO_2 embodied value (15.1 ton CO_2/ton for aluminium and 0.35 ton CO_2/ton for timber [17]).

The HUF system has already been previously studied but more in the scope of its hygrothermal performance [18–20]. This study focuses on the quantification of the HUF carbon footprint. The HUF is composed by three different zones (Fig. 2), namely: (A) Opaque zone—external finishing, mineral wool and tin sheet (U-value of 0.129 W/(m^{2}K) [20]), (B) Frames—aluminium profiles and glue laminated timber (U-value of 0.375 W/(m^{2}K) [20]), and (C) Transparent zone—triple glazed glass unit (U_{window}-value of 0.5 W/(m^{2}K) [20]).

Fig. 2 Example of the Hybrid Unitized Façade (HUF) system

2.2 Life Cycle Assessment Database

A comprehensive *cradle-to-grave* LCA will be performed here to determine the carbon footprint of a HUF unit. The materials used to build a unit of the HUF were covered by their respective EPDs. These were obtained by contacting their respective producers. Each of the inputted materials' amounts was adopted in accordance with the respective EPD declared units.

The major contributors to the total weight of each HUF unit are the following materials: (1) windows, (2) timber, (3) steel, (4) aluminium, and (5) insulation (Table 1). Of course, these materials will have different embodied GHG emissions given their associated environmental impacts and resource use [7].

Table 1 presents the major material families that compose a unit of HUF and their global warming potential (A1–A3) per family weight. This latter index allows to ascertain the most pollutant material families while considering their weight. It is visible that the sealants family is the most polluting, while timber family is the less polluting one. A total of 16 product-specific EPDs were used to determine carbon footprint of the HUF and assess its global warming potential (GWP).

2.3 Building Energy Simulation

The building energy simulation (BES) model used in this study was previously developed by Coelho and Kraniotis [20] in WUFI®Plus. It corresponds to a room with 150 m^2 of a generic office building that has the HUF installed in its building envelope. The exterior envelope satisfies the TEK17 [8] limits imposed to attain a minimum level of energy efficiency. As it was demonstrated by Coelho and Kraniotis [20], the total net energy for office building for the three simulated Norwegian climates was well below the limit imposed by TEK17, that is, 40% for the three tested climates [20].

Table 1 Major material families and respective weights (in %) in relation to the total weight of a HUF unit and global warming potential (A1–A3) per family total weight (in kg CO_2e/kg)

Material family	Aluminium	Windows	Insulation	Sealants	Steel	Timber
Weight	10%	53%	6%	1%	11%	16%
GWP/ Weight	1.5 kg CO_2e/kg	1.4 kg CO_2e/kg	0.5 kg CO_2e/kg	7.6 kg CO_2e/kg	2.1 kg CO_2e/kg	0.3 kg CO_2e/kg

Minor materials are not represented (total < 3%)

Table 2 Legal limits (minimum requirements) in Norway for *U*-values and leakage number according to its regulation [8] for office buildings

Parameter	$U_{ext,\ wall}$ [W/(m^{2}K)]	U_{roof} [W/(m^{2}K)]	U_{floor} [W/(m^{2}K)]	$U_{windows}$ [W/(m^{2}K)]	Air leakage [h^{-1}]
Norway	0.22	0.18	0.18	1.20	1.50

Table 3 Minimum air flow rates for mechanical ventilation in office buildings in Norway and setpoint temperatures for heating and cooling according to SN-NSPEK 3031 [21] during operating hours (DOH) and outside operating hours (OOH)

Specific airflow rate (m^3/(h.m^2))	*DOH*		*OOH*	
	7		2	
Setpoint temperature (°C)	*DOH*		*OOH*	
	Min	Max	Min	Max
	21	24	21	24

In addition, it was also reviewed the legal minimum limits for *U*-values and leakage number (Table 2), which were considered when defining the envelopes. The opaque zone and frame zone *U*-values (Sect. 2.1) yield an equivalent *U*-value of 0.17 W/(m^{2}K), which guarantees the legal limits in Norway. Additionally, the window *U*-value (triple glazing) is also below the minimum value for Norway.

The model assumed the indoor gains depicted in the Norwegian specification SN-NSPEK 3031 [21] for office building by means of day profiles, which account for the occupants' use of the space. The model considers the occupants, technical equipment and lighting system influence on the heat and moisture load that the software considers (WUFI Plus). In addition, this specification also defines the ventilation during and outside operating hours and the setpoint temperatures during and outside the operating hours (Table 3). All these aspects can be a significant source of variability in LCA [22].

An efficiency of the heat recovery of the ventilation system of 80% was assumed, as it is a typical value for all systems with balanced ventilation in new buildings in Norway [8]. In addition, the same energy use as the ones depicted in SN-NSPEK 3031 for lighting, technical equipment, hot water and specific fan power was assumed. A more detailed explanation about the assumed loads and performed conversions can be found in Ref. [20].

2.4 Climate Files

Climate change, which has been largely caused by anthropogenic GHGs emissions, is expected to change considerably the outdoor meteorological conditions [23]. This change will depend on the location, but a great variability exists in future climate modelling. This is due to the long span of time that it takes into consideration and the variance of all the parameters that influence the climate models.

Hence, two climate change scenarios were selected for this study, namely, (1) RCP 4.5 corresponds to a mid GHGs emissions scenario [24] and (2) RCP 8.5 corresponds to a high GHG emissions scenario [24]. Consequently, the energy simulations were run for 60 years, which corresponds to the lifespan of the product (HUF). The climate files—current and future conditions—were downloaded from Meteonorm tool [16].

3 Results and Discussion

3.1 General Considerations

This study explores two strategies for long-term sustainability (Sect. 3.4): (i) examining the impact of retrofitting the façade system elements in accordance with their respective service life and (ii) examining the impact of a complete retrofit of the façade system at 30 years. Two future scenarios are considered—RCP 4.5 & 8.5—for one European capital—Oslo (cold climate).

The facility that produces the HUF units is in Vilnius, Lithuania. The building's location corresponds to sites in which Staticus has a lot of installed façade projects: Oslo, Norway. For this location, the HUF will be transported using articulated trucks that are partly including ferry trips. The following distance, which consist of the actual routes, was considered in stage A4 (Transport): 1261 km, including 275 km in ferry.

3.2 Future Energy Demand with the HUF System

The total energy demand (Fig. 3a), which includes heating and cooling demands obtained from the BES simulation while accounting for climate change, and the other components as described in Sect. 2.3, had to be annually average. These values include heating and cooling demands from the BES model, and hot water, technical equipment, lighting and specific fan power uses in accordance with SN-NSPEK 3031 [21]. The obtained averages were 65.8 kWh/m^2 for RCP 4.5 and 65.3 kWh/m^2 for RCP 8.5, which is atypical, but understandable if the heating and cooling demands are assessed.

It is interesting to see the substantial difference in terms of heating and cooling energy demand between the two scenarios (Fig. 3b, c), more substantial at the end of the century. While for RCP 8.5, the heating demand decreases considerable due to the increase of the global air temperature, the cooling demand also increases considerably. For RCP 4.5, these changes are not so significant. Note that this behaviour is understandable in a cold climate, but it is expected to differ for other climate typologies [25].

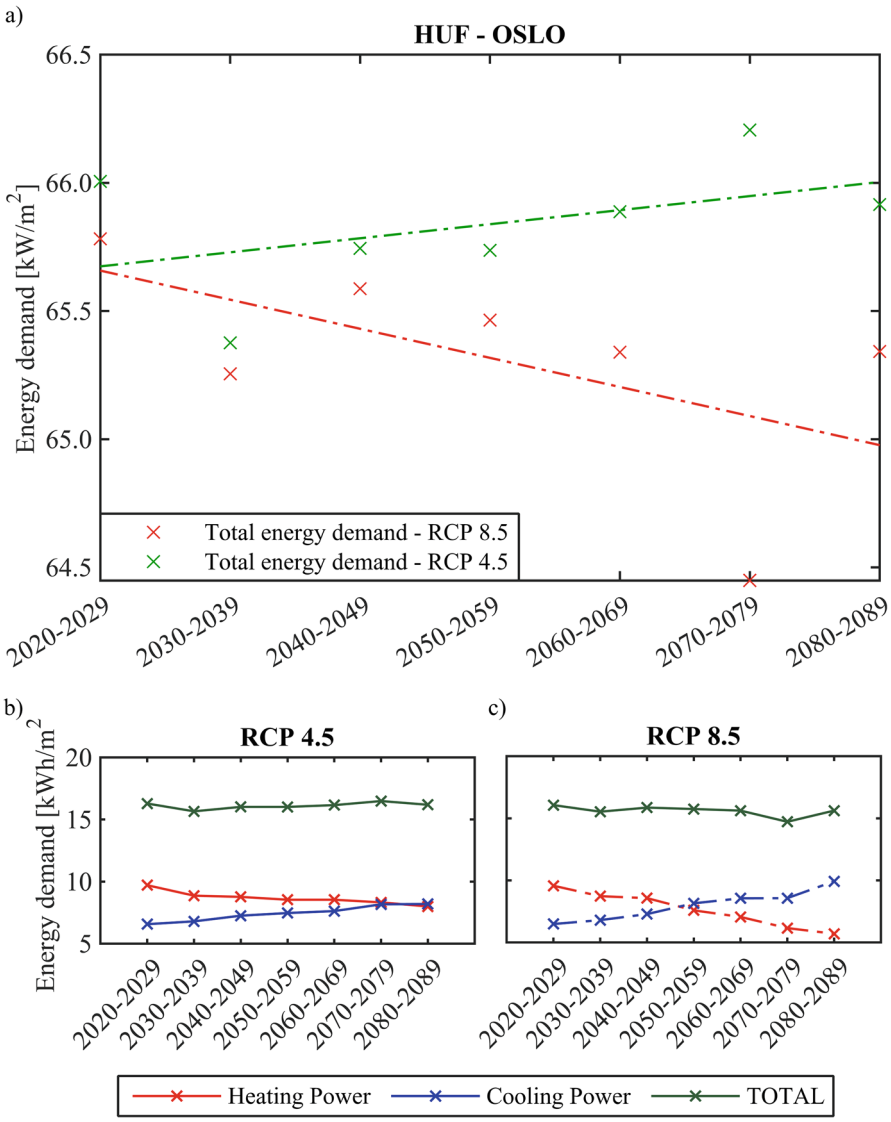

Fig. 3 Average energy demands for each 10-year period from 2020 to 2089 for RCP 4.5 & 8.5 scenarios (**a**), and heating, cooling and sum energy demand for RCP 4.5 (**b**) & 8.5 (**c**)

The limitation of having to calculate an average energy consumption occurs because the calculation methodology of One Click LCA automatically multiplies the energy demand by the admitted service life of the product. This, unfortunately, is a limitation when aiming for a dynamic LCA [22], since the energy demand has to be adopted and, therefore, the two software are not fully connected.

3.3 Carbon Footprint of the HUF System

Figure 4 shows the global warming potential (GWP) obtained for the HUF system for Oslo based on a cradle-to-grave LCA for two climate change scenarios—RCP 4.5 and RCP 8.5. It is visible that both stage A4 (*Transport to construction site*) and stage C1–C4 (*End of life*) are negligible when compared to the other stages. Stage B6 (*operational energy*) has the highest responsibility in terms GWP—72% for RCP 4.5 and 71% for RCP 8.5. This stage is then followed by A1–A3 (*Product stage*)—21% for both RCP 4.5 and RCP 8.5.

It is also visible that the differences between the two cases are slightly visible in stage B6, which is natural given that the outdoor climate differs [19]. However, it is important to state that only the HUF is accounted in stages A1–A3, neglecting the remaining envelopes' contribution to this stage and the other stages. This is a limitation of this study, but it also allows to assess the LCA results that correspond to just the HUF. Finally, in total, the HUF corresponds to a GWP of 129 kg CO_2e/m^2 for scenario RCP 4.5 and 128 kg CO_2e/m^2 for scenario RCP 8.5.

3.4 Refurbishment Measures Influence on the HUF's LCA

A LCA can be used as a tool to define a building's material replacement and refurbishment strategy by means of its CO_2 emission. This methodology was applied here by means of using two different retrofit strategies: (1) using the materials'

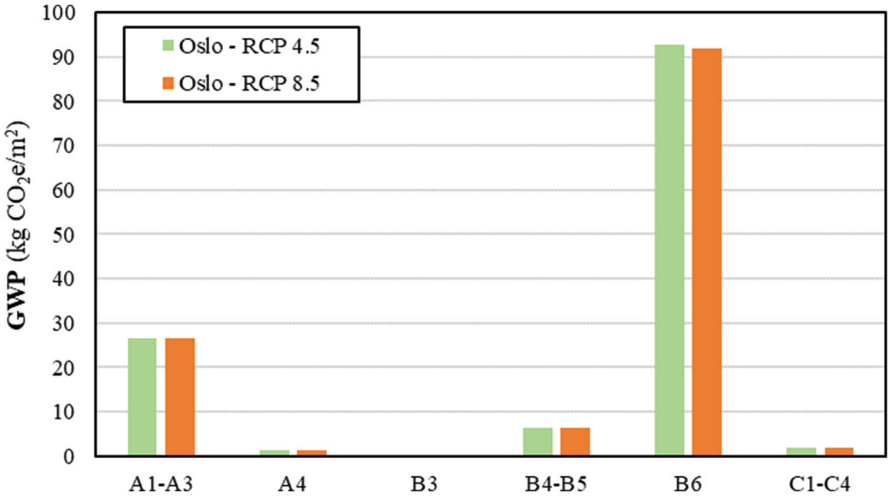

Fig. 4 Global warming potential of the HUF for Oslo (Norway) for two climate change scenarios—RCP 4.5 & RCP 8.5

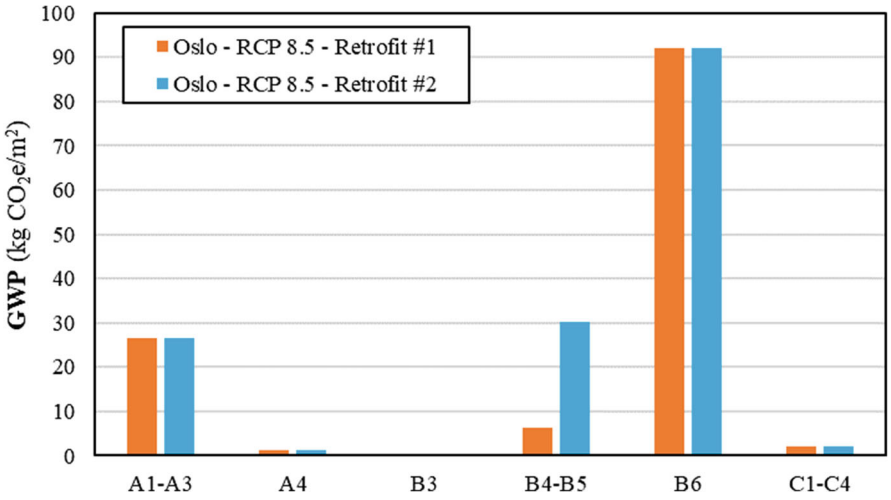

Fig. 5 Global warming potential of the HUF for Oslo (Norway) for scenario RCP 4.5 for two retrofit options

defined service life (retrofit #1) and (2) all materials are replaced at 30 years except for the glues and silicones, which must be replaced with a lower frequency (retrofit #2).

The influence of this second strategy is only visible in the B4–B5 stage (*Material replacement and refurbishment*) which goes from an individual GWP of 6 kg CO_2e/m^2 (4%) to 30 kg CO_2e/m^2 (18%) (Fig. 5). However, it is important to take into consideration that the natural wear of the building materials will cause the decrease of the building's energy performance, which means a higher consumption of energy. Hence, it is necessary to incorporate the material deterioration into stage B6 in future studies to obtain a more comprehensive value.

4 Conclusions

This study reflects on a cradle-to-grave life cycle assessment (LCA) of an innovative hybrid unitized façade (HUF) system using One Click LCA. The energy demands were determined using a representative office building model for Oslo, Norway. Two future climate scenarios were considered, namely, (1) RCP 4.5 (mid-emissions scenario) and (2) RCP 8.5 (high-emission scenario).

The global warming potential for HUF in Oslo is 129 kg CO_2e/m^2 if the world evolves according to what is depicted in scenario RCP 4.5, or 128 kg CO_2e/m^2, if it follows scenario RCP 8.5 pathway. The operational energy state is responsible for the highest emissions of the total life cycle impact—56% for RCP 4.5 and 55% for RCP 8.5, followed by the product stage—21% for both RCPs.

Two refurbishment strategies were tested: (1) using the materials' defined service life and (2) materials are all replaced at 30 years. It was shown that this second strategy increases substantially the CO_2 emissions by 24 kg CO_2e/m^2 in the material replacement and refurbishment stage (B4–B5) emissions. However, it is necessary to account in future studies for the material deterioration in the energy simulations to determine if this second strategy effectively decreases or not the total GWP of the HUF.

One of the observed limitations of the applied methodology was the fact that it is not possible to account for the energy demand for the whole period, that is, adopted service life. Consequently, it is necessary to use an average value that is representative of the whole period. This is a limitation that needs to be overcome, so that the LCA results can better reflect the influence of the stochastic nature of the outdoor climate on the energy demand. The authors are currently developing a Revit plug-in designed to execute cradle-to-cradle LCAs directly from Revit, using material quantities derived from the Building Information Modelling (BIM) and dynamically linking them to the energy needs shaped by the external climate. This integration will provide sensor data to fine-tune energy simulations within Revit, eliminating the dependency on external software by embedding this capability through a software-as-a-service (SaaS) model. Such an approach ensures the plug-in streamlines dynamic LCA studies for new buildings and embeds energy simulation tools within Revit. Furthermore, future developments will explore methodologies to quantify the impact of material/product deterioration on a building's energy demand, enhancing strategies for effective refurbishment. This tool will allow dynamic LCA studies to be more accessible, thus addressing current challenges.

Acknowledgments The authors acknowledge the EEA and Norway grants for the financial support through project LT07-1-EIM-K01-003 ("*Development of a less polluting, automated façade system integrated into building management systems*").

1 Introduction

Optimizing the use of ultra-high-performance concrete (UHPC) in critical structural applications has become an important topic in the building and construction industries [1–7]. Although there are a number of studies carried out to utilize the strength and durability characteristics of UHPC [4–6], very few dedicated studies have focused on the excellent impact resistance capabilities of UHPC, which can be utilized in structures in the event of accidental impact loads [7–13]. The implementation of UHPC to resist impact loads is vital mainly where there is a high risk of windborne debris hazard, such as tornado-alley within the United States or other tornado/hurricane-prone regions within the other parts of the world. Majority of the buildings (residential and commercial) in the United States are constructed using construction friendly methods and lightweight materials. These types of buildings

have been found to be at a higher risk of damage under the debris impact [14]. Therefore, to enhance building protection and mitigate the risk of structural damage due to windborne debris impact, while also minimizing the concrete usage, UHPC wall systems present a promising solution for entire construction industry in tornado/hurricane-prone regions. With the increase in the fluctuating weather and environment, it has become imperative to assess the impacts of extreme events and also improve the resiliency of the structures.

In typical residential and commercial construction, various types of walls are employed, including wood stud walls, light-gauge metal stud walls, precast concrete walls (solid, composite, and ribbed), tilt-up panels, and cast-in-place concrete walls are used. Such conventional wall assemblies typically exhibit poor performance when subjected to impact forces from different windborne debris missiles [15, 16]. The performance of these conventional walls, however, can be improved by modifying the structural section of the wall systems or utilizing a composite section to enhance their impact resistance capability. However, such alternatives involve an increase in the material quantities, additional weight and corresponding increase in the cost of construction, which further becomes unpractical [14–16].

A review of the existing literature by Kulkarni and Shafei [12] reveals that many of the most used wall assemblies are insufficiently robust to endure both the basic and enhanced impact tests. Thus, there is ample scope to consider UHPC wall panels as a potential alternative. UHPC offers excellent compressive, tensile, and flexural strengths compared to normal-strength concrete. Although numerous studies have explored the performance of reinforced concrete (RC) walls under impact loads, there exists a gap in the literature concerning the application of UHPC walls to provide the anticipated impact protection particularly against the windborne debris. This gap served as the motivation for the present study, which aims to conduct comprehensive investigation of UHPC wall panels of varying thicknesses subjected to different debris impact scenarios. In order to address a diverse range of impact intensities, lumber debris specified in ICC (2014) [16] and a schedule 40 steel pipe outlined in DOE [17] are utilized. These objects serve as representative projectiles commonly employed for assessing windborne debris impact on both basic and enhanced protection facilities, respectively.

2 Walls Under Impact

To study the impact of windborne debris on UHPC and NSC panels, the Karagozian and Case (K&C) concrete damage model was utilized within the LS-DYNA software package. This model, developed through physics-based analyses of RC walls under blast effects, served as the foundation for the investigation [18–24]. In the simulations, eight-node solid elements with a single-point integration algorithm with a mesh size of 10 mm were used. Several validation simulations were carried out to accurately predict the values of different material parameters of UHPC material. Uniaxial compression, uniaxial tension, four-point flexure tests were simulated

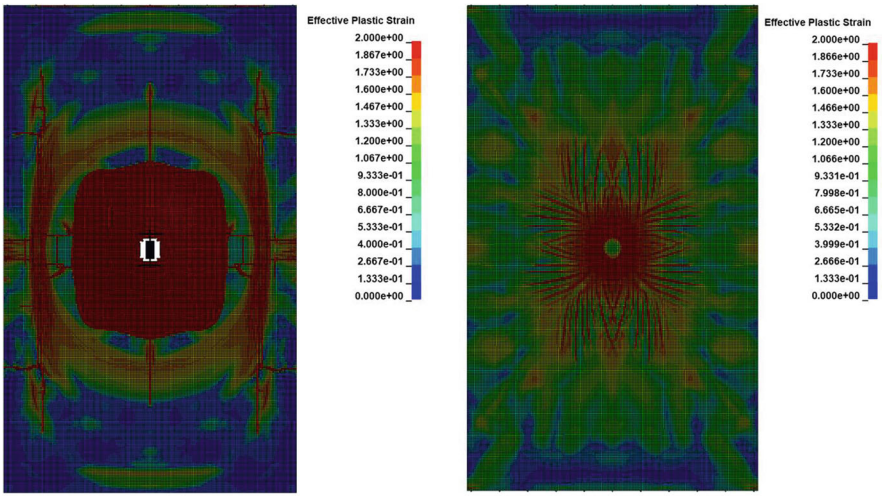
within the LS-Dyna package. Detailed discussion on validation at the material and full-scale levels is presented in Kulkarni and Shafei [12]. After validating the entire simulation setup, including the UHPC material model, the simulations of windborne debris impact were conducted. In these simulations, UHPC with compressive strength of 175.3 MPa was assumed. The panels were 1830 mm × 3050 mm (6 ft × 10 ft) in dimensions. The panels were assumed to have thicknesses of 80 mm (3.15 in), 100 mm (4 in), and 150 mm (6 in). The top and bottom faces of the walls were assumed to be fixed. Further, unreinforced and reinforced UHPC panels were studied.

In the case of reinforced UHPC panels, minimum reinforcement of 0.0018 times the gross cross-sectional area was assumed. The missile 2″ × 4″ (50 mm × 100 mm) 15 lb. (6.2 kg) was modeled per the specifications of ICC 500. For the enhanced protection test, pipe missile having a diameter of 6 in. (152.4 mm) with a mass of 130 kg as per the DOE standard was employed. A rigid model was used for the impacting debris in windborne debris impact simulations. The simulations were developed for a vertical surface, for which ICC 500 recommends a velocity ranging from 35.5 to 44.7 m/s and DOE further recommends using 49.1–67.0 m/s for testing of impact protective assemblies. To conduct simulations, FE models of lumber with velocities of 10, 30, 40, 50, and 70 m/s, and pipe with velocities of 22.2, 34.0, 45.1, and 55.5 m/s were developed.

3 Results of Impact on UHPC and NSC Walls

The response measures of the simulations such as deflection of the walls, type and extent of damage, and residual velocity of the projectiles are reported in Table 1 for the reinforced UHPC walls, under lumber and pipe projectiles. In the presented tables, MS refers to minor spalling, which is noted when some pieces of concrete are separated from the impacted face of the wall panel, while the panel maintains its overall integrity; PN refers to the situation where the debris begins to penetrate into the panel, forming a hole (or footprint), which is often equal to or slightly larger than the debris diameter; SB is reported if the spalling of concrete from the rear surface occurs, while the panel maintains its overall integrity; and PR is noted when the scabbing and depth of debris penetration increases to a level that a perforation is observed.

4 Findings and Discussion



From the simulation results obtained for the 76.2 mm UHPC wall (with embedded reinforcement) under the impact velocity of 70.0 m/s of the lumber missile, the projectile perforated the wall panel with a rebound velocity of −1.4 and a deflection of 6.5 mm. For the 101.6 mm UHPC wall (with embedded reinforcement), at impact

velocity of 70.0 m/s, the 101.6 mm wall provided protection from perforation with damage to its back in the form of scabbing. In the case of 152.4 and 203.2 mm UHPC walls, the lumber missile with an impact velocity of 70.0 m/s was not able to cause any damage and rebounded. From the simulation results obtained for the

(a) (b)

Fig. 1 Damage in wall panels under a lumber missile with an impact velocity of 70 m/s: (**a**) 76.2 mm UHPC wall, and (**b**) 101.2 mm UHPC wall

76.2 mm UHPC wall (with embedded reinforcement) under the impact velocity of 22.2 m/s of the pipe missile, the projectile perforated the wall panel, and the pipe missile was able continue with a velocity of 15.4 m/s. The size of the perforation was 272 mm × 272 mm (Fig. 1).

For all the other impact velocities (34.0, 44.1, and 55.5 m/s), the wall was perforated by the pipe missile, with the increase in perforation damage dimension. For the 101.2 mm UHPC wall (with embedded reinforcement) under the impact velocity of 22.2 m/s of the pipe missile, the projectile again perforated the wall panel, and the pipe missile was able continue with a velocity of 11.6 m/s. The size of the perforation was 265 mm × 272 mm. For all other impact velocities (34.0, 44.1, and 55.5 m/s) the wall was perforated by the pipe missile, with the increase in perforation damage dimension. For the 152.4 mm UHPC wall (with embedded reinforcement) under the impact velocity of 22.2 m/s for pipe missile, the projectile perforated the wall panel, however its residual velocity was significantly reduced to 2.0 m/s. For all other impact velocities (34.0, 44.1, and 55.5 m/s) the wall was perforated by the pipe missile, with the increase in perforation damage dimension. For the 203.2 mm UHPC wall (with embedded reinforcement) under the impact velocity of 22.2 m/s of the pipe missile, the wall panel was able to withhold the pipe missile from incurring any damage, and only minor damage was caused in the form of minor scabbing. With the increase in the impact velocities (34.0, 44.1, and 55.5 m/s) the wall was perforated by the pipe missile, with the increase in perforation damage dimension.

5 Material Saving and Embodied Carbon

The use of UHPC in applications where windborne debris hazard is significant can reduce the material usage and amount of carbon emission contribution. To calculate the amount of carbon contribution of UHPC and NSC walls, the embodied carbon of typical UHPC mix and typical NSC mix were calculated using the ICE Database. The database provides emission factors for more than 200 materials including cement, aggregates, bricks, mortars, glass, and timber. For a typical UHPC mix of 175–200 MPa compressive strength, the embodied carbon content was found to be 1031 kg/m^3. For a typical concrete mix of 35 MPa compressive strength, the embodied carbon contribution was found to be 521 kg/m^3. Figure 2 shows the embodied carbon prediction of typical 175 MPa UHPC and 35 MPa NSC concrete mix.

Based on only embodied carbon contribution UHPC and NSC walls, UHPC mix shows two times embodied carbon contribution than NSC concrete of 35 MPa. The required thickness of UHPC wall to resist the perforation of the lumber missile when the velocity is less than 50 m/s is 76.2 mm, whereas for NSC walls, it is 152.4 mm, which is twice the thickness of the UHPC wall. While embodied carbon contribution of UHPC and NSC walls are the same, the amount of material saved by the use of UHPC wall in lieu of NSC concrete wall is on average 0.56 kg/m^3. With the advancement in the UHPC mixes, the benefit of UHPC can be maximized and its overall CO_2 contribution can be reduced further to make it viable from environmental point of view as well.

The highest contribution of CO_2 in UHPC mix comes from cement. Utilizing industrial by-products like fly ash, slag, or silica fume as partial replacements for cement, thereby reducing the carbon footprint associated with cement production can reduce the cement dependency and thereby reducing the carbon contribution. Another potential strategy in reducing the carbon contribution of UHPC is to use

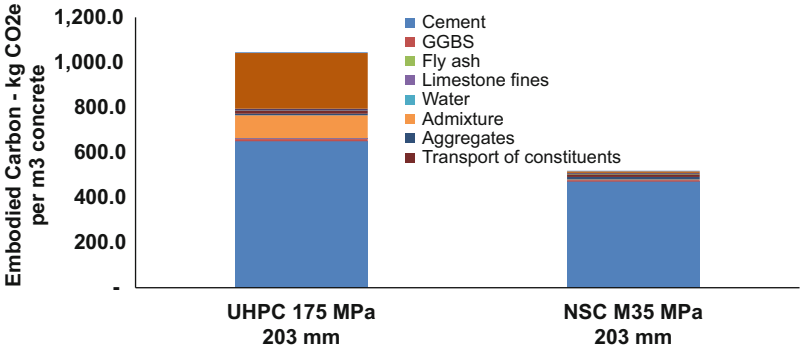

Fig. 2 Embodied carbon contribution of NSC and UHPC

locally available aggregates to reduce the emissions from transportation activities. The third potential strategy is to use optimum levels of admixtures to reduce the emissions arising from the admixture.

6 Conclusions

Small or large windborne debris travelling at a medium (20–50 m/s) to high (50 m/s and above) velocity can cause severe damage to structures within the tornado or hurricane prone regions, which can lead to partial or complete collapse of the structure. In this study, windborne debris impact assessment of UHPC and NSC walls was systematically performed considering two objects, i.e., lumber and pipe. Afterward, the embodied carbon contribution and savings in material quantities was evaluated. The results show that 76.2 mm UHPC can withstand the impact of lumber object at medium velocities (20–50 m/s). For the same range of medium velocities, NSC wall requires a thickness of 152.4 mm. At the highest impact velocity (70 m/s) of the lumber object, 101.6 mm UHPC wall can stop the object from perforating the wall barrier. For the same highest impact velocity (70 m/s), 152.4 mm NSC thick wall is required to stop the lumber object from perforating. The embodied carbon contribution of the reduced UHPC wall and NSC wall was found to be the same. However, the use of UHPC wall can offer additional advantages by reducing the required concrete volume.

1 Introduction

Shear walls are crucial structural members used as a part of lateral-resisting systems of buildings to resist lateral loads such as seismic and wind forces. Reinforced concrete shear walls have traditionally been constructed using normal-strength concrete (NSC); however, there has been increased research in the last decade to substitute the NSC and reinforcement with nonconventional materials of higher strength such as ultra-high-performance concrete (UHPC) and high-strength steel (HSS). The former provides greater lateral performance such as greater energy dissipation capacity, higher shear strength, and greater ductility when utilized in shear walls [1]. A transition to shear walls with nonconventional materials in the building industry would benefit sustainability by requiring less material.

Hung et al. [2] experimentally assessed the seismic behavior of four UHPC shear walls reinforced with HSS and tested them under displacement reversals. The study found that the specimens with steel fibers performed greater in terms of 50% better flexural strength and an increase in 70% in shear capacity, thus the utilization of UHPC in shear walls gave an advantage of better earthquake-resisting ability. Similarly, Li et al. [3] conducted cyclic tests on five squat UHPC shear walls and one high-strength concrete (HSC) counterpart. The study found that the shear capacity and ultimate deformation of the UHPC specimens significantly improved by 85% and 95%, respectively, compared to HSC.

In another comparative study, Kulkarni et al. [4] performed a holistic investigation of various UHPC shear walls exposed to cyclic loading to imitate the loading shear walls during earthquake and wind exposures. FE models were initially developed and verified with experiments. Simulations were then carried out to grasp the response of UHPC shear walls compared to NSC shear walls. The results indicated that the UHPC shear walls had on average 32% greater shear capacity than their conventional counterparts. On the other hand, the study found that a transition from normal-strength steel bars to high-strength steel-embedded bars increased the maximum shear capacity of the wall specimen as well.

The literature review reveals an increasing interest of UHPC in shear walls designed for seismic-prone zones. However, the previous investigations have been limited to only a few geometric details. Therefore, it is crucial to explore the structural performance characteristics of various shear wall sections to minimize material usage and meet design requirements. This study numerically assesses the benefits of utilizing UHPC instead of NSC by developing a set of finite elements (FE) models in the Abaqus software subjected to a nonlinear static analysis (pushover analysis). Initially, the study verifies a benchmark wall model for NSC and one for UHPC against existing research. This is followed by an examination of the load-bearing capacity and the damage progression of the walls. Furthermore, an investigation was carried out on the NSC walls, wherein their thickness was incrementally increased to evaluate if they could achieve strength levels comparable to those of UHPC.

2 Finite Element Modeling

A total of three specimens are modeled in this study using Abaqus. Table 1 provides their geometry and dimensions. The UHPC specimens are assumed to have a steel fiber content of 2%. The concrete compressive strength was 35 MPa for NSC and 140 MPa for UHPC. The steel bars, made of S500B grade steel, had a yield strength of 500 MPa and a diameter of 4.5 mm. These specimens were analyzed under a pushover load which was horizontally applied to the top section of the walls.

Table 1 List of the six different FE models

Model number	S1	S2	S3

Thickness	0.08 m	0.08 m	0.16 m
Length	0.6 m	0.6 m	0.6 m
Aspect ratio	2.5	2.5	2.5
Concrete type	NSC	UHPC	NSC

2.1 Material Properties

The concrete damage plasticity (CDP) model is one of the possible material models that can predict the constitutive behavior of concrete in Abaqus [5]. This model assumes that the two main failure mechanisms are tensile cracking and compressive crushing of the concrete material. The plasticity parameters for NSC are adopted from the experimental investigations conducted by Krahl et al. [6]. The skeleton curve is based on the stress–strain data of the NSC material, while the damage parameters, d_c and d_t are calculated based on the "effective" tensile and compressive cohesion stresses as described in Eqs. 1 and 2 [7].

$$d_c = 1 - \frac{\sigma_c}{\overline{\sigma}_c} \tag{1}$$

$$d_t = 1 - \frac{\sigma_t}{\overline{\sigma}_t} \tag{2}$$

where σ_c and σ_t are the compressive and tensile stresses, respectively, while $\overline{\sigma}_c$ and $\overline{\sigma}_t$ are the nominal compressive and tensile stresses, respectively.

While the CDP model has proved to accurately predict the behavior of NSC, numerous studies have validated the material model for its accuracy in simulating the behavior of UHPC as well [1, 8–10]. Consequently, this study employs the CDP model based on its established effectiveness. The constitutive behavior is defined by the skeleton curves derived from Singh et al. [11]. Furthermore, the compression damage parameters are also sourced from Krahl et al. [6], given their extensive research on damage characterization. In contrast, the tensile damage parameters were calculated using Eq. 2.

For the reinforcement, the elastoplastic model was adopted. Initially, the material behaves elastically, deforming under load and returning to its original shape upon unloading. This phase continues until the stress reaches the yield point, where plastic deformation begins, and the material undergoes a permanent change in shape.

2.2 Establishment of the Model

In Abaqus, the shear wall was modeled using three distinct parts: the main wall, vertical rebars, and horizontal rebars, which were then connected using the

embedded region constraint method to create an interaction between the concrete and reinforcement elements. Two reference points were placed at the top and bottom sections of the walls using coupling constraints for easier application of loads and boundary conditions. The shear wall models were simulated by eight-node reduced three-dimensional solid elements (C3D8R), and the steel bars were simulated by three-dimensional two-node truss elements (T3D2). The wall experienced a constant axial load ratio (ALR) of 6% applied at the top and was simultaneously subjected to a lateral pushover load, expressed in terms of drift ratios. The bottom section of the wall remained fixed throughout this process. The drift ratio was calculated as the ratio of the lateral displacement at the top of the specimen to the specimen height (1500 mm). For the simulation, the mesh size was established at 25 mm for both the wall and reinforcement, after a rigorous mesh sensitivity analysis.

2.3 Verification of the Normal Strength Concrete Model

The numerical model of the NSC shear wall constructed by Nguyen et al. [12] is employed for model verification. The slender shear wall was subjected to a consistent vertical compressive load of 90 kN at the top, accompanied by a progressively increasing horizontal displacement of 14.2 mm, while the bottom was fixed.

Figure 1 illustrates the damage patterns between the experimentally tested specimen and the established FE model. Initially, damage manifests along the bottom edge of the wall at a displacement of 2.02 mm. The wall experiences a bending failure which occurs at a displacement of 14.2 mm. As shown, the results from the FE model aligned well with the experimentally tested specimen. From the pushover curves that compare load and displacement for both the experimental and FE models of the NSC shear wall, it can be observed that the numerical pushover curves closely match the experimental data, with some slight differences of strength at various displacements. The experimental shear wall underwent abrupt failure at an approximate displacement of 14 mm, where it exhibited a sudden reduction in strength

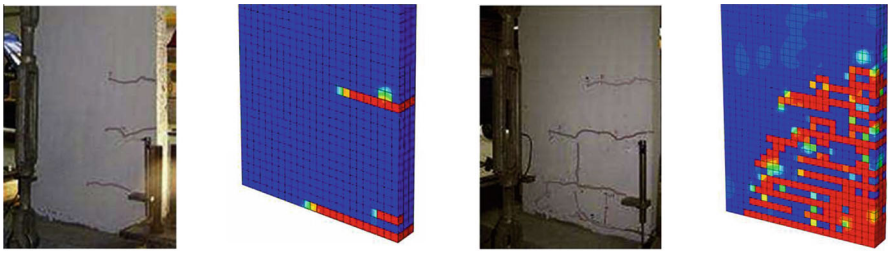

Fig. 1 Comparison of experimental test [12] and FE failure modes of NSC shear wall (**a**) 2.02 mm displacement, (**b**) 14.2 mm displacement

[12]. At this ultimate displacement, the loads recorded were 25 kN for the experimental model and 23.5 kN for the FE model, indicating a close correlation between the two specimens with a percentage error of 6%.

2.4 Verification of the UHPC Model

The shear wall model constructed with UHPC is validated through comparisons with the studies by Hu et al. [1, 13]. The bottom of the wall was fixed, and a constant vertical axial load of 1428 kN was applied at the top. Additionally, a pushover displacement of 39 mm was implemented to simulate the effect of a cyclic load.

Following the approach of Hu et al. [1], which simplified their investigation by modeling a half-scale UHPC shear wall, this study adopts the same strategy for consistency. Whereas their analysis focused on cyclic loading, this research explores the effects of pushover loads on shear walls. To ensure the methodology's reliability, this study conducts a comparison between the skeleton curves obtained from Hu et al. research and the skeleton curves generated in this investigation. These results display a notable similarity, although the verification model exhibits a lower load at various drift levels, except in the range of 0.25% to 1%, where it demonstrates higher loads. This discrepancy is likely due to simplifications in the numerical model concerning the mechanical properties of UHPC and steel rebars, in addition to considerations of geometry, loading configurations, and the material model used. The FE model and experimental outcomes exhibit maximum load capacities of 743 kN and 794 kN, respectively, resulting in a percentage error of 6.86%. This indicates that the load capacity of UHPC can be accurately predicted using the developed FE details alongside the adopted CDP model, despite the minor deviations observed.

3 Results and Discussions

This section details the results for the six models simulated in Abaqus. It begins by comparing the shear walls, focusing on the differences in damage development, and load-bearing capacities between NSC and UHPC. Subsequently, an investigation is undertaken, which involves increasing the thickness of the NSC walls, aiming to align their strength with that of UHPC walls.

3.1 Slender Shear Walls

This section examines the slender shear wall models for NSC (S1) and UHPC (S2). Figure 2 shows the damage progression of the two models and illustrates that both exhibit horizontal shear cracks at their lower sections. For the S1 model, horizontal

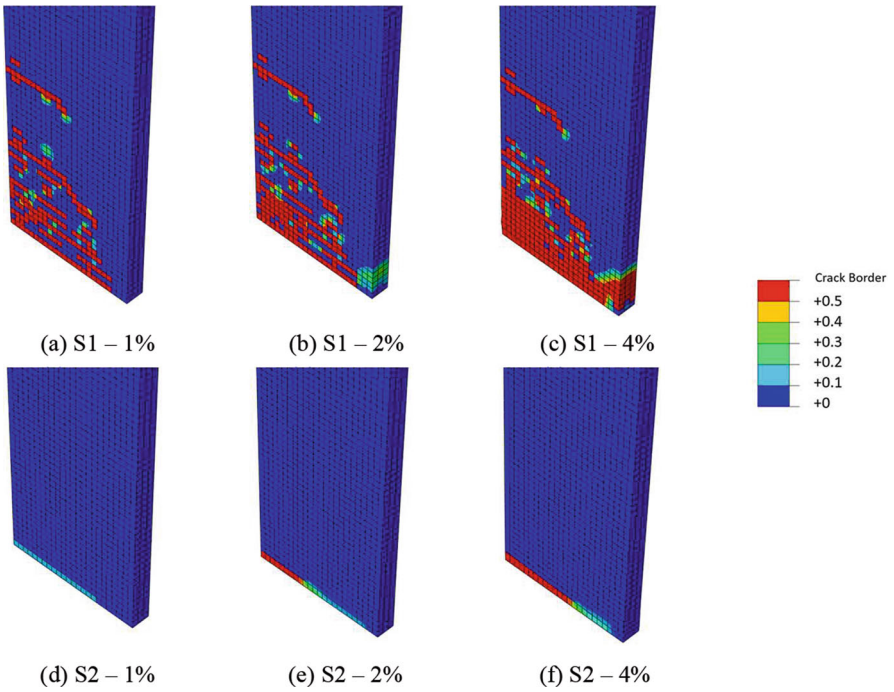

Fig. 2 Damage progression of the shear walls for models S1 (NSC) and S2 (UHPC) (**a**) S1–1% (**b**) S1–2% (**c**) S1–4% (**d**) S2–1% (**e**) S2–2% (**f**) S2–4%

cracks initiate at the bottom of the wall and propagate toward the center. Concurrently, diagonal cracks develop in the middle of the shear wall, expanding diagonally across its surface. After reaching a 2% drift, the wall started to develop cracks along the bottom edge on the opposite side which became more noticeable once the wall achieved the maximum drift ratio of 4%. In contrast to S1, cracks in S2 were solely located in the concrete elements at the base. The damage progressed linearly without significant deterioration. Based on the side-by-side comparison of the shear walls, it can be noticed that the UHPC shear wall is capable of handling much higher loads before experiencing failure compared to its NSC counterpart. The biggest factor influencing this is considered to be the addition of steel fibers, which have been noted to significantly increase the shear capacity and tensile strength of the shear walls. The UHPC shear wall showed its structural integrity with the potential to resist larger displacements than the ones investigated in this study.

Initial cracking in both models occurs at a drift ratio of 0.06%, with Model S1 experiencing a load of 10.8 kN and Model S2 a load of 14.5 kN. The enhanced material strength, along with the addition of fibers allows the material to exhibit superior crack control behavior. The peak strength achieved by the NSC shear wall was 29 kN with a 0.6% drift ratio, while the UHPC model attained a peak strength of 132 kN at a lower drift ratio of 0.95%. This indicates a substantial enhancement in

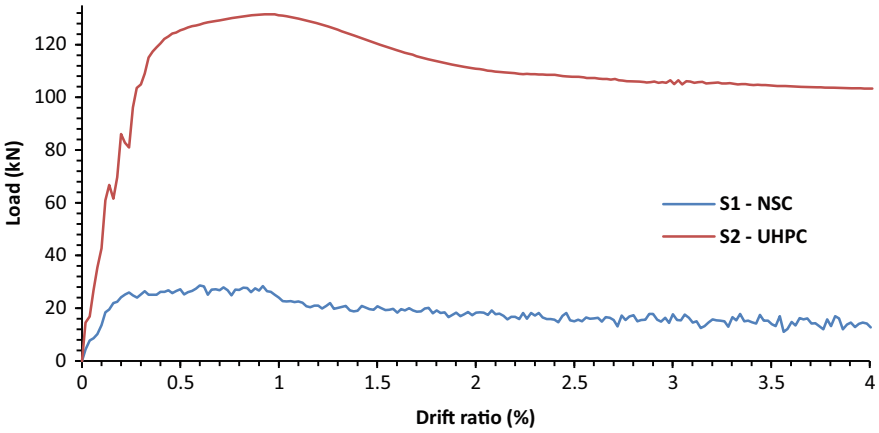

Fig. 3 Load–displacement curves comparing the FE models for S1 and S2 shear walls

peak strength for the UHPC, surpassing the NSC by 103 kN. The S1 model maintained its strength fairly consistently after reaching peak levels, exhibiting a gradual linear decrease rather than a significant drop. Upon reaching 85% of its maximum drift capacity, the load diminished to 12.4 kN, corresponding to a modest reduction of 14.8% in strength. In contrast, S2 exhibited a decline to 109 kN in strength, which was then stabilized and followed a linear decrease towards the maximum drift.

This behavior can be attributed to the inherent strength of the UHPC material. Given that the reinforcement was identical to that in the NSC model, it likely could not complement the advanced performance of UHPC, thus becoming less effective in bearing additional loads once the UHPC reached its peak strength. After reaching 85% of its maximum drift, the load dropped to 104 kN, resulting in a drop of approximately 21%. Figure 3 presents the load-displacement curves of the two models, showcasing a distinct divergence that highlights the UHPC model's substantial load-bearing advantage.

3.2 Shear Wall Thickness Evaluation

An investigation was conducted on the slender shear walls to enhance the understanding of the model's response with different thicknesses. This study focused on a single variable: increasing the thickness of the NSC shear walls to evaluate if their load-bearing capacity and damage characteristics could match those of the UHPC specimens. Model S3, designed for this scenario, features a thickness of 160 mm and is detailed in Table 1. Furthermore, when increasing the wall thickness, it is essential to evaluate two crucial parameters: the axial load ratio (ALR) and the reinforcement ratio. The ALR is assumed to be uniform across all models, calculated as per Eq. 3.

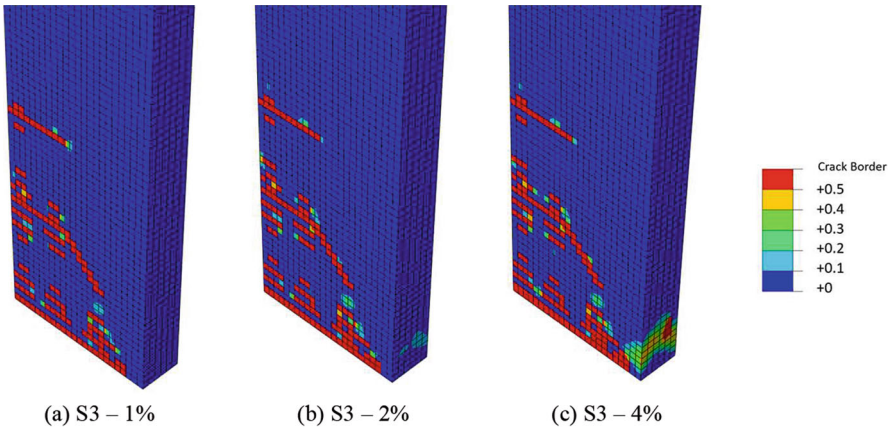

Fig. 4 Damage progression at different drift ratios for model S3. (**a**) S3–1% (**b**) S3–2% (**c**) S3–4%

$$ALR = \frac{N}{f_c A} \tag{3}$$

where N is the constant vertical axial force, f_c is the compressive strength, and A is the cross-sectional area of the wall. This equals an axial load of 201.6 kN for model S3. The cross-section of the reinforcement is determined by calculating the reinforcement ratio which resulted in a cross-section of 31.77 mm^2.

The damage progression of S3 is shown in Fig. 4. It can be noted that the damage progression begins similarly to the NSC shear wall. However, due to the increased thickness, there was less damage progression, even at the maximum drift ratio of 4%. Notably, the extent of damage remains consistent across the three drift ratios (1%, 2%, and 4%), with the primary observable change being the emergence of minor cracks on the lower edge of the opposite side post-2% drift. The increased thickness of the wall and cross-section of the reinforcement for S3 contribute to a decelerated damage progression, attributed to enhanced robustness.

Figure 5 presents the load-displacement curves of models S1, S2, and S3. The curve for S3 indicates a marked enhancement, with a load-bearing capacity double that of S1, and a 93% increase in peak load compared to the original. This significant improvement is mainly due to the augmented wall thickness, which offers a larger cross-sectional area, facilitating a more efficient stress distribution across the wall and thus increasing its ability to resist pushover loads. Additionally, the increased thickness of the wall not only provides additional space for reinforcement but also contributes to a larger cross-sectional area for the reinforcing materials, increasing the wall's strength. While increasing the thickness of the wall enhances its material qualities compared to the standard, the UHPC in model S2 shows a distinctly superior performance, with a 138% greater peak load. This stark difference between the performance of models S2 and S3 suggests that the advanced material properties

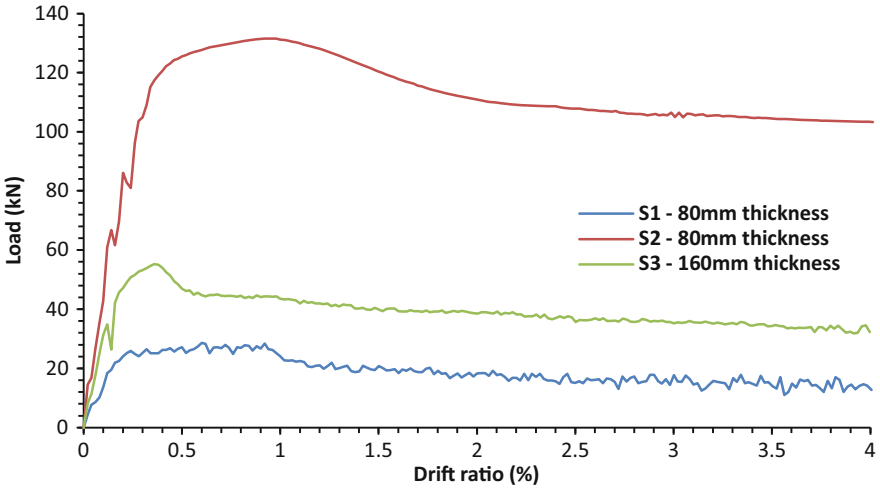

Fig. 5 Comparison of the load–displacement curves for S1, S2, and S3

of UHPC greatly enhance the structural capacity of shear walls, potentially allowing for thinner walls to be used without compromising, and even enhancing, lateral load performance.

4 Conclusions

A comparative study on the lateral load performance between UHPC and NSC shear walls was conducted. The objective of the pushover analysis conducted in Abaqus software was to evaluate the performance of UHPC relative to NSC in terms of strength and damage resistance. The findings indicated that UHPC walls exhibit superior damage resistance with damage primarily localized at the base elements and having the capacity to support increased loads due to the integration of steel fibers. Additionally, the UHPC walls demonstrated superior load-bearing capabilities, achieving a peak strength that surpassed the NSC model by 103 kN. Even when the thickness of the NSC shear wall was doubled, it failed to match the performance metrics of UHPC in terms of both damage progression and load-bearing capacity. This enhanced NSC wall exhibited damage patterns akin to the standard NSC wall, and while its peak load capacity increased by 93%, the UHPC model still outperformed it by 138%.

1 Introduction

1.1 Reclaimed Timber

Circularity emphasizes the importance of maximizing service time for wood products through cascading use, directing them towards various destinations [1]. This approach ensures that these products contribute the highest value to society for as long as possible, primarily due to their capacity for carbon storage [2]. For wood, it is

the objective to maintain its use at the highest utility level and structural integrity before it transitions in multiple use cycles to lower-grade applications and incineration. This circular concept is challenged [3, 4]. Key issues for timber reuse are concerns around the treatment, usage, and storage, and especially the quality of reclaimed wood. While virgin wood comes with certification and other data, this lacks for used timber. Here, data might have never been determined, or have been regarded as unnecessary and deleted, or lost during a building's life. This complicates its reintegration into the building industry [5]. Robust and automated methods for efficient non-destructive estimation of mechanical properties and quality assurance become crucial to bridge these gaps, ensuring reclaimed timber's reapplication in the construction, including means to ensure the longevity of data and its maximized use in material passports, templates, or catalogues of secondary material suppliers.

1.2 Goal and Objectives

This study is based on an ongoing investigation with the goal of developing a non-destructive modelling pipeline for the prediction of mechanical properties of reclaimed timber based on X-ray CT scanning and numerical modelling. The objectives of this paper are to (i) provide a background of the challenges that the current practice of quality assessment of timber is confronted with regarding reclaimed material and (ii) propose and describe a data-driven modelling pipeline for the prediction of stiffness and strength of individual reclaimed timber elements based on CT scans.

2 Background

2.1 Challenges of Traditional Grading Regarding Reclaimed Timber

Timber used in the structural capacity in European buildings must adhere to the harmonized standard EN14081 and supporting standards. It sorts rectangular cross-section timber into categories based on the three grade-determining properties (GDPs) strength (MoR), stiffness (MoE), and density. These categories do not state anything about the actual properties of the individual piece of timber but solely operate on a statistical level. In particular, the lower fifth percentile of the underlying distribution defines the strength and density of a class, whereas the mean is used for stiffness. Similar approaches are used for all materials with inherent uncertainty induced, e.g. by heterogeneity as in wood (see EN 1990). Building codes consider these uncertainties and make, e.g. engineers apply structural calculations (punitive)

safety factors on the mechanical properties of materials. This results—at least from a structural engineering and economic perspective—in an overengineering of timber buildings and increased consumption of resources.

2.2 Non-Destructive Assessment of Virgin Timber

The challenge of the resources' heterogeneity and uniqueness of every piece is addressed in the non-destructive assessment of each piece in the grading process. The current European system for grading allows visual and machine grading. In both cases, some measurements are used to establish a correlation to the three GDPs, which in turn must be elicited during destructive testing on a sufficiently large sample from the specific growth area [6]. Visual grading is executed by humans, who assess a range of features that affect strength, stiffness, and density, including knots, slope of grain, ring width, and reaction wood. Machine Grading assesses in contrast only one or a few properties of the timber. The measurement results of e.g. resonance or density establish indicating properties (IPs) that are then used to predict the GDPs and thus the grade. IPs typically serve as more robust indicators of quality compared to those assessable through visual grading. Machine strength grading expedites the process significantly and reduces susceptibility to human errors.

The underlying principle of both approaches is the correlation between detected features and grades. This correlation is established in large test series and is upheld through repeated testing of samples. The correlation is specific to a species and a growth area, which limits the use of the data to a specific region and even individual sawmills or other manufacturers have their own set of IPs.

2.3 Towards Non-Destructive Assessment of Reclaimed Timber

The transition of these assessment practices to reclaimed timber introduces significant challenges due to the inherent diversity and unpredictability of reclaimed materials [7]. Unlike virgin timber, reclaimed wood comes in a wide range of dimensions and conditions and contains potential contaminants such as metals in the form of nails or dust and surface modifications (e.g. brushed surfaces, impregnation, and coating). This variability, resulting from, e.g. mechanical wear, environmental exposure, and alterations from previous uses, demands flexible and robust systems for quality assurance.

The current rules for non-destructive timber assessment have been developed for a narrow set of variations in the input material with respect to, e.g. geometry and moisture content, while factors, which affect the quality of reclaimed timber, such as

loading history or cracks would today in most cases disqualify the timber from use in a building context [8]. A further challenge is the classification systems focus on specific species and their place of growth to determine IPs, such as density. While this approach fits well with sawmills with a regional intake of wood, it becomes challenging when an urban area with heterogeneous buildings becomes the site for timber sourcing.

Related research and standardization efforts are going on for many years, motivated by emerging circular timber practices, or preceding this in building conservation and restoration, where the quality of old timber needs in structures needs to be assessed. Recently standards have been proposed to deal with the terminology and general rules for reclaimed timber and how contamination and treatments of reclaimed timber shall be evaluated [9]. The first standard for the visual grading of reclaimed timber shall undergo a hearing in the summer of 2024. Some existing standards, such as the Italian UNI11119, provide already means for the assessment of old timber using a combination of on-site inspections and non-destructive techniques [8], while other research shows how measurement of samples in accordance with US standards might provide means to assess the necessary mechanical properties for construction [7]. While the latter approach is cost intensive and project specific, reports about the former show that neither visual nor non-destructive testing methods, such as ultrasound or stress wave methods or local methods such as pilodyn or resistograph measurements show a sufficient correlation with mechanical properties determined in mechanical tests [8]. Bergsagel and Heisel list a series of criteria that should be considered, when characterizing reused timber: (i) the different dimensions of traditional timber elements with respect to actual sawmill products, (ii) technological characteristics, such as wane, must not exclude timber from being assessed, but simply influence the effective resistant cross-sectional area, (iii) the importance of knots on the mechanical properties and the need to take the actual size, shape, and direction of the internal knots into account and not solely their 'superficial incidence', (iv) the need to have a homogenous moisture distribution in the timber elements, and (v) the frequent use of hardwood in existing structures and the need for its improved characterization.

A transfer of the current quality assessment for timber, based on grading with its limitations regarding region and species, into a circular economy faces inhibitive challenges. It is, therefore, necessary to develop alternative assessment methods, adapted to dissimilar pieces of timber with unknown origins and with a large variety of defects and additional unknowns.

2.4 CT Scanning for Reclaimed Timber

X-ray computed tomography (CT) has originally been developed for clinical applications, but today it is also an industrially available technology which can provide information about the internal density distribution of a scanned object non-destructively. CT scanning of wood at the millimetre scale is used in the sawmill

industry for optimizing the positioning of the cut [10], but research has shown that CT images at this resolution (growth ring scale) can also be used for investigations of wood physical [11–13] and wood mechanical properties, in particular, if the local variations of fibre orientations can be estimated from the image gradient. The field-based nature of the gathered data enables the creation of models based on computational mechanics, e.g. finite element (FE) models, which have been used to successfully predict the stiffness, strength, and initial crack location in individual pieces of dry virgin sawn timber [14].

CT-based modelling presents an opportunity for an accurate and detailed assessment of the mechanical properties of individual reclaimed timber elements, especially since their moisture content is typically below fibre saturation, which yields a higher contrast between the various biological features in the CT images.

CT scanning at the required scale for modelling can be performed at high feed speeds like a sawmill's processing speed, i.e. approximately 1–2 m/s. However, CT-based numerical modelling, like in [16], may depend on the model complexity and the specific hardware and software implementation, currently not be able to keep up with this pace. If individual pieces of timber can be tracked throughout a processing facility, then in-line high-speed evaluations may not be necessary. Instead, once a piece of timber has been scanned, it could be stored until its mechanical properties have been estimated and its optimal use has been determined. CT-based numerical modelling at a high level of detail may also be a precursor for more simplified data-driven modelling, e.g. based on laser scanning or discrete X-ray scanning, which both require less investment in equipment.

3 Materials and Non-Destructive Data Acquisition

The reclaimed timber for this study was supplied by the Norwegian company Omtre AS. From their storage in Hønefoss, Omtre contributed timber samples, including 56 planks with cross-sectional dimensions 49×98 mm^2 and five round barn logs, all varying in length. The materials represent two exemplary histories of reclaimed elements: one for premium barn elements and one for reclaimed construction wood.

The barn timber originated from an old barn in Brøttum, Ringsaker (Fig. 1). Constructed in 1870, the barn was a timber-framed structure with exterior cladding.

Fig. 1 Demounting the barn in 2022, provided by Omtre

This style of barn, known as an ‘enhetslåve’ or ‘one-unit barn’, became prevalent in Norway around 1850 and consolidated multiple farm functions (storage for hay, equipment, and animal shelter). The log house portion provided weather and cold protection for the animals, utilizing pine for its rot-resistant heartwood.

The original positioning of the barn logs in the building could not be reconstructed, since this information was lost during Omtre’s reclaiming of the logs [17]. Nevertheless, based on knowledge concerning cultural heritage preservation, Omtre estimates that the barn logs used in this study very likely served as the supporting foundation and beams under the first floor.

The reclaimed construction timber originated from a building site of student apartments at Kringsjå (Norway) and had been temporarily used in the construction process and was subsequently regarded as waste. Due to Omtre’s collaboration with contractors, this wood was collected in containers at the site and saved from incineration. Any remaining metal fasteners were removed from all timber elements prior to storage in Hønefoss, where shelter from precipitation was provided, but neither heating nor air conditioning. The timber remained in storage for approximately 2 years.

The timber was *CT scanned* without additional treatment or cleaning at the Division of Wood Science and Engineering of Luleå University of Technology (LTU) in Skellefteå, in January 2024. For the construction timber, all samples were positioned standing upright in the scanner, maintaining consistent orientation regarding the pith and the ends corresponding to the top and bottom of the tree (see Fig. 2). A consistent identification (ID) numbering system was applied and a specific positioning sequence was followed in the image plane to identify the individual beams in the scans.

The timber was scanned employing a helical scanning trajectory in an industrial CT scanner (Microtec MiTO) adapted for research, at a tube voltage of 180 kV and current of 5.55 mA. The images were reconstructed to an equally spaced voxel grid of $0.5 \times 0.5 \times 0.5$ mm^3, and the density in kg/m^3 was calculated from the CT number.

Fig. 2 56 planks and 5 barn timber logs (left), sample setup during CT scanning (middle) and a section of the scan (right)

4 Computational Modelling Framework

The workflow of the developed framework is illustrated in Fig. 3. On a conceptual level, it consists of three steps: (1) image analysis and feature detection, (2) geometry extraction and volumetric discretization, and (3) data-driven material modelling. Prior to analysis, the 3D CT images were cropped to represent only single timber elements including a small frame of 30 voxels containing the surrounding air. All image processing was performed using the free and open-source libraries SimpleITK, DIPlib, and OpenCV in Python.

For *step (1)*, the CT image data of each beam can be regarded as a volumetric density field, $J(x, y, z)$, on an equally spaced rectangular grid. First, wood needs to be separated from the background (e.g. air), which can be achieved by thresholding on J and subsequent image closing operations to remove internal holes. The segmentation results in a Boolean mask which allows a fast estimation of the element boundary and its rough shape. The total volume of the object can be derived simply by summing up the voxels contained within the mask and accounting for the voxel scale. For segmenting other regions of interest with distinctly different densities, like knots, growth rings, high-density inclusions, or contaminants, e.g. nails, thresholding may be also suitable. Some features may require a more subtle analysis of the density field and its spatial rate of change, i.e. its gradient and higher-order derivatives. These include the separation of early- and latewood, the location of the pith [18], and the estimation of the fibre tensor (longitudinal, radial, and tangential material orientations) using the gradient structure tensor [15]. For the preliminary trials of our study, only the volume mask and outer shape of the timber were extracted, and the fibre tensor was calculated.

The density field and the extracted biological regions and features—the volume mask, the knots and contaminant regions, the early- and latewood regions, and the fibre tensor—were collected in a data structure referred to as the *Body of Properties* (BoP). The BoP serves as an expandable record of relevant properties in the underlying continuum that can be 'harvested' for subsequent modelling and simulation steps. Most properties are stored as volumetric samples at various resolutions, depending on the property. For example, density is available at the full scanning resolution, while material orientation might be available at a coarser resolution

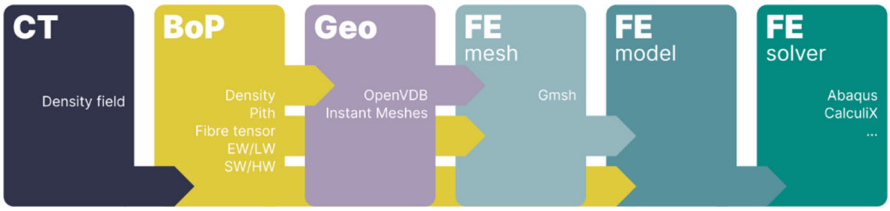

Fig. 3 Schematic overview of the prototyped framework

depending on the radius of the kernel that is used to analyze the volume gradient. Features such as knots are stored as volume regions, but they could also be represented by a lightweight parametrized shape or a computer-aided design (CAD) surface.

In *step (2)*, for usage in further analysis, simulation, and CAD environments, the volumetric data is converted to a boundary representation such as a non-uniform rational B-spline surface (NURBS) or a discrete triangle or quad mesh. The most straightforward method is to extract the isosurface of the density field at the masking threshold described above, which results in a robust and watertight mesh. For this study, the open VDB library and toolset were used to extract the surface mesh. In applications, where a surface mesh at the full scanning resolution is undesirable or too unwieldy, the volume grid may be down-sampled to a coarser resolution prior to meshing. Here, the remeshing software Instant Meshes was used to decimate the surface mesh and generate a higher-quality mesh topology to facilitate further usage. The remeshed surfaces contained only quad elements that follow the topology of the original timber element (Fig. 4). The quads were subsequently converted to NURBS patches, creating a solid NURBS model for use in traditional CAD environments, which provides high flexibility for downstream applications and modelling.

For volumetric finite element (FE) meshing of the identified geometry of the scanned object, the free and open-source meshing software Gmsh was used in Python. Its interface is particularly convenient regarding finding the locations of Gauss quadrature integration points for each element, which is required for the subsequent material modelling (Fig. 5a).

For *step (3)*, the FE mesh is incorporated into an FE model, where loads and boundary conditions were applied according to the desired analysis, and a material model was employed which was informed about the underlying properties from the BoP at each integration point. The model was written to an input file (.inp) which is interpretable by the commercial FE solver Abaqus and open-source solvers like CalculiX. The material model was implemented by user subroutines for either Abaqus or CalculiX, in which the local material orientations and the density were imported at each integration point (Fig. 5b). Since any information from the BoP

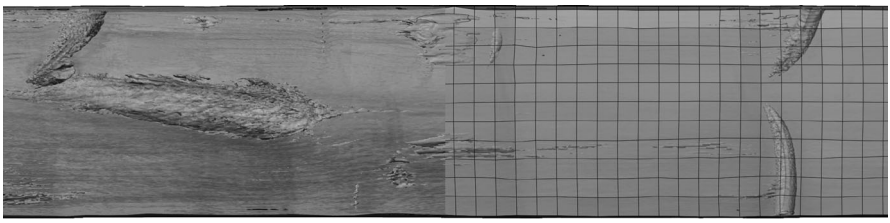

Fig. 4 The isosurface of the timber element boundary (left) is remeshed into a coarser quad-only surface mesh, suitable for further conversion into NURBS surfaces (right). The isosurfaces of knots are included for reference. The information about these is finally stored in the BoP

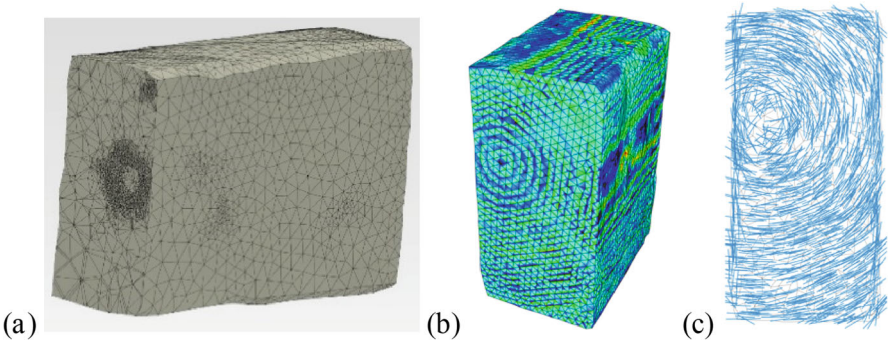

Fig. 5 Adaptive 3D meshing of a portion of the timber element using Gmsh, with a smaller element size around high-density regions, such as knots (**a**), 'harvested' density field in a FE model (**b**), and corresponding tangential material orientations (**c**)

could be accessed by the material model, arbitrarily refined approaches could be implemented, e.g. scaling the stiffness tensor by factors related to density and proximity to knots [16] or varying a hygromechanical material behaviour depending on features in the BoP [12].

For CalculiX, a custom user material was created as a stand-alone shared library which is called by the solver. Currently, it replicates the behaviour of a standard orthotropic material model; however, it can be adapted to incorporate the range of properties from the BoP, as well as different methods of loading and querying them. Typical procedures for loading external data into the solver in user material involve writing per-integration point data to one or many files and then opening these files during the model initialization. In this study, the user material accesses a block of shared memory that is populated by another process, allowing it to query the BoP directly without writing and reading files. While the primary advantage is to access speed, it also means that this procedure could be expanded to query the BoP dynamically or include other behaviours defined during runtime. The vision is to arrive at a model ecosystem where the BoP—or several BsoP—can inform and mediate between design, material analysis, and simulation models in a flexible and extensible way.

A linear elastic orthotropic material law was applied using a stiffness tensor with constant textbook values for spruce, while the material orientations were varied according to the BoP (Fig. 5c). To evaluate the mechanical properties of the modelled timber, pure bending was simulated on partial lengthwise sections along the beam and on the full beam. The mid-point deflection during bending was recorded and the local bending stiffness (MoE) was calculated from it using the approach in [16]. In addition, a frequency analysis with free boundary conditions was conducted to extract eigenfrequencies and eigenmodes.

5 Preliminary Trials and Discussion

Our investigations are part of an ongoing study, and therefore the results mainly serve demonstrative purposes. Results of the analysis of a single beam from the construction timber are presented. From the CT image analysis, an average density of 536 kg/m^3, a total weight of 5.694 kg, and a length of 2.194 m were elicited. Figures 6 and 7 show the 'harvested' density field in the FE model of the beam and, respectively, for a partial section with corresponding absolute transverse stress (perpendicular to the fibre) during pure bending. All displacements are scaled, and the plotted values are qualitative for comparison (red indicates higher, and blue indicates lower values). Figure 6 additionally shows the first longitudinal mode in the frequency analysis, at a longitudinal eigenfrequency of 440 Hz. The bending stiffness was evaluated for consecutive 250 mm long sections along the beam (Fig. 8) and in the resulting profile, the bending stiffness dropped as expected in regions with large knots.

The simulation-based bending deflections, eigenfrequencies, and stiffness profile may be used to assess the stiffness of the individual pieces of reclaimed timber and serve as predictors for bending strength. The stress field during bending may be used

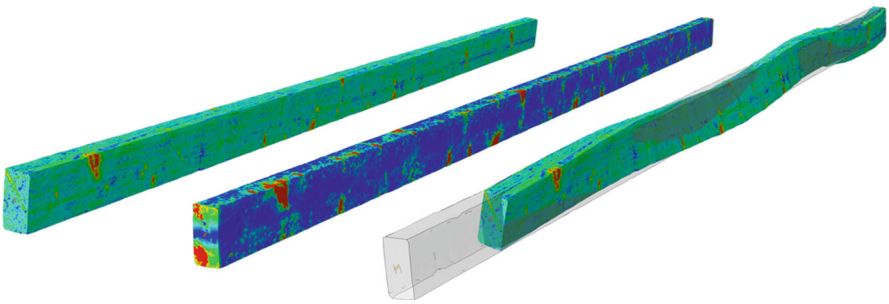

Fig. 6 Full beam FE model showing the density field (left), the absolute transverse stress field under pure bending (middle), and the first predominantly longitudinal vibration mode (right)

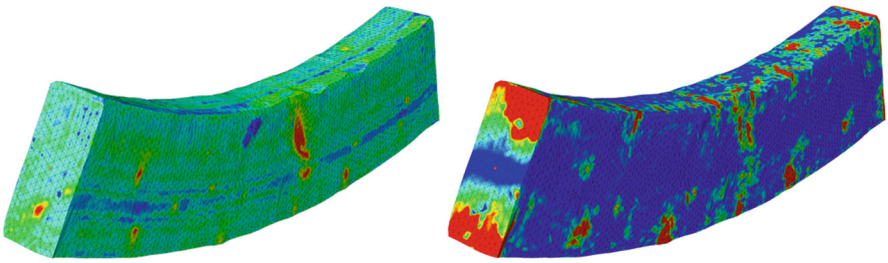

Fig. 7 FE model for a partial section of the beam, density field (left) and corresponding absolute transverse stress field (right)

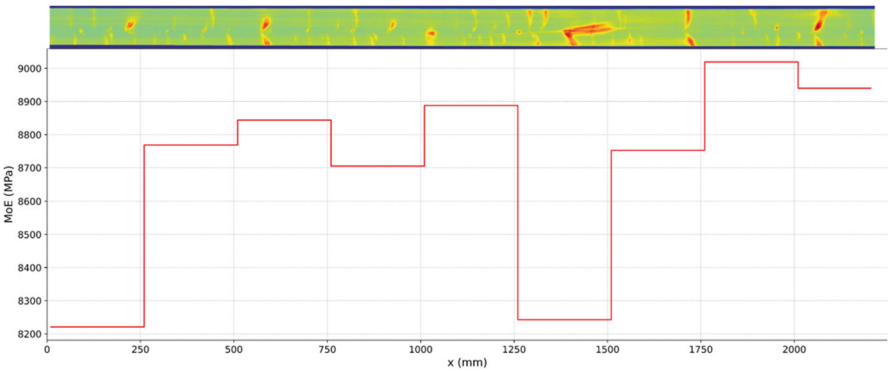

Fig. 8 Bending stiffness profiles for the evaluated sections of the studied beam. The average density along the thickness direction is plotted on top, and red colours indicate higher and blue lower values

to evaluate the susceptibility to failure under increasing load, e.g. by employing maximum stress or a Tsai-Wu anisotropic failure criterion.

The preliminary trials of our presented pipeline demonstrate the soundness of its working principle and that the simulation results already reside in a reasonable range. The used models have not yet been fine-tuned, e.g. by error checking the fibre reconstruction, in specific at boundaries, or by letting the stiffness tensor vary depending on the underlying biological tissue (knot, latewood, earlywood, etc.), which are both expected to increase the resulting bending stiffness. In addition, the models need to be adjusted for the climatic conditions monitored during storage before scanning and the resulting approximate moisture content (MC).

Once the development of the pipeline has reached a state that enables a more automated treatment of irregularities in the input geometries (diverse shapes of timber, cut or broken ends) and thus the analysis of a larger number of beams, extensive validations will be conducted. For this purpose, we are currently collecting mechanical data on all the scanned timber, i.e. longitudinal eigenfrequency by dynamic excitation, local and global bending stiffness and strength by non-destructive and destructive four-point bending, and measurements of the MC during testing. This data and the corresponding models will yield a base for validation of our framework and enable a comparison to alternative methods, like stress grading based on mechanical tests and even visual grading (using, e.g. surface visualizations from the CT images).

Sources, propagation, and impact of uncertainties need to be assessed to evaluate the framework's robustness. To achieve this, we will conduct sensitivity studies on input factors to establish uncertainty ranges for the predictions, instead of single point values. We will include factors from the data acquisition stage (e.g. scanning speed, CT artefacts, and effects of timber surface quality), the image analysis and model creation stage (e.g. image resolution, geometric assumptions, and discretization strategies), the modelling stage (e.g. material parameters and their

dependency on the underlying tissue, fibre reconstruction, model boundary conditions, and load application), and the evaluation stage (e.g. stiffness evaluation and failure criterion).

We expect our framework's accuracy to be limited to the amount of information extractable from the density field of a piece of timber. In practice, also the available computational resources will limit the achievable fidelity.

6 Conclusion and Future Steps

We highlight the limitations of current timber assessment methods with reclaimed timber and the need for the development of a non-destructive assessment method that is independent of regional data and species. This paper presents a first step into the necessary groundwork by demonstrating a framework to assess the mechanical properties of individual reclaimed timber elements by models based on the extraction of properties from CT scans. The preliminary results demonstrate the modelling pipeline and outline the evaluation of mechanical properties. This reduces some uncertainty concerning the reuse of the reclaimed timber and its reuse as structural. Further research is required for validation and demonstration of the robustness of our method, specifically regarding the large variability of reclaimed timber.

The modelling framework is based on free and open-source software to promote interchangeability, extensibility, and longevity. Its design is modular, minimizing dependency on specific formats and maximizing its flexibility. It allows for varying resolutions and degrees of approximation and may in principle also be adapted to different modes of data describing the BoP, e.g. laser and X-ray scanning. Finally, this study is part of a larger research effort to compare different non-destructive methods which can be deployed to classify and sort for different destinations. Herein, the assessment and validation of reclaimed timber is a crucial component.

To this effect, we position our work within this collective effort to show how these advancements in a digital timber practice can lead to an increased utilization of reclaimed timber and a more sophisticated usage of this new resource—an integrative 'hyper-grading' of timber that spans the digital value chain between resource, analysis, design, and re-utilization.

Acknowledgements The research by MT, TS, MR and the materials and shipment have received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation program (grant agreement No 101019693). JH gratefully acknowledges the scholarship from His Majesty King Carl XVI Gustaf's 50th Anniversary Fund for Science, Technology, and Environment and the funding from the CT WOOD research program at LTU Skellefteå. The contribution by WW is co-funded by the European Commission under the DRASTIC project (grant agreement 101123330). The timber elements are supplied by Omtre AS. We thank Christine Jørgensen and Ivar Ragnhildstveit from Omtre AS for providing background information about the material supply.

1 Introduction

Among the plain masonry, the structural units of burnt bricks are an age-old masonry constituent used from prehistoric times. The durability of these units is permanently found due to their continuous exposure to different climates over the years. They have gained wide popularity, and 62% of the residential units in South Asian region are already made up of burnt clay bricks [1]. It is one of the most commonly used building materials in developing countries. Despite the durability, bricks are inherently brittle materials. Mortar joints between them are also often weaker than the bricks themselves. The brick masonry in overall lacks the ductility needed to absorb and dissipate seismic energy effectively. In general, masonry constructions are highly vulnerable to lateral loads, even though they are inherently good at resisting compressive loads. Such a scenario, especially for plain masonry construction, is detrimental since they lack any reinforcing element. Even though the use of alter-

natives or innovative materials for new masonry construction is gaining interest in the modern era, existing masonry structures also contribute to about 70% of the building stock worldwide (whether plain, confined, or reinforced masonry).

There are different practices which are aimed at improving the performance of such existing brick masonry structure. Various conventional strengthening methods have been proposed to enhance the seismic performance of existing unreinforced brick masonry (URM) structures which includes surface treatment, stitching, grout/epoxy injection, and re-pointing. Additionally, external reinforcement techniques have been investigated, such as reinforcing wall junctions with L-form and polypropylene (PP) bands, rubber tire posttensioning, and employing textile-reinforced mortars. Efforts have also focused on improving performance by implementing confinement measures like external tie columns, mesh reinforcement, and similar approaches [2–4]. Some research has explored the effectiveness of techniques such as steel or fiber-reinforced mortar/concrete coating and engineered cementitious composite overlays for reinforcing masonry infill walls [4–6]. Additionally, the utilization of stainless-steel reinforcing bars and high-strength steel cords has demonstrated utility in stabilizing and enhancing the performance of masonry walls [7, 8]. In the context of load-bearing masonry structures, Indian standards (IS 4326-BIS 1993, IS 1893-BIS 2002, IS 13935-BIS 2009) recommend the incorporation of reinforced concrete (RC) elements and corner reinforcement as measures to improve seismic performance, especially in the absence of specific Indian standards for confined masonry (CM) constructions [9–11]. Confined masonry construction is all good for a new construction. Confined masonry with full confinement through the thickness of wall will be intrusive. For an existing brick masonry structure, research by authors found that partial confinement of existing masonry structure is a notable method [12]. The study clearly demonstrates that the suggested retrofitting approach for existing deficient masonry buildings is minimally invasive, easily executable, and cost-effective, while substantially improving seismic performance. This sustainable approach also minimizes material usage by focusing on nominal RC bands, reducing the demand for new resources. It also avoids generating significant construction and demolition wastes (CDW) and requires minimal energy. Moreover, it causes minimal disruption to the surrounding environment, creating little sound and dust pollution. Additionally, this approach improves the seismic performance of seismically deficient buildings, potentially avoiding the need for their demolition and subsequent environmental impacts in terms of material usage, carbon footprint due to new materials and construction, and environmental pollutions. Moreover, the utilization of partial confining elements proved highly beneficial in enhancing the overall performance of masonry walls in terms of ductility, energy dissipation capacity, integrity, and stability under slow-cyclic lateral loading tests. Further, the cyclic testing of the masonry structures resulted in the formation of cracks. The main emphasis of this study is to restore the structural integrity of the cracked masonry structures, to explore variations of the semiconfinement technique and to perform an immediate assessment of these structures. The overall idea is to set the stage for future studies of these masonry structures considering environmental

sustainability and structural durability. Exploring variations of semiconfinement technique may contribute to the ongoing evolution of such retrofitting strategies for masonry structures enhancing their resilience and longevity.

For ensuring structural integrity (for safe and functional structures), the understanding of modal characteristics of structures is crucial. The insights gained from modal analysis can help in maintaining the structural integrity of buildings during earthquakes etc. The immediate effects of earthquakes as well as long-term impacts which explores the damage from past seismic events on structural as well as nonstructural elements can be well understood. Thus, modal analysis would help in understanding real-world structural responses. Experimental Modal Analysis (EMA), also referred to as frequency response function testing, is commonly considered for dynamically identifying structures. Hence, this study utilized EMA to evaluate the dynamic parameters. EMA entails stimulating the structure with known inputs, such as impulse hammers, drop weights, or electrodynamics shakers, and then measuring the resulting structural response. These techniques offer important information about modal characteristics, such as natural frequencies, damping ratios, and mode shapes, which are crucial for model analysis, validation, and ensuring overall structural safety. Obtaining modal parameters like natural frequency and mode shapes is a significant concern in designing structures to withstand dynamic loading conditions.

EMA provides the advantage of allowing precise excitation characteristics, including type, location, and amplitude. Additionally, it facilitates the selective stimulation of specific vibration modes. Genovese and Vestroni (1998) have considered low amplitude forced oscillations for investigating dynamic behavior of an existing masonry building [13]. Zonta (2000) has considered impact hammer and shaker excitations for experimental modal testing on a Roman amphitheater with structural problems due to aging and material deterioration [14]. Atamturktur (2009) considered Bayesian inference to update the parameters of a masonry vault model based on EMA data using Bayesian inference [15]. Atamturktur et al. (2010) considered modal testing of masonry vaults using operational modal analysis and experimental modal analysis [16]. Cakir et al. (2016) considered experimental modal analysis for masonry arches which was strengthened with graphene nanoplatelets-reinforced prepreg composites [17]. De Felice et al. (2022) evaluated seismic behavior of rubble masonry using shake table test, and experimental modal analysis has been used to evaluate the modal properties [18].

Here, experimental modal analysis using shaker test is considered to evaluate the effectiveness of crack sealing using grouting by considering the accelerometer data. The main idea of considering the grouting to regain the lost strength of masonry wall is lay foundation for future studies on the un-reinforced as well as retrofitted masonry wall. The repair process focuses on effective and sustainable sealing of cracks in the masonry structures by grouting. Most importantly, it emphasized on environmental considerations by minimizing material usage and needs only light application for an eco-friendly repair in order to reuse these buildings. The judicious application of it targeting needed areas may not require excessive use of materials

like traditional repair methods. This may reduce the environmental footprint of the repair and will be cost-effective method. This may not introduce additional load on the structure as well which can have unintended consequences for the structural integrity of the masonry. For the reuse of such masonry structures, the method considers both structural and environmental aspects for a comprehensive and eco-friendly solution. Now, the effectiveness of the method on the performance of both buildings need to evaluated for further studies. Experimental Modal Analysis (EMA) is employed to analyze the accelerometer data, providing insights into the modal characteristics, of the masonry structures. This condition assessment helps in identifying potential improvements in the overall dynamic characteristics of the masonry structures.

2 Experimental Program

2.1 Test Buildings for Condition Assessment

The slow-cyclic lateral loading tests have been conducted on two identical one-room buildings, one without reinforcement (un-reinforced brick masonry building or URM) and the other retrofitted with semiconfining elements (semiconfined brick masonry building or SCURM) of nominal reinforced concrete bands. Tests have been conducted on both buildings to assess the in-plane behavior of their masonry walls under simulated gravity loads. The loading conditions followed FEMA 461 guidelines, aiming to replicate deformations experienced during earthquake events. The focus of the investigation was on comprehending the hysteretic behavior, strength, ductility, energy dissipation, stiffness degradation, and associated failure mechanisms. The main objective was to quantify the impact of the semiconfining bands on the in-plane behavior of masonry walls, considering a specific arrangement of vertical and horizontal semiconfining elements. Detailed experimental investigations and observation can be found in Latha et al. (2022) [12]. Both the structures had developed cracks during testing. Figures 1 and 2 show the structures and the developed cracks after cyclic lateral loading test. These cracks were further sealed using mortar grouting sustainably.

For SCURM building, the anchoring of steel bar has been considered full (for past cyclic test only partial anchoring was considered), and all the cracks were sealed. Only a minimal amount of grouting material was considered and applied to fill the cracks. Typical mortar grouting at the base of cracked-retrofitted building after cyclic lateral loading test is shown in Fig. 3, and same was followed for un-reinforced building as well. In this way, test specimens were made ready for the condition assessment. For the condition assessment, accelerometers were strategically placed at various locations of both the buildings for shaker tests and the schematic is shown in Fig. 4.

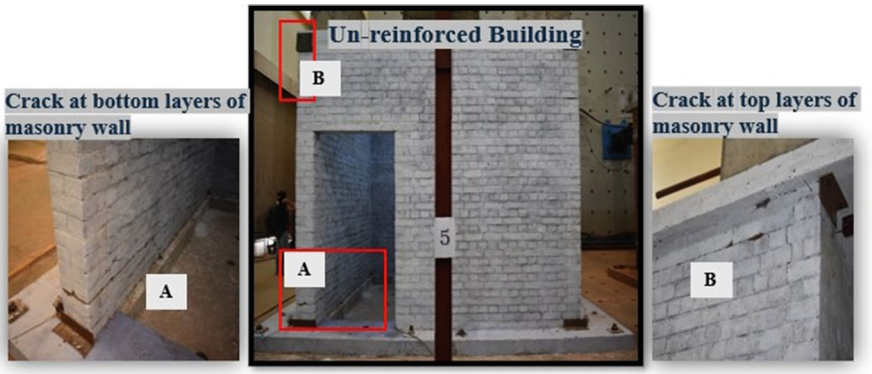

Fig. 1 Un-reinforced building (or URM) and developed cracks on the building after cyclic lateral loading test

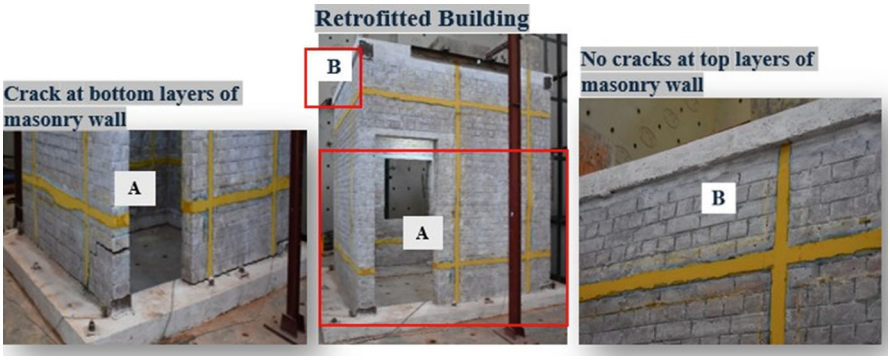

Fig. 2 Retrofitted building (or SCURM) and developed cracks on the building after cyclic lateral loading test

Fig. 3 Mortar grouting at the base of cracked-retrofitted building after cyclic lateral loading test

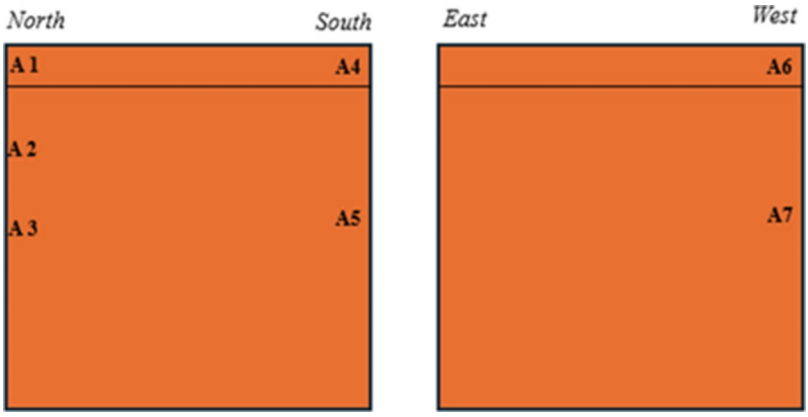

Fig. 4 Schematic for location of sensors for both the buildings (in addition to these eighth one is on the shaker as well)

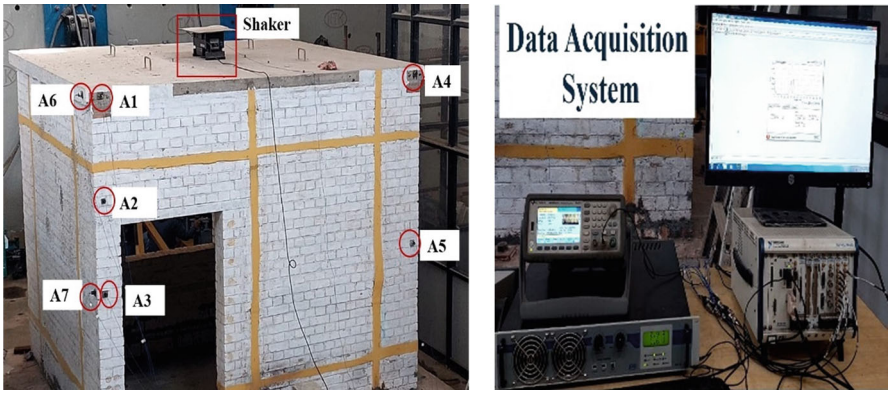

Fig. 5 Retrofitted building with shaker and accelerometers (A1 to A7 are locations of seven accelerometers, and eighth accelerometer is on the shaker) and data acquisition system with connected sensors and computer during the testing

2.2 Test Setup and Instrumentation

In order to examine the effectiveness of the repair, shaker tests have been done on both the buildings. The accelerations were recorded during the shaker test which are used to experimentally determine the modal characteristics of masonry. Shear accelerometers of model 393B04 manufactured by PCB Piezotronics, Inc. were employed, possessing a frequency range spanning from 0.02 to 1700 Hz and a sensitivity of 1000 mV/g. Figure 5 shows the retrofitted building with the shaker, accelerometers, and data acquisition system with connected sensors and computer during the testing. The same test set-up and instrumentation was considered for un-reinforced masonry building as well.

3 Results and Discussions

The acceleration data obtained from the shaker test is considered and further analyzed for the modal characteristics of masonry structures. This assessment aids in identifying areas for potential enhancements in the overall dynamic properties of these structures. The changes in the dynamic behavior of control and retrofitted buildings after the grouting are found from the comparison of test results obtained from the shaker tests. Three trials are considered for the white noise input motion for both the buildings. The transfer function plot generated from the white noise data for obtaining the modal characteristics for control building and retrofitted building are shown in Figs. 6 and 7. The fundamental frequencies of both control and retrofitted buildings obtained for three trials for both the buildings are shown in Table 1. Here, the fundamental frequency is considered as the frequency with most significant power or energy content; hence, the peaks are considered accordingly. For three trials, the percentage increase of the fundamental frequency of retrofitted building when compared with un-reinforced building are 4%, 2.8%, and 4.3%. There is a notable change in the fundamental frequency of retrofitted building when compared with un-reinforced one after grouting, which may be due to the semiconfinement by RC bands. The change in the value of percentage increase for different trials indicates that the parameters obtained from the real-time monitoring at different times are affected by some variability. The variability can be due to data acquisition or processing or may be due to environmental conditions.

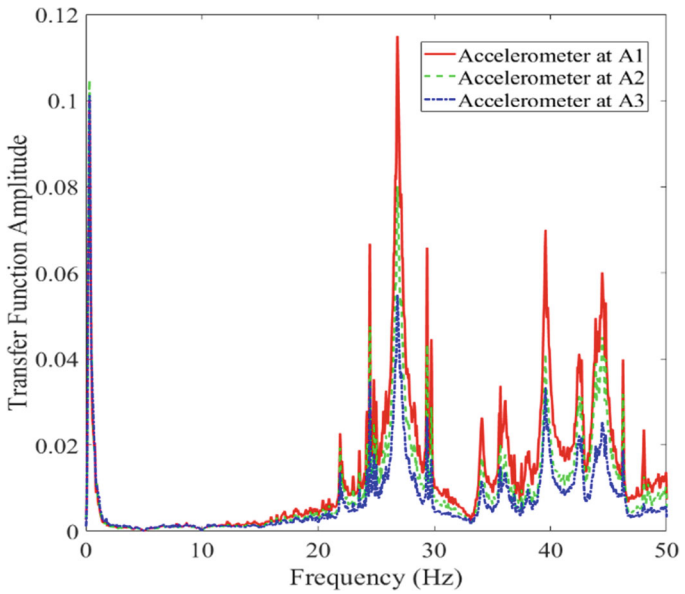

Fig. 6 Transfer function amplitude vs. frequency from white noise input for un-reinforced building

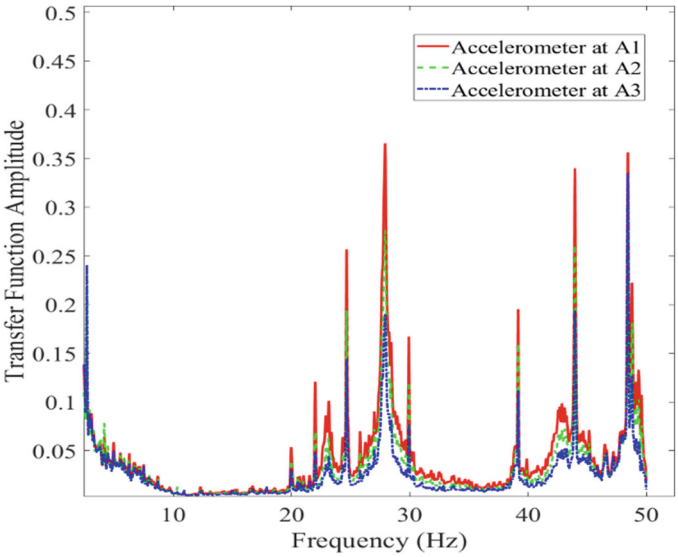

Fig. 7 Transfer function amplitude vs. frequency from white noise input for full-scale retrofitted building

Table 1 Fundamental frequencies (in Hz) obtained for control and retrofitted building at different sensor locations

Sensor locations	Trial 1	Trial 2	Trial 3
Control building at A1	26.83	26.97	26.94
Retrofitted building at A1	27.91	27.71	28.09
Control building at A2	26.83	26.96	26.94
Retrofitted building at A2	27.91	27.72	28.09
Control building at A3	26.83	26.98	26.94
Retrofitted building at A3	27.91	27.72	28.09

In order to understand the mode shape along the height of the buildings, the acceleration transfer function amplitudes obtained for sensors at various positions (A1 at 3 m, A2 at 2.25 m and A3 at 1.5 m) along the height were considered. The mode shapes of the control and retrofitted buildings are shown in Fig. 8. The fundamental mode shape of retrofitted building is observed to be pure shear type when compared with control building which may depict the lateral load resistance action due to semiconfining elements. The behavior was observed similar for control and retrofitted building during the cyclic testing as well [12].

4 Conclusions

The utilization of experimental modal analysis by shaker tests is considered in this study to assess the effectiveness of crack sealing using grouting as a repair method for already cracked unreinforced and retrofitted masonry walls during cyclic testing.

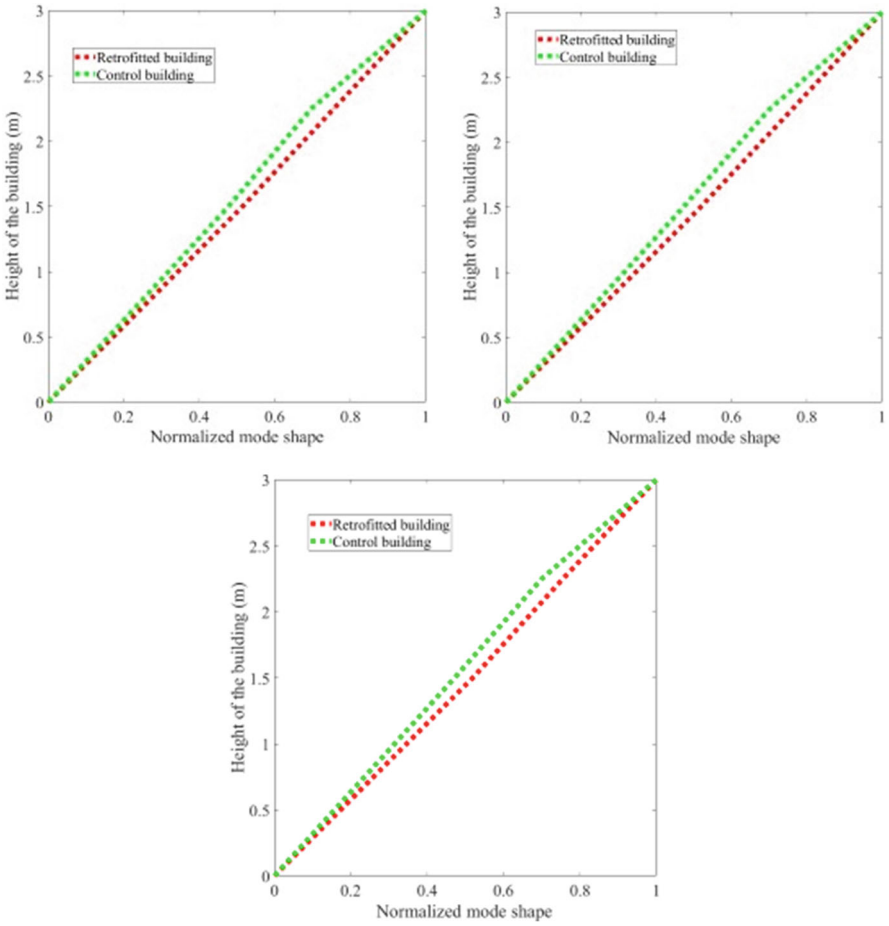

Fig. 8 Mode shapes of both control and retrofitted building obtained from: (**a**) Trial 1, (**b**) Trial 2, and (**c**) Trial 3 data

The cyclic testing was done to assess the performance of retrofitted structure when compared with un-reinforced structure. The method of retrofitting was found to be very effective in improving the overall performance of the structure with enhanced ductility, energy dissipation capacity, integrity, and stability. The findings could establish the effectiveness of the proposed retrofitting approach for existing deficient URM buildings. The approach has only minimal intrusion, possess ease of implementation, and cost-effectiveness. This sustainable retrofitting strategy reduces material consumption by concentrating on nominal RC bands, thus lessening the need for additional resources. It also sidesteps the creation of substantial construction and demolition wastes (CDW) while keeping energy requirements low. Furthermore, it minimizes disturbances to the nearby environment, resulting in limited

noise and dust pollution. Moreover, it enhances the seismic resilience of buildings, possibly preventing the need to demolish them and thus reducing environmental impacts like increased material usage, carbon emissions from new materials, and pollution from construction activities. Further studies on the scheme of retrofitting are essential for its wide implementation. So, the already tested structures are further repaired. The reuse of such masonry structures is considered such that it offers both structural and environmental aspects for a comprehensive and eco-friendly solution. The emphasis of the study is on effective and sustainable way of preserving the integrity of structure which prioritizes environmental considerations (minimal material usage and eco-friendly repair method), by lowering the environmental footprint and offering a cost-effective solution compared to traditional methods.

The repair method is aimed to restore the initial behavior enabling further research on both unreinforced and retrofitted masonry walls. Modal characteristics evaluation has found the increase of global stiffness of the retrofitted building than the un-reinforced repaired building. The pure shear type mode shape of retrofitted building depicts lateral load resistance action of semiconfining elements. The behavior of the repaired buildings observed is found similar to that observed during cyclic testing. In general, it is found that the retrofitting of the masonry building using RC bands does not alter modal behavior of the buildings. However, such retrofitting significantly enhances the ductility, thereby improving the seismic performance as shown through reverse cyclic test results.

The dynamic identification of the structures is crucial for an immediate assessment of the performance by considering sustainable preservation. This may facilitate further studies on retrofitting the repaired control masonry or enhancing the scheme of retrofitting or strengthening of semiconfined masonry for improved performance and wide implementation.

1 Introduction

The construction industry plays a significant role in global emissions, contributing up to 40% of total emissions and posing challenges to environmental sustainability [1]. With the increasing demand for infrastructure and urban development, the industry's carbon footprint continues to grow, highlighting the urgent need to address the impact of construction activities on climate change and ecological integrity. Greenhouse gas emissions from construction processes, material extraction, and transportation, coupled with the embodied carbon in built environments,

underscore the complexity of mitigating the industry's environmental impact [2]. Conventional construction practices, reliant on resource-intensive methodologies and materials, present formidable barriers to sustainability efforts. Despite these challenges, opportunities for innovation and collaboration emerge, calling stakeholders to pave the way toward a more sustainable future.

The concept of circularity is one of the main promising solutions to the construction industry's environmental challenges [3]. Circularity represents a departure from the linear "take-make-dispose" model, emphasizing resource efficiency, waste reduction, and sustainable practices. Reuse, defined as using products or materials again for a similar purpose as before without significant processing [4], is a key component of circularity. It prioritizes preserving materials' value and minimizing waste generation, thus opening new avenues for innovation and resource conservation. By embracing reuse, the construction industry can reduce its reliance on virgin resources and mitigate carbon emissions.

Structural timber, including cross-laminated timber (CLT), glue-laminated timber (glulam), and solid timber (e.g. log), emerges as a highly suitable option for reuse due to its unique properties and environmental advantages. As a renewable resource, timber is sourced from sustainably managed forests, resulting in a lower environmental impact compared to non-renewable materials like concrete and steel [5–7]. Studies across Europe have shown the potential for reuse of structural timber components [8, 9]. For instance, a case study in Finland concluded that while the technical feasibility of reusing structural timber exists, the establishment of efficient and standardized assessment criteria is needed to ensure the mechanical integrity of these materials [9].

Aligned with principles of circularity and resource efficiency, timber offers versatility, flexibility, and precision in design and construction [10]. However, to ensure the effective reuse of structural timber, guidelines, and quality criteria must be established to confirm their structural integrity and compliance with technical regulations. Presently, a lack of comprehensive guidelines and standards for the reuse of structural timber poses a significant challenge. This study aims to address this gap by providing a flowchart for quality checks in the reuse of structural timber, with the following research question guiding the investigation: "*What specific quality criteria should be considered to facilitate the reuse of structural timber in construction projects?*"

This study addresses the challenge of limited guidelines for reusing structural timber by developing a flowchart for quality checks. This flowchart, informed by literature reviews, document studies, and interviews with Norwegian construction industry professionals, establishes specific quality criteria for evaluating the suitability of structural timber components for reuse in construction projects. This research contributes to the advancement of circular economy principles within the construction industry by facilitating the effective reuse of timber and promoting sustainable practices.

2 Method

This study employed a qualitative research method by conducting a series of interviews as well as literature and document study. The document study includes reports from SINTEF,[1] an independent research organization, and relevant Norwegian standards to acquire a deeper understanding of the subject matter. The aim was to have a solid foundation of knowledge about the subject before stepping into the interviews. By triangulating data from these various sources, the study aimed to enhance the validity and reliability of its findings.

2.1 Literature and Document Study

In developing the theoretical framework for this study, a literature review was conducted in accordance with the guidelines outlined by Blumberg et al. [11]. The literature review utilized the search engines Oria (Norwegian library resource) and ScienceDirect. Different keywords such as "reuse," "circularity," "timber," "CLT," "solid wood," "glulam," "regulations," and "structural" were used during the search process. This approach enabled the retrieval of relevant articles to support the topic of this study. Additionally, a document study was employed, examining reports from DiBK[2] and, as well as relevant standards such as NS-INSTA 142 [12], which focuses on the visual strength grading of timber. Moreover, unpublished standards for evaluation of reclaimed timber, such as prNS-3691-1 [13] and prNS3691–2 [14], were also analyzed. This method allowed for the extraction of valuable information aligning with thechapter study's objectives.

2.2 Interviews

In this study, a total of nine interviews with ten participants were conducted digitally, each lasting approximately 50 to 60 minutes. Following the guidelines outlined in the book "Design Methods and Practices for Research of Project Management," [15] all interviews were recorded and transcribed. The interviews were conducted as semi-structural interviews to enable a balance between flexibility and structure in gathering information. The objective was to gather information relevant to the topic of the, thus the conduct of the interview was adapted based on the dynamics between the respondent and the interviewer. Additional questions did arise based on the flow of the interview and insights gained between interviews.

[1] An independent research organization in Norway

[2] The Norwegian Directorate of Building Quality

Table 1 Participant information

Participants	Position	Organization
1	Chief executive officer (CEO)	Treteknisk—Norwegian institute of wood technology
2	Senior engineer	DiBK—Directorate of Building Quality
3	Research and innovative manager	OmTre—Company that works with circular economy regarding timber
4	Project manager	BundeBygg—Contractor firm
5 & 6	Construction manager, environmental adviser	Veidekke—Contractor firm
7	Production manager	Skanska—Contractor firm
8	Project manager	Statsbygg—State-owned contractor firm
9	Project developer	Betonmast—Contractor firm
10	Project manager	Seltor—Contractor firm

The selection of participants was carefully considered to ensure a diverse range of perspectives. Specific criteria were established for participant selection, including individuals with knowledge of industry standards and those familiar with relevant building regulations in Norway. Additionally, experts specializing in the circular economy regarding timber were sought after. Lastly, participants actively involved in building practices were also included. Table 1 presents the participants as well as their positions in the respective organizations.

2.3 Data Analysis

A data analysis was applied to synthesize and examine information gathered from the literature study, document study, and interviews. All interviews were transcribed to ensure the utilization of information in our findings. Subsequently, the transcribed data, the data from the literature study, and the document analysis underwent a systematic coding process to categorize content according to predefined themes relevant to the study's topic. This systematic approach allowed for the efficient utilization of data for further analysis and interpretation [16].

3 Theoretical Background

3.1 Relevant Wood Properties and Conditions

For structural timber to be reused in construction projects, it must meet specific standards for physical and mechanical properties, including strength, stiffness, and density as well as being in a certain level of condition with respect to moisture content, and durability [17]. The difference between wood and timber is that wood

refers to the raw material, whereas timber refers to the processed product resulting from manufacturing [18].

Strength is a key mechanical aspect of reused structural timber. It ensures the timber can handle loads and maintain its structural integrity over time. For instance, CLT has typically strong bending and shear strength due to its layered construction and adhesive bonding. Glulam, made by bonding wood laminations, also exhibits strong tensile and bending strength, making it suitable for longer spans. Meanwhile, solid wood, that comes directly from a tree trunk retains its original characteristics such as grain pattern and knots. Understanding these differences helps in selecting timber that can withstand loads during reuse, ensuring safety and durability in construction [19].

Stiffness is also crucial for repurposed structural timber. It determines the timber's ability to resist deformation under load, crucial for stability and preventing structural failure. CLT, glulam, and solid wood have different stiffness properties based on their construction and materials. Assessing stiffness helps determine if the timber is suitable for specific reuse scenarios, ensuring good performance and structural integrity across different construction contexts [19].

Moisture content, along with the thermal performance as they are cross correlated, plays a significant role in the dimensional stability and durability of repurposed structural timber. Timber exposed to continuous sunlight may develop cracks, while during rain, it can absorb water, leading to moisture retention. Excessive moisture can cause changes in size, warping, and decay, risking structural integrity. Managing moisture is important to preserve the quality and lifespan of structural timber during reuse, preventing damage from excessive moisture [19].

Durability is essential for repurposed structural timber, defining its resistance to decay, insects, and moisture-induced problems over time. CLT, glulam, and solid wood vary in durability based on their properties and treatment methods. Understanding the durability of each timber type helps choose materials that can withstand environmental challenges and ensure long-term structural performance. By prioritizing durability in reused structural timber, stakeholders can improve the sustainability and resilience of construction practices, reducing the need for frequent replacements and promoting efficiency in resource use [19].

3.2 Regulations in Norway

To ensure the safety, sustainability, and fire resistance of buildings and structures, both old and new building materials must undergo quality documentation. In Norway, building materials must comply with regulations such as the Planning and Building Act, Documentation of Building Products (DOK), the Building Product Regulation, TEK17 (Building Technical Regulations 2017), and SAK 10 (Building Regulations) [20]. Table 2 provides an overview of the various regulations that building products must comply with in Norway.

Table 2 Regulatory framework for a building material

Regulatory framework	Purpose	Regulates
Planning and Building Act [21]	Primary law for planning and construction in Norway	Planning and executing construction and demolition work, cultural heritage, esthetics, and universal design
Documentation of building product (DOK) [22]	Ensure documentation of the quality and characteristics of the building	Technical solutions, material consumption, energy use, and environmental impact
Building Technical Regulations 2017 (TEK17) [23]	Ensure that buildings have satisfactory quality and functionality and are safe to use	For example, fire safety, structural safety, energy efficiency, health, and moisture
Building Product Regulation [24]	Establish rules for the sale and supervision of CE-marked building products	Regulates the sale and supervision of CE-marked building products throughout Europe
Building Regulations (SAK 10) [25]	How municipalities should conduct building permit processing, quality assurance, control, supervision, and approval of companies	Conducting building permit processing, quality assurance, control, supervision, and approval of companies for responsibility

From 1 July 2022, changes were made to the energy, climate, and environmental re quirements in TEK17 and corresponding changes in SAK10. These changes aim to reduce the climate and environmental footprint of buildings and increase the turnover and use of used building materials [26]. This will be achieved by having stakeholders in the building process assess whether the building material is suitable for reuse and provide documentation for relevant properties.

In general, if a building product adheres to the required documentation as per building product regulations, developers or responsible companies are exempt from conducting their own testing of the product's properties before its use in a building [27]. However, if the product lacks or contains incorrect documentation, it becomes necessary to verify that the building product possesses the required properties for the finished building to meet the stipulated requirements of the building technical regulations [27]. This verification process may entail testing or other forms of control to define the performance level. When utilizing a used product for a specific project, it is only necessary to document the properties relevant to that project, which can vary based on the product type and its intended use within the project [28]. To determine the relevant properties for documentation, one can examine the properties typically documented for similar new products, such as reviewing a performance declaration or consulting the harmonized standard for the product.

The relevant standards for the reuse of structural timber are listed in Table 3 and referenced in the flowchart shown in Fig. 1. These standards are necessary to ensure that the mechanical properties are adequate, along with other requirements needed for reusing structural timber.

Table 3 Relevant standards to consider for the reuse of structural timber

Standard	Describe
NS-INSTA-142 [12]	Visual inspection—Created for new timber
prNS 3691–1 [13]	Evaluation of reclaimed timber—General rules
prNS 3691–2 [14]	Evaluation of reclaimed timber—Impurities
NS-EN 16351 [29]	Requirements for CLT
NS-EN 14080 [30]	Requirements for glulam
NS-EN 408 [31]	Requirements for solid wood and glulam

4 Findings and Discussion

This paper aims to address the research question from Sect. 1. This is achieved by gathering and combining information from the literature review, document study, and interviews, resulting in a flowchart shown in Fig. 1. This flowchart is the main part of answering the research question. The flowchart begins with reclaimed structural timber, which is evaluated according to the standard under development known as pr-NS 3691, divided into three parts. The first part establishes terminology and general rules for evaluating reclaimed timber, while the second part addresses impurities found in reclaimed timber. The third part focuses on visual strength grading, although it is not yet finalized and is not considered in this flowchart. According to one of the participating researchers, they stated, *"For now, we use the standard NS-INSTA 142 for visual grading. However, we are working on creating a new standard that is more aligned with reclaimed timber, but that will come later."* The main difference between pr-NS 3691 and NS-INSTA 142 [12] is that the first standard is specific to reclaimed timber, while the second standard is for virgin timber.

The standard pr-NS 3691 is divided into three parallel processes, P1, P2, and P3, as shown in Fig. 1. P3 is included in the flowchart; however, its detailed content has not been yet published. Process P1 incorporates requirements from pr-NS 3691–1 [13] and recommendations from a SINTEF report [32] detailing various types of impairments that structural timber should avoid. The flowchart then assesses whether these damages affect the reclaimed timber. If yes, the timber is unsuitable for reuse; if not, it may be considered temporarily suitable for reuse.

Process P2 addresses impurities in structural timber based on pr-NS 3691–2 [14]. Impurities in timber can be hazardous waste, humus and minerals, metal fasteners, surface treatments, and impregnation. Those impurities can be categorized as clear, partially clear, or unclear based on their presence. Only clear and partially clear timber is considered temporarily suitable for reuse.

Reclaimed structural timber undergoes visual inspection according to NS-INSTA 142 (marked as P3*) and in the near future according to pr-NS 3691–3 as well. Visual strength grading is conducted by inspecting knots, annual ring width, slope of grain, and cracks. The tolerance values for these features can be found in the standard, which is currently based on virgin timber. However, one of the researchers

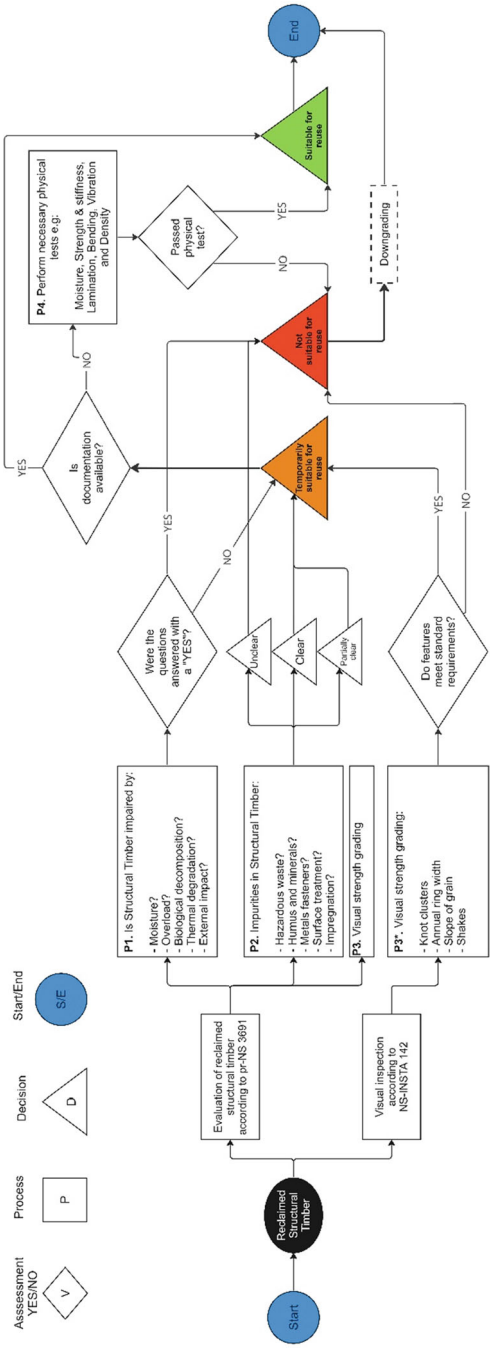

Fig. 1 Flowchart for reuse assessment for structural timber

interviewed mentioned that the standard for reclaimed timber is under process, *"It is part of the follow-up projects that come to SirkTre, which will automate and industrialize tests that correspond to today's sorting methods and are more suited to reclaimed timber."* SirkTre is a NRF[3]project that OmTre leads [33].

Timber categorized as temporarily suitable for reuse undergoes further inspection regarding documentation availability. If documentation is available, the timber is suitable for reuse; if not, it proceeds to process P4 for necessary physical tests. If the timber passes, it's suitable for reuse; if not, it's no longer suitable for reuse as structural timber.

Timber categorized as unsuitable for reuse can be downgraded for alternative uses, as highlighted during an interview with a contractor firm. "*Downgrading, meaning that if it's not sufficient as a load-bearing element for reuse, it can still be repurposed for other uses, such as decoration, playground equipment, or something else. There are many possibilities for reusing an element."* It is important to note that unclear wood from P2 is considered a waste due to potential health risks associated with impurities.

Reflecting on the findings gathered through literature review, document analysis, and interviews, the flowchart we developed emerges as a valuable tool for incorporating the reuse of structural timber in building practices. During the interviews, particularly those conducted with various contractor firms, a recurring pattern surfaced regarding their perception of whether the regulatory changes had indeed simplified material reuse. Previously, regulations posed significant barriers, making material reuse seem impractical. However, with the regulatory changes effective from July 1, 2022, material reuse became more feasible. Findings from the interviews showed that the current obstacle lies in the lack of standards for reclaimed timber, which is essential for effectively promoting the reuse of structural timber. Summarizing the changes in TEK17 as mentioned in the Sect. 3.2, new buildings must be constructed with future dismantling in mind, and materials must be identified for reuse during major renovations in existing buildings.

However, the transfer of responsibility from producers to contractors was another change in the regulations, and it may pose a challenge. The crucial question arises: who is willing to bear such a significant responsibility? Responses from interviews varied. While some expressed readiness to assume responsibility, they emphasized the importance of industry collaboration and support from clients, such as the building owner. "*I don't think going alone as a contractor, there must be industry collaboration, really*" commented a participant from a contractor firm, echoing sentiments shared by others.

Furthermore, the economic aspect of material reuse cannot be overlooked. While materials themselves may be inexpensive, the process of reusing them often incurs higher costs compared to using new materials. "*But as it stands now, in terms of economic benefits, my observation is that we haven't reached a point where the*

[3]The Research Council of Norway

commercial aspect of reuse is substantial enough to provide economic advantages," stated a participant from a contractor firm. The construction industry prioritizes cost-saving measures, necessitating clear directives from building owners and sufficient project funding to support material reuse initiatives.

Another significant barrier to promoting material reuse in building practices is the absence of standardized procedures for integrating reused materials into new projects. As one participant from contractor firm highlighted, "[. . .] *but that's also because there haven't been established standard procedures for testing and preparing it for new use.*" Establishing standardized procedures, such as those outlined in prNS-3691, could effectively address this issue. While these standards have not yet been published, they are currently under review and will be available for implementation in the near future.

Participants also highlighted a lack of information on how to effectively reuse materials. To address participants' concerns, we developed a flowchart outlining a step-by-step procedure for evaluating reused timber materials. The flowchart is designed to streamline the process of reusing structural timber. For the development of the flowchart, we used the mentioned standards listed in Table 3 as well as information gathered from the literature study.

5 Conclusion

This study investigated the challenges associated with reusing structural timber in construction projects, particularly the lack of standardized procedures for quality documentation. Key findings from this study are:

- The research question, "What specific quality criteria should be considered to facilitate the reuse of structural timber in construction projects?" was addressed through the development of a flowchart for quality checks.
- The proposed flowchart establishes a framework for evaluating the suitability of structural timber components for reuse, considering various quality criteria.
- This research contributes to the advancement of circular economy principles in construction by promoting the effective reuse of timber and reducing reliance on virgin resources.
- The flowchart currently has limitations, particularly in the area of assessing the longevity and durability of adhesives used in glued laminated timber (glulam) and cross-laminated timber (CLT).
- Additionally, future studies could explore the economic feasibility of implementing structural timber reuse on a larger scale within the construction industry.

1 Introduction

Compared to the two most commonly used construction materials; concrete and steel, cross-laminated timber (CLT) usage entails advantages such as high dimension ability, energy efficiency, high strength-to-weight ratio, and great sustainability and aesthetics [1]. The overall conclusion is that the timber product has an impressively low toll on the environment if sustainable forestry sources are utilized, which is well achievable in several parts of the world where such resources are abundant. However, despite these advantages, the application of CLT in bridge construction remains under-explored. Apart from North America and Europe, research has also proven that using CLT in other regions may be highly beneficial. A study presented by Yeh and Chiao [2], conducted in Taiwan, showed that CLT and other timber

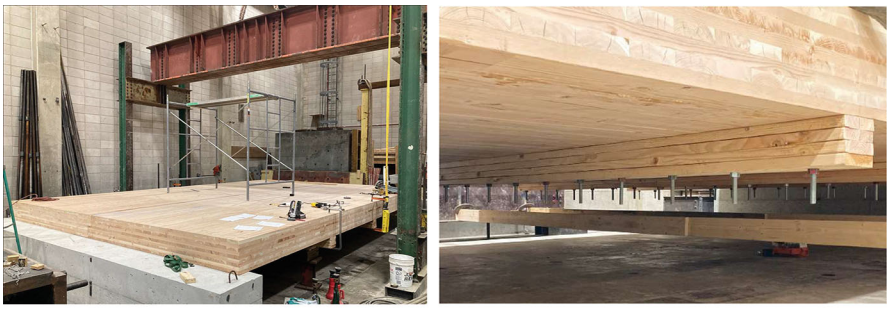
products are significantly more environment-friendly than reinforced concrete (RC) and steel. This statement was validated using life-cycle analysis (LCA) on buildings and structures within the country. Another significant advantage is that the product does not corrode, eliminating the most common type of deterioration mechanism that a vast number of reinforced concrete (RC) bridges are prone to.

Engineers have developed various product designs to best utilize the properties and behavior of timber for particular service conditions, and the most innovative and well-known timber designs for bridge decks include Glulam, SLT, and CLT [3]. Glulam was first introduced in Europe during the 1890s and later patented in 1901. This engineered wood product consists of several laminates stacked and glued together to form a strong composite structural element. SLT is widely used for structural components such as bridge decks and was initially developed in the North American region in the late 1970s and has in the subsequent decades been utilized in Australia and various Nordic countries [4, 5]. SLT decks are composed by arranging several parallel timber beams side by side with pre-stressed steel rods applied to compress timber laminations such as structural timber or glulam beams together.

CLT is an engineered wood product and the concept of CLT originated in Austria and Germany in the early 1990s [6]. CLT is another highly prevalent timber product that is commonly utilized within the construction domain. Though it is a very popular choice and is extensively used for commercial building projects, its application, particularly in bridge structures, is relatively limited in comparison. CLT boards are commonly derived from softwood species such as spruce, pine, or fir and are fabricated by arranging multiple layers of laminates perpendicularly and bonding them using adhesives. The cross-lamination process involves gluing the boards in each layer perpendicular to the previous layer. The number of layers, the thickness of each layer, and the grade of the timber are dependent on the specific design requirements of its intended application. CLT construction elements are always prefabricated and available in the maximum dimensions allowed by transportation agencies, leading to elevated levels of quality control and efficient site practices. Commercially available thicknesses range from $<$100 mm to over 500 mm [7]. CLT is highly suitable for bridge applications due to its inherent strength and durability. The cross-lamination orientation of each layer provides sufficient strength in both directions, making it a versatile material for applications that require robust load-bearing capacity. Its lightweight, ease of application, and ability to have dimensions customized along with its structural integrity make CLT an excellent alternative for bridge decks.

The design process of the link slab was based on the principles of reinforced concrete materials [8, 9]. It focused on the loads that the girder end rotations exerted on the link slabs. Although different studies have researched various aspects of slabs and decks [10–12], studies on CLT bridge deck systems are limited. In response to this opportunity, this study aims to explore the characteristics of CLT bridge deck system and determine their suitability for rural bridge applications. The bridge was designed to resemble a full-scale bridge based on standardized lane dimensions, but with some reduced widths to facilitate feasible testing in a laboratory environment. It



was experimentally tested while subjected to both static and cyclic loading exposure simulating American design trucks. The main objective of this research is to assess how suitable various available CLT deck systems are for rural bridge applications. The main focus is on distinguishing their advantages and limitations in terms of serviceability and structural performance. Specifically, the elastic, fatigue, and failure behaviors are to be examined while primarily focusing on vehicle-induced vertical displacements, stresses, and strains.

2 Experimental Testing

The experiments were carried out to comprehensively investigate the performance of CLT deck under varying loading conditions. To achieve this, CLT deck were carefully constructed to assess its durability, strength, and overall performance under both static and dynamic loads that simulate real-life bridge applications. The deck configuration is presented consecutively with geometry, technical information, and properties. Relevant information on the static and dynamic tests is described and finally, the results are presented with an associated discussion.

2.1 Geometry and Connections

The longitudinal panels were assembled using 36 laminates from Douglas Fir, grade select structural, with the dimensions 5-3/8″ × 1-1/2″ × 312″ inch^3 (135 × 38 × 7925 mm^3). In the transverse direction, the continuous panels were assembled using 59 laminates from Douglas Fir of grade No. 2 with the dimensions 5-3/8″ × 1–1/2″ × 192 inch^3 (135 × 38 × 3962 mm^3). The panels were then attached using an overlapping intersection that was bolted together using a cross-fastening method with three bolts per connection every 11″ (280 mm) along the longitudinal direction. The two 45° diagonal bolts were fully threaded countersunk heads with dimensions 3/8″ × 15-3/4″ (10 × 400 mm^2) and the vertical bolt was a fully threaded cylinder head with dimensions 5/16″ × 11-7/8″ (8 × 300 mm^2). The cross-fastening bolts were made of hardened steel. The top and bottom laminates were aligned toward the longitudinal direction to support the major strength direction in which the loads were to be applied. The deck was simply supported on both ends resting on concrete abutments. Figure 1a displays the Deck 1 test setup overview. Spreader beams consisting of four layers of wooden boards with dimensions 2″ × 8″ (50.8 × 203.2 mm^2) were placed on the bottom exterior side of the deck. The beams were fastened using fully threaded zinc-plated bolts made from grade A steel (Fig. 1b). They were placed along the transverse direction with centroid distances of 1 ft (305 mm).

(a) (b)

Fig. 1 Test setup: (**a**) deck and abutment, (**b**) bolted spreader beam along the transverse direction

2.2 Mechanical and Material Properties

The mechanical properties of both Douglas fir-North select Structural and No. 1/No. 2 are taken with a 12% moisture content, which is a standard reference value for well-seasoned timber with developed strength and durability characteristics. The chosen species is native to North America and extensively used for structural applications where the loading demand is high. The characteristic values vary greatly depending on the considered axes of the members. The values were either provided by or calculated using "Mechanical Properties of Wood" in the Wood Handbook [13]. The density is 480 kg/m^3, the modulus of elasticity in longitudinal, radial, and tangential axes of wood are 13,100, 891, and 655 MPa respectively.

2.3 Loading Protocols

Two loading configurations were employed to assess the behavior of CLT deck composed of the timber type Douglas Fir-North. The configurations involved static and fatigue loading, as further elaborated herein. The load was exerted on the bridge deck using a hydraulic actuator, where the loads were imposed by the actuators through two steel beams with two protrusions each. These protrusions applied 2-point vertical loads distributed over surface areas with dimensions of 8″ × 20″ (203.2 × 508 mm^2). This setup amounts to a four-point loading with 12.5-kip (55.60 kN) force per point and is conducted similarly to the AASHTO HL-93 design tandem to represent a 50-kip (222.41 kN) load from one heavy vehicle.

For the static loading configuration, the CLT bridge deck was subjected to constant quasi-static loading. As such, the vertical force was applied at a slow enough rate that inertia effects could be neglected. The static loading was performed on several locations to measure the deflection and strain on the decks when applied to a long-term constant force. Four distinct loading locations were chosen; centered

on midspan (CM), offset on midspan (OM), centered on end span (CE), and offset on ends pan (OE). The static tests lasted about 20 min. The locations of CM and CE were designated to target and capture maximum midspan deflections due to bending moment, meanwhile, OM and OE were two locations anticipated to provide large horizontal elongations throughout the depth of the deck where only one panel was loaded. As for CE, the loading position is also employed to induce the greatest overall shear forces that may visually assess the system's resistance to interlaminar slippage and shear cracking.

In the second load configuration, fatigue test was performed on the CLT deck to assess properties such as durability and fatigue life, by exposing it to repeated cycling loading. The decks were subjected to 500,000 AASTHO fatigue II load cycles with a cycle duration of 2 s, the same amplitude of 50 kips, and about 277 h of continuous loading. The data acquisition system extracted 1 min of data at the start of every hour.

3 Experimental Results and Discussion

The raw data were subjected to data analysis and the results are presented in a graphical form, where the findings are accompanied by a continuous discussion. Figure 2 shows the force/displacement relationship for the two centrally positioned sensors on each side of the panel intersection. A close to perfectly linear elastic behavior is exhibited for both sensors up to maximum load. This further indicates that the system is operating safely below the yield limit, and any local defects such as drying laminar shrinkage and internal cracks have a low impact on global performance. Utilizing derivation on the graphs provides an approximate linear force/

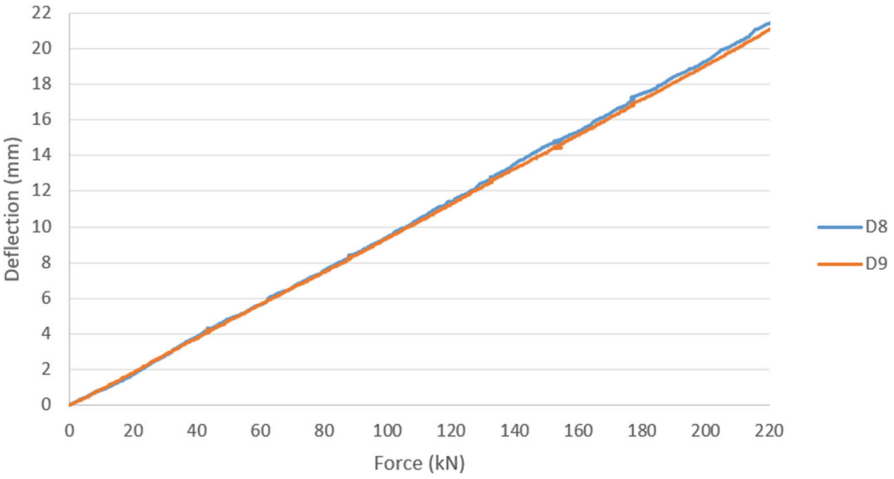


Fig. 2 Force/displacement relationship recorded by the two center gages as a function of force

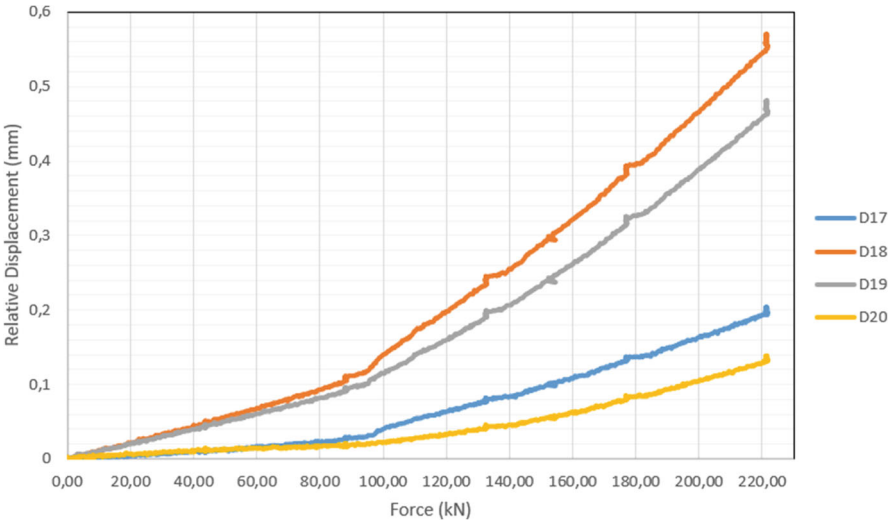

Fig. 3 Relative horizontal displacement between the panels when the load is applied at CM with a magnitude ranging from zero to maximum load

deflection relationship of 0.096 mm maximum deflection per kN of the centrally applied load. As such, in the current deck configuration, the system is evaluated to only be able to accommodate a single vehicle with a weight of 103.23 kN (less than half of the design tandem) while satisfying the AASHTO recommended displacement value of 9.91 mm with the given deck length. However, this is a simplification as the vehicle load is applied as a quasi-static force in the laboratory. In realistic applications, dynamic loading would be present, and the deformation would be influenced by the frequency of the load applied by the vehicle and the natural frequency of the system, which would impact the given values to a certain extent.

Figure 3 displays relative horizontal displacement between the panels when the load is applied at CM with a magnitude ranging from zero to maximum load. As shown in this figure, the two intermediate Sensors D18 and D19 exhibit the greatest relative horizontal displacement as functions of the applied load. The exceedingly low deflection value of 0.6 mm with a corresponding force of 222.41 kN indicates robust bonding between panels due to the cross-fastening method that is applied. Therefore, the system can be assumed to behave symmetrically and homogenously due to the marginal discrepancies between the panels and that it exhibits negligible lateral slippage.

Further to static loading, the behavior of deck under cyclic loading conditions was investigated. Figure 4 displays the increased fatigue-induced deflections in percentages as a function of transverse distance. The increases range between 4.6% and 9.9%, indicating that some stiffness reduction may have occurred over time due to the cyclic loading. A visual assessment was conducted after both the cyclic loading and the static test aiming to identify any visible damage to the structure and determine how it may have impacted the obtained results. No major cracks or

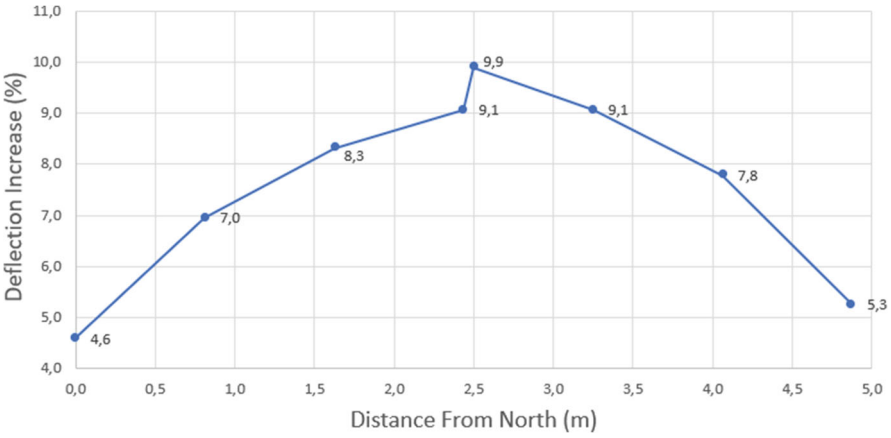

Fig. 4 Maximum displacement relative increases over time along the transverse direction

other obvious damage were detected after the loading schemes and the overall condition was concluded to be unchanged. Upon visual inspection, some splits were observed in the longitudinal direction on the bottom and top surface of deck, including splits in the annual rings of the west surface. These splits may have resulted from a 1-year storage period of the CLT deck in significantly low-humidity conditions, leading to an increased drying rate. It is plausible that the stresses and strains imposed on the deck from the cyclic loading may have resulted in the growth of these splits, although it is not immediately noticeable. Overall, the deck was found to be in good condition where only some minor delamination lines were found at a local scale.

4 Conclusions

The purpose of this study was to assess the structural performance of different CLT deck systems in terms of rural bridge applications. This included experimental testing and data processing of fabricated full-scale bridges by applying static and dynamic loads resembling design trucks in a laboratory setting. The study addressed factors such as general advantages and limitations, load-carrying capacity, durability, and long-term performance. During the experimental testing, it was found that the deck setups behaved linear elastically under the considered loading configurations. It was further subjected to 500,000 loading cycles and found that no measurable stiffness-reduction was exhibited, and no noticeable damage was shown other than some minor local cracking. It is thus concluded that CLT bridge decks may resist fatigue exceptionally well. In conclusion, this research provides valuable insights into the structural performance of CLT deck systems for rural bridge applications. The findings highlight the importance of optimizing design parameters

to meet serviceability guidelines and address the challenges of fiber compression as a potential failure mode. The study addressed a research gap in the field and contributed to the understanding and future development of CLT bridges. Furthermore, the study highlighted the environmental advantages of CLT bridges. Compared to traditional materials like concrete and steel, CLT bridges have the potential to significantly reduce carbon footprint due to the carbon sequestration properties of wood. Sustainable timber resources are utilized in the construction of CLT bridges, allowing them to store carbon dioxide instead of emitting it during production. These findings emphasize the importance of using CLT technology in infrastructure projects to not only improve structural performance but also promote environmental sustainability.

1 Introduction

The integration of hybrid facades marks a big step forward in the field of civil engineering, offering a highly efficient building envelope that enhances structural and thermal performance. Typically, they combine different materials. In the case of sandwich panels, they comprise an outer and inner layer, commonly separated by an insulating material. The connection between these layers is established either through shear transfer connection or adhesive bonding. In contemporary construction industry, a diverse range of hybrid facade types is employed, with steel connectors being the most prevalent. However, the thermal conductivity of steel connectors tends to be higher than that of the constituent materials leading to heat loss, diminishing the energy efficiency of buildings [1] and increasing heating and cooling costs [2]. Studies have shown that the use of metal fasteners spaced 16″ on center can elevate the thermal transmittance of a sandwich wall panel by over 20% [2]. To offset this effect connectors made from materials like carbon fiber and

fiberglass is taken into consideration, offering the potential to eliminate thermal bridges [3, 4]. However, the difficulty lies in ensuring the connector's thermal conductivity matches that of the insulation layer, a factor frequently dependent on specific suppliers, potentially leading to rising costs. Examination carried out on the studies of [5], involved testing precast concrete insulated sandwich wall panels with glass fiber-reinforced polymer (GFRP) shear connectors, revealed an increase of up to 80% in ultimate loads. Another study [6] demonstrated an 80% increase in adhesion using GRP connectors, while the research carried out by [7] by a precast concrete sandwich panel made of Ultra-high-performance concrete (UHPC) and fiberglass shear connectors showed a gradual deflection increase with rising composite action.

A challenge of this system is the difference in thermal stress caused by temperature differentials leading to the deflection of the panel. This phenomenon becomes more pronounced in panels with a higher span and composite action, where insulation limits the temperature flow, intensifying the temperature gradient [8]. In response to the thermal binding, adhesive bonding has emerged as a sophisticated method, offering advantages such as reduced weight, increased durability, and weather resistance. The use of adhesive ensures a continuous and uniform distribution of loads and stresses across the facade [9] and eliminates the need for drilling or thermally attacking materials before assembly. Research and studies on bonding applications [10] [11–13] further contribute to the diverse landscape of hybrid facades. The thermo-mechanical performances of the GFRP-glass Sandwich facade were also studied by [19], reporting improved thermal and structural performances compared to traditional systems. In related investigation, [14] aimed to characterize the thermal and structural properties, confirming linear behavior up to the ultimate load. However, environmental factors, especially humidity and heat, play a crucial role, causing alterations in adhesive materials and reducing bond strength [15]. Epoxies, commonly used in adhesive joints, lose rigidity around 45–55 °C, impacting the durability of bonded assemblies [16] [17].

In a related context, [18–20] demonstrated an improvement in the mixed behavior of the beams by using bonded connections leading to enhanced ductility.

This chapter covers an in-depth study detailing the experimental results obtained using wood–concrete composite façade panels. The main objective of this research was to analyze the thermal responses and expansions generated by the application of a specific thermal gradient to these panels. It also presents an extensive program of experimental tests, featuring two distinct facade configurations, the first incorporates a glass-fiber-reinforced concrete, while the second uses welded mesh for reinforcement.

2 Materials and Structures

The wood used in the facade design consisted of glulam elements of strength class GL24H. Table 1 shows the mechanical properties derived from EN1994 [21], bending strength $f_{m,\,g,\,k}$; tensile strength parallel to the grain $f_{t,\,0,\,g,\,k}$ compressive

Table 1 Mechanical properties of the materials

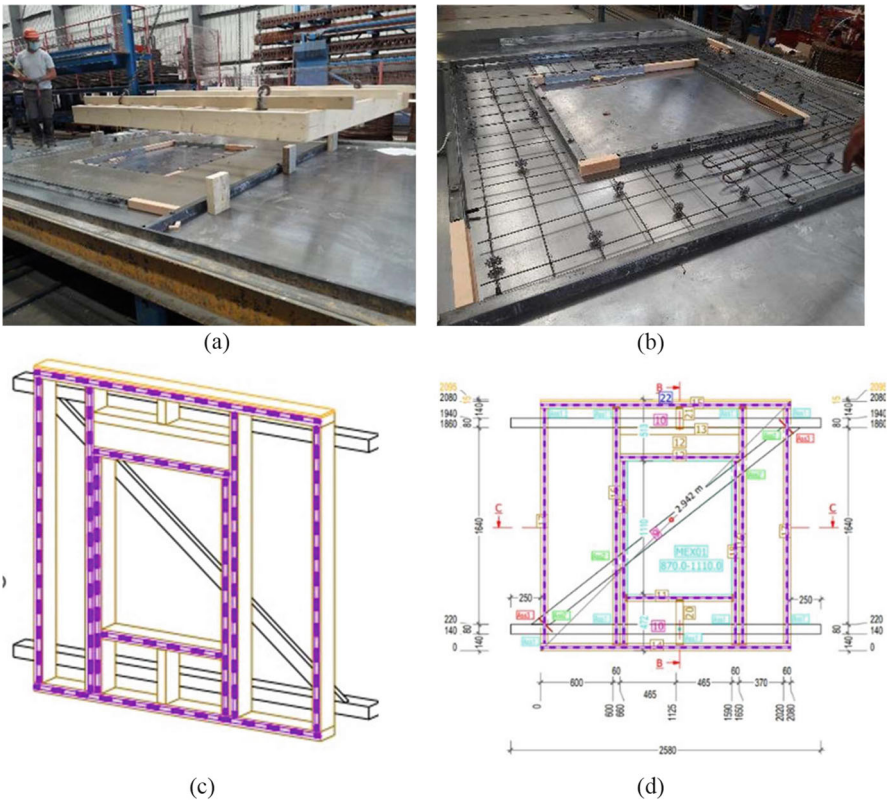
Material	Parameter	Value
Concrete	f_{ck}[MPa] ε_{cu} [%] E_{cm} [MPa]	40.8 0.38 33,546
Timber (GL24h)	$f_{m,\,g,\,k}$ [MPa] $f_{t,\,0,\,g,\,k}$ [MPa] $f_{c,\,0,\,g,\,k}$ [MPa] $f_{v,\,g,\,k}$ [MPa] $E_{0,\,g,\,mean}$ [MPa] $E_{0,\,g,\,05}$ [MPa]	24 16.5 24 2.7 11,600 9400
Resin	f_c [MPa] f_t [MPa] ε_t [%] E_t [MPa]	83 ± 4 32 ± 3 1.2 ± 0.2 3500 ± 500

Table 2 Measurement condition

Specimens	Medium temperature (°C)	Average hygrometry (%HR)	Change in mass (%)
RC-01	23.5	51.5	0.08
RC-02	24.2	55.1	0.00
FC-01	23.5	59.9	0.15
FC-02	25.5	64.4	0.02

strength parallel to the grain $f_{c,\,0,\,g,\,k}$ shear strength $f_{v,\,g,\,k}$; mean modulus of elasticity parallel to the grain $E_{0,\,g,\,05}$; and characteristic modulus of elasticity parallel to the grain $E_{0,\,g,\,mean}$. The external skin of the concrete is strength class C40/50 concrete. The mechanical properties of the concrete are summarized below [22], where f_{ck}, ε_{cu}, E_{cm} represent the cylindrical compression strength, strain corresponding to the maximum compression stress, and Young's modulus, respectively. The adhesive used is a two-component epoxy resin (Eponal 371) whose main mechanical properties, as specified by the manufacturer.

Table 2 summarizes the test conditions for thermal conductivity on four concrete specimens each with the dimensions of 150*150 (mm). The formulations include anti-Crack fiberglass concrete dosed at 10 kg/m^3 and steel-reinforced concrete with a diameter of 6 mm, and the measuring temperature was set as 15 °C, 25 °C, and 40 °C.



2.1 Experimental Program and Test Conditions

Temperature tests were conducted on two prototypes of wood/concrete facades (Fig. 1). One of the facades was reinforced with fiberglass concrete and welded mesh, as shown in Fig. 2. These prototypes have dimensions of 2.5 m in height, 2.5 m (Fig. 2d) in width, with a concrete thickness of 7 cm and 16 cm for the GL24 h glued laminated wood elements. The purpose of these experiments was to reproduce a temperature difference between the intrados and extrados of the façade (Table 3).

Specimens	Pressure	Air-conditioning speed	Air speed
Hot enclosure	From 0 to 40 pa	0.5 °C/min	0.2 to 2 m/s
Cold enclosure			0.2 to 6 m/s

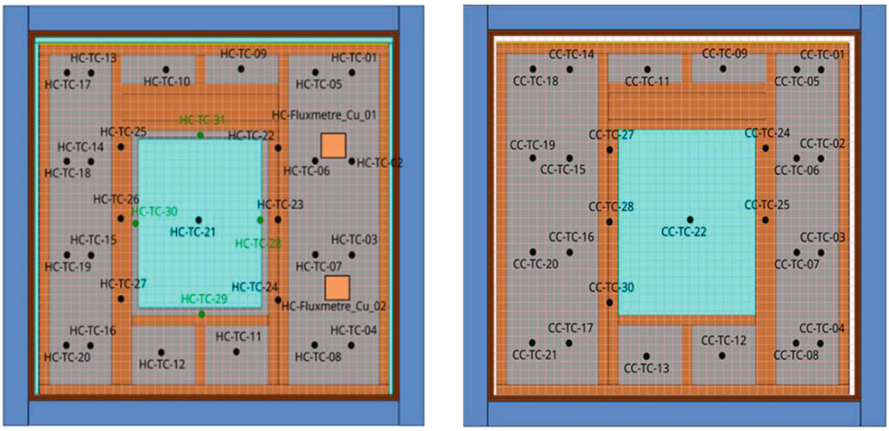

Fig. 3 Location of the sensors (**a**) Location of sensors on the hot side test tube, position of the flux meters, (**b**) Location of sensors on the cold side test tube

The initial conditions for the first two tests were considered adequate, involving temperature control in the enclosures ranging from −10 °C to 40 °C. However, in the last test, the temperature on both sides of the facade was elevated to intensify the temperature gradient. A supporting frame was set up to secure the panels in position.

2.2 Instrumentation

In each chamber, a set of 40 T-type thermocouples and 10 Pt100 probes were positioned for temperature measurements, Pt100 probes were used to measure and transmit air parameters, as well as to validate the uniformity of boundary conditions, with reference to the hot and cold air flows generated by the two chambers. Temperature gradient measurements were conducted for the first test. Two fluxmeters were installed on the heated inner surface of the concrete to force an increase in heat flow through the wall. Of 40 thermocouples installed in each chamber, those bearing the numbers CC-TC-15, CC-TC-20, CC-TC-27, HC-TC-03, and HC-TC-06 were included in the thermal expansion study, these sensors are positioned close to the gauges.

For the evaluation of thermal expansion, 30 mm strain gauges were strategically employed. Positioned at the Mid-height of the panel and near windows, at the distance of 48 cm, covering both the cooled and heated sections (Figs. 3 and 4, Table 4).

3 Experimental Results

3.1 Thermal Conductivity Results

Thermal conductivity values are predictably lower for fiber-reinforced concrete than for reinforced concrete. The values shown in the table below represent the average conductivity values (Table 5).

3.2 Temperature at Interface

Figure 5 illustrates the temporal evolution of the temperature gradient for the first panel. An initial rise of ΔT before stabilizing during the heating period was observed, followed by a gradual decrease during the cooling phase, reaching around 20 °C and 18 °C when the climate chambers were shut down.

A higher temperature gradient is observed at thermocouple K1, reaching up to 30 °C, positioned proximate to the window, as compared to thermocouple K2, which registers 27 °C. The recorded data manifests a discernible temperature differential of 3 °C between the initial and subsequent facades. The temperature drop is recorded. The graphs below (Fig. 6) depict the temperature rise profiles of hot and cold air and moisture. Despite pronounced similarities in the thermal profiles of each panel, panels 1 and 2 showed a temperature rise ranging from 40 °C to 45 °C on the side exposed to the heat source, compared with the side exposed to the cold, where the temperature reached −15 °C. For the last panel, the temperature conditions imposed are 40 °C on the cold side and 45 °C on the hot side, to increase the thermal gradient at the interface.

Table 5 Concrete thermal conductivity results

Specimens	ΔT (K)	Thermal conductivity (mW/mK)	Measurement uncertainty (mW/mK)
RC-01	15	1449.50	41.8
RC-02	15	1132.90	32.8
FC-01	15	935.49	27.1
FC-02	15	859.88	24.9

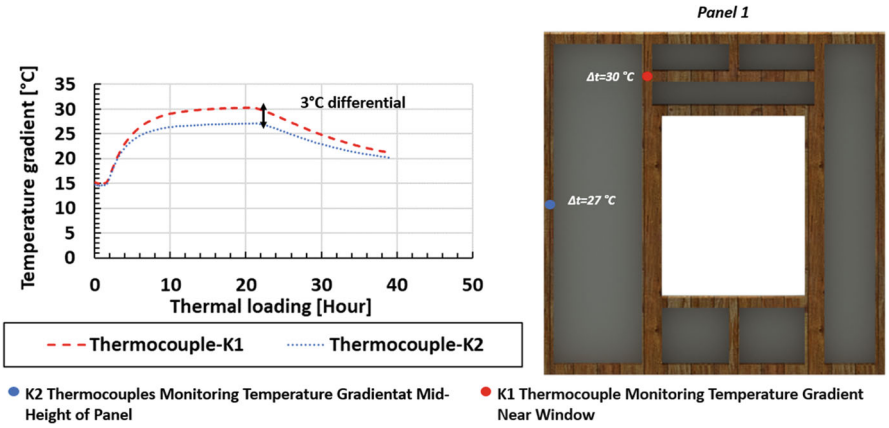

Fig. 5 Evolution of the thermal gradient inside the panel

3.3 Thermomechanical Response of Panels

At a temperature variation of 30 °C (HC-TC-06), thermal strains were observed on the heated surface indicating a compression of the concrete, the thermal strains ranged from 226 με (G'8-C-P2) and 184 με (G'7-C-P2) for the fiber reinforced concrete panel (Panel1). The second panel, which had been reinforced with welded mesh, showed thermal expansions comparable to those of the first one, the thermal strains were assessed as follows to 237με (G'8-C-P3) and 185 με (G'7-C-P3), in the cooled part of the panel, the gauges show tensile strains ranging between 100 and 250 με, no improvement was reported with the addition of fiber. Regarding the last heated panel on both sides, all gauges recorded a compression (Fig. 7).

It is essential to consider the specific boundary conditions that have been set up this multidirectional stress has a significant influence on the thermomechanical behavior of materials, modifying the way wood and concrete react to temperature variations. In relation to the results obtained, no fractures were noted at the interface, and no cracking was observed at the façade.

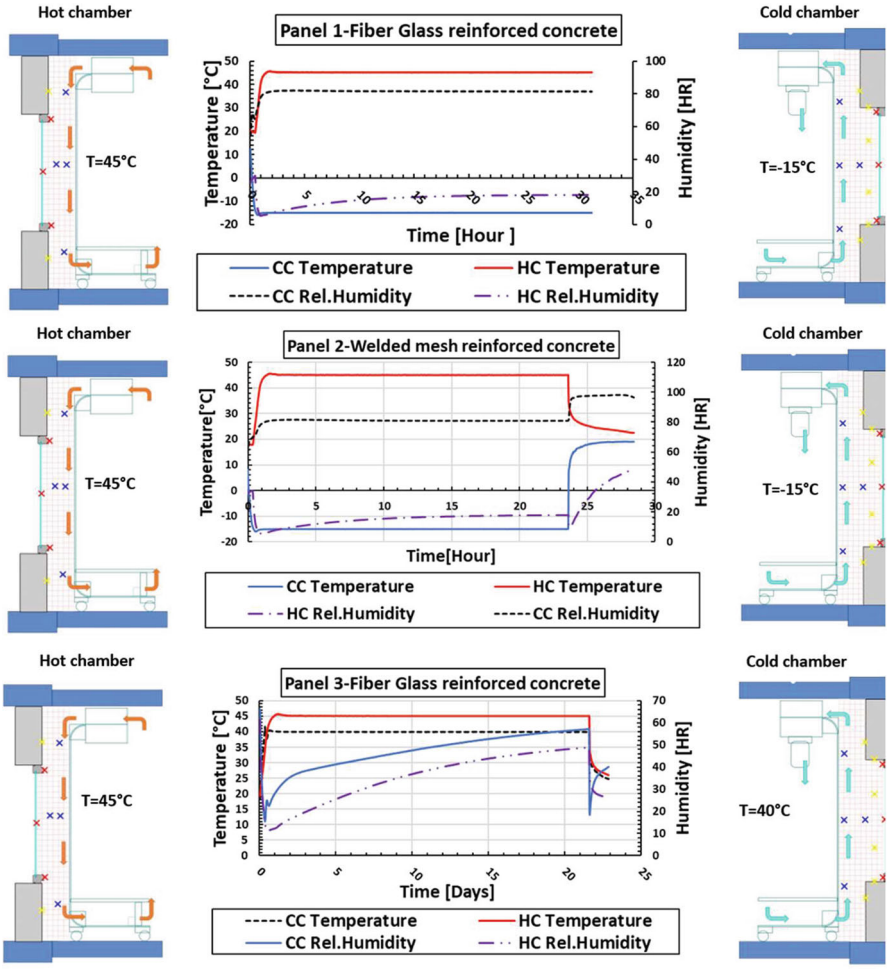

Fig. 6 Change in temperature of generated air inside the hot chamber and cold chamber and moisture for all panels

4 Conclusions

Data analysis focused on temperature variations recorded on the facade surface, as well as thermal expansion measurements taken on the wood and concrete segments.

The observed temperature variations led to diverse expansions or contractions depending on the thermal and mechanical properties of the materials involved.

The results underlined the influence of boundary conditions in influencing the distribution of the stresses between wood and concrete.

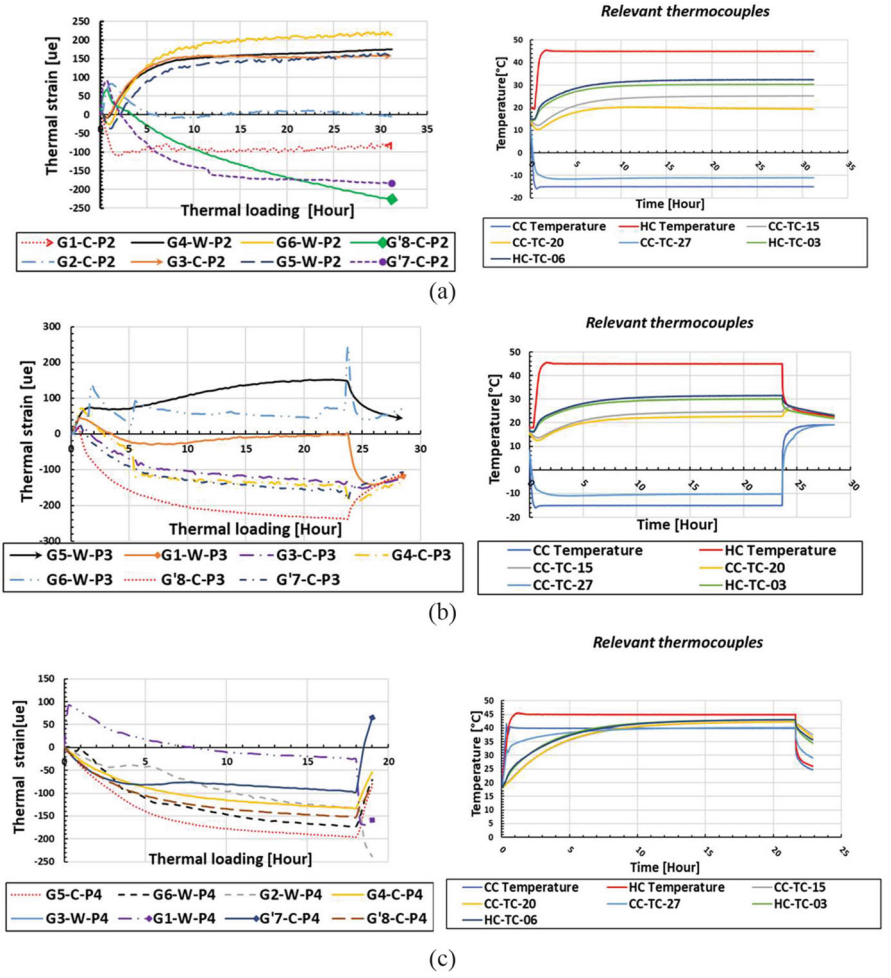

Fig. 7 Simultaneous evolution of thermal deformations and temperatures from thermocouples near strain gauges for (**a**) Panel l, (**b**) Panel 2, (**c**) Pane 3

The correlation between the thermal expansion of wood and the contraction of heated concrete during a temperature increase raises concerns regarding the thermomechanical properties of the materials studied. Wood, with a naturally higher thermal expansion than concrete, reacts more intensely to temperature variations. Its fibrous structure and flexible mechanical properties enable it to withstand high compressive loads. In contrast, although concrete can also expand thermally, its mechanical properties, such as rigidity, restrict this expansion.

1 Introduction

Heritage structures offer valuable insights into past architecture, construction techniques, materials used, and cultural practices [1]. These structures attract tourists and contribute to the economy, making their preservation and maintenance crucial [2]. Many historical buildings, typically made of masonry materials, lack lateral load-bearing systems to withstand forces like earthquakes. Because of their low tensile strength, they are prone to collapse under loads [3, 4]. Understanding the structural behavior of each unique historical building is essential for developing

appropriate restoration and retrofitting plans. This knowledge helps researchers ensure the structural integrity of these buildings [5, 6].

The geometry of historical monuments is highly intricate. These structures typically consist of walls, pillars, vaults, arches, roofs, and stairs, along with numerous doors and windows [7]. Thick walls help them withstand gravity loads effectively [8]. However, the absence of lateral structural elements poses challenges for these buildings [9]. The presence of multiple doors and windows makes them susceptible to lateral loads. The connections between different structural elements, such as roofs to walls or arches and domes to walls, are complex in such structures. Laser scanning, digital cameras, or drones can be employed to obtain the precise geometry of these structures [10]. These tools allow capturing the complex geometry of buildings, which can then be translated into numerical modeling using drawing software [11].

Ambient vibration testing (AVT), a powerful tool for determining the dynamic characteristics of structures, is a noninvasive method. It provides valuable insights into structural integrity by measuring ambient vibrations, particularly for cultural heritage structures like towers, monumental buildings, and bridges, where minimal interference with normal use is crucial [12]. Operational modal analysis (OMA), a technique in structural health monitoring (SHM), extracts modal parameters from ambient vibration data [13]. OMA identifies resonant frequencies, mode shapes, and damping ratios, offering insights into a structure's dynamic properties under real-world conditions [14]. Calibrating structures using OMA results is a nondestructive method to determine the material properties of historical structures and reduce differences between the dynamic characteristics of numerical models and the actual structure [15, 16].

The main objective of this study is to introduce a comprehensive methodology for creating three-dimensional (3D) simulation-based digital twins of cultural heritage assets using various technologies such as 3D laser scanners, drones, digital cameras, total stations, and accelerometers. The methodology was applied to develop a 3D digital twin of the Naillac tower in Rhodes Island, Greece. Initially, the material properties of the stone masonry were estimated using empirical equations. However, following model calibration based on OMA results, the updated finite element (FE) model's material properties were compared with the initially assumed values. Finally, the study discusses the significance of model calibration based on OMA results and its impact on the structure's performance.

2 An Overview of the Case Study

Constructed in 1400 AD by Grand Master Philibert de Naillac, the Tower of Naillac in Rhodes was a medieval fortress and lighthouse, renowned for its architectural brilliance [17]. Serving as a strategic defense for the commercial port, the tower featured a nightly use massive chain to block the harbor entrance. With canons, vigilant knights, and defensive chains, Rhodes, under Grand Master Naillac's

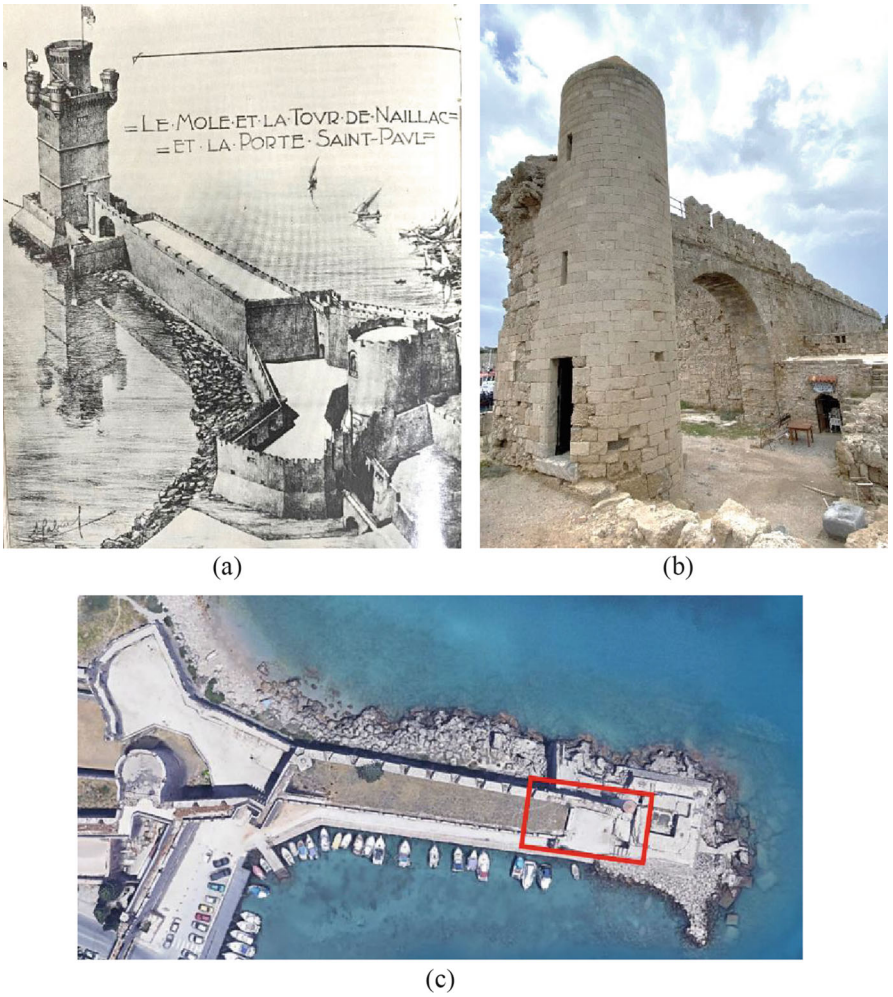

Fig. 1 (**a**) A drawing of the old Naillac tower [18]. (**b**) The remaining part of the tower and the arch (**c**) top view of the fortification taken from Google Earth

leadership, became one of the world's most fortified places [18]. Figure 1a shows the old Naillac tower and the arch bridge, which was the entrance to the tower. Unfortunately, the tower fell during a massive earthquake in 1863, leaving only its foundations visible in the sea [19]. Figure 1b shows the current corner tower, which was built during the Italian occupation to house a staircase leading to the entrance of the big rectangular tower and the arch, and Fig. 1c shows the top view of the fortification and the selected structure in the red box as the case study.

3 Numerical Modeling

3.1 3D Geometric Documentation

A holistic approach was employed for the 3D geometric documentation of the structure based on Kolokoussis et al. [20] and Shabani et al. [21]. A total of 736 ground digital images were captured, along with 1117 aerial images using drones, which had lower resolution due to difficulties in accessing certain parts of the structure. Subsequently, the digital images underwent processing in image-based modeling software, involving filtering and noise reduction, to generate a dense point cloud. Additionally, gaps in the point clouds derived from the digital images were addressed using 3D laser scanners, resulting in the final dense point cloud [20]. A total of 38 scans were captured using 2 terrestrial laser scanners. Establishing a local coordinate system involved the use of two total stations to define target points for laser scanner point clouds and ground control points for image orientation. The completion of the 3D model involved processing the triangulated irregular network representation model, converting each point into a polygon object. Following this process, a 3D dense point cloud, a 3D light model, and the cross sections were produced [20]. The height of the tower from the entrance level to the top is 11.3 m, the diameter of the tower and the thickness of its wall are 3 m and 0.2 m, respectively. The arch span is 7.65 m with a thickness of 2.7 m.

3.2 Numerical Modeling

The homogenized method was used for 3D FE modeling of the tower, neglecting the discretization of masonry units and mortar, which is commonly done for modeling full-scale structures [22, 23]. A 3D model was created using Revit software [24] based on the products from the previous step and imported into Abaqus software. The 3D FE model in Abaqus was split into two components: the tower and the fortification wall, with rigid boundary conditions assigned. The structure is built of Sfouggaria stone, a common material on the island of Rhodes in the past, with a compressive strength estimated at 9 MPa [25]. The elastic modulus of the homogenized masonry was assumed to be 1.001 GPa, considering the presence of soft mortar with a compressive strength of 1 MPa based on the empirical equations provided in Ghiassi et al. [26]. The density and Poisson's ratio of the homogenized masonry were assumed to be 2200 $\frac{\text{kg}}{\text{m}^3}$ and 0.3, respectively [27]. Figure 2a shows the 3D model of the structure. The interaction between the wall of the fortification in the western part of the structure and the 3D model of the structure was simulated using axial springs. Figure 2b shows the 3D FE model and the axial springs on the side of the wall highlighted with red stripes. The axial stiffness per area of the springs was calculated to be 0.39 $\frac{\text{GPa}}{\text{m}}$ considering the fortification wall with the length of 70 m based on Aghabeigi et al. [28]. After meshing, the model was then imported into FEMTools software for calibration as shown in Fig. 2c, d.

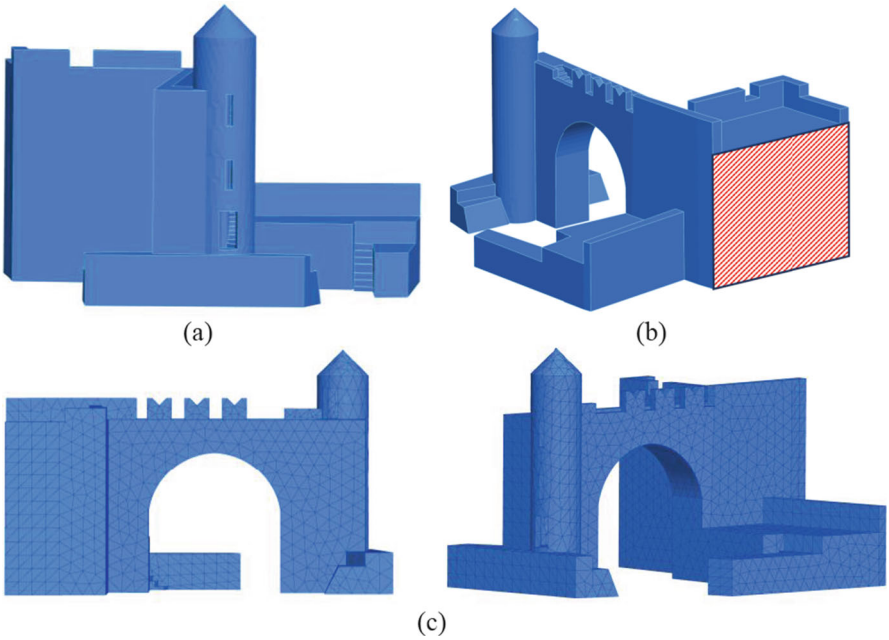

Fig. 2 (**a**) A 3D model of the structure. (**b**) A 3D model of the structure and the wall with axial springs. (**c**) A 3D mesh of the structure from different views

4 System Identification

4.1 Ambient Vibration Testing

Ambient vibration testing was carried out using 3-Axis MEMS digital Unquake accelerometers with a sampling rate of 250 Hz. Six accelerometers were placed in the tower, whereas none were placed outside due to stormy weather. The positions of the accelerometers were determined based on engineering judgment and previous studies [29, 30]. Sensors were selected based on the results of fast Fourier transform analysis, which examined the natural frequency values for each sensor measurement in each direction. After this analysis, three accelerometers were found to be functioning properly and were kept for further analysis. The locations of the three sensors were on the first opening, on the stair between the first and second opening, and on the top stair of the tower in front of the door. The accelerometers come with a Global Positioning System (GPS) antenna and a global navigation satellite system (GNSS) receiver. The recorded time from the GPS data was used to synchronize all the data collected by the accelerometers [29].

4.2 *Operational Modal Analysis*

All synchronized sensor data from the setups were brought into the ARTeMIS modal software package [31] to conduct OMA on a sensor network in order to determine the mode shapes. Three methods of frequency domain OMA were used: frequency domain decomposition (FDD), enhanced frequency domain decomposition, and curve-fitted enhanced frequency domain decomposition [32]. The results show that there was little difference in the natural frequency values obtained from these methods. Figure 3a shows the singular value decomposition (SVD) graph of the FDD method and the first two peaks [33]. The first two peaks show the first two natural frequencies of the structure, which are 5.981 Hz and 9.253 Hz. The acquired mode shapes from OMA indicate that the first and second modes correspond to the transverse and longitudinal directions of the fortification wall, respectively.

5 Finite Element Model Updating

The goal of the FE model updating is to reduce the disparities between the natural frequencies of the numerical model and the actual structure and to enhance the modal assurance criterion (MAC) values of the correlated modes by adjusting the material properties [34]. The tower is discretized into two sets: the tower itself and the remainder of the structure, which includes the arch and a small section of the fortification wall. This division is aimed at better addressing the variations in material properties across different components and facilitating the updating process by increasing the number of parameters. For model updating, a sensitivity-based

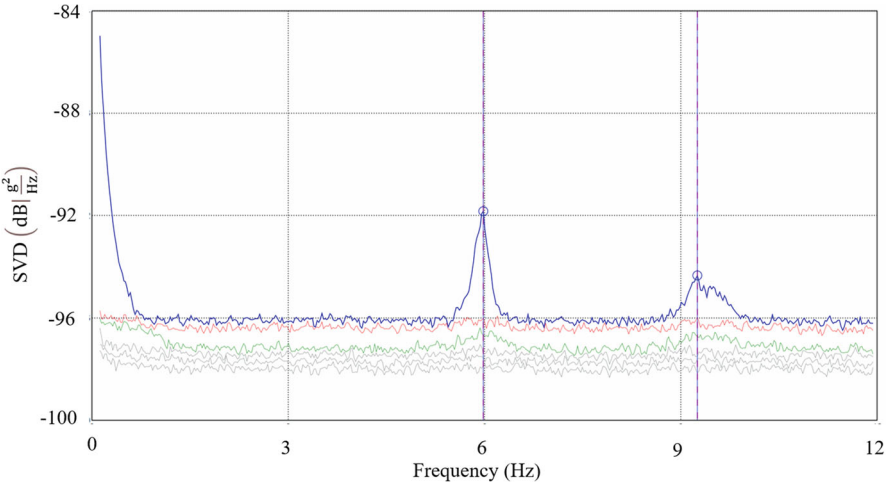

Fig. 3 An SVD graph of the FDD method with the selected two peaks

parameter estimation method was employed using the FEMTools software package [35]. Figure 4a, b shows the first and second mode shapes of the calibrated models, respectively, and Fig. 4c, d shows the OMA mode shapes correlated with the numerical model. The yellow dots in Figure (c) and (d) show the sensors' location.

Table 1 shows the absolute difference in natural frequency (ADF) for both modes. The ADF values are less than 0.03%, indicating a high degree of conformity between the frequency values obtained from the numerical model and those of the actual structure. The MAC values for the first and second modes are 87.921% and 75.568%, respectively, which shows a good correlation between the OMA and the numerical analysis results in terms of mode shapes. The MAC matrix is illustrated in Fig. 5. Higher values of the diagonal elements of the MAC matrix and lower values of the off-diagonal elements show that mode shapes from finite element analysis (FEA) follow the OMA mode shapes [29].

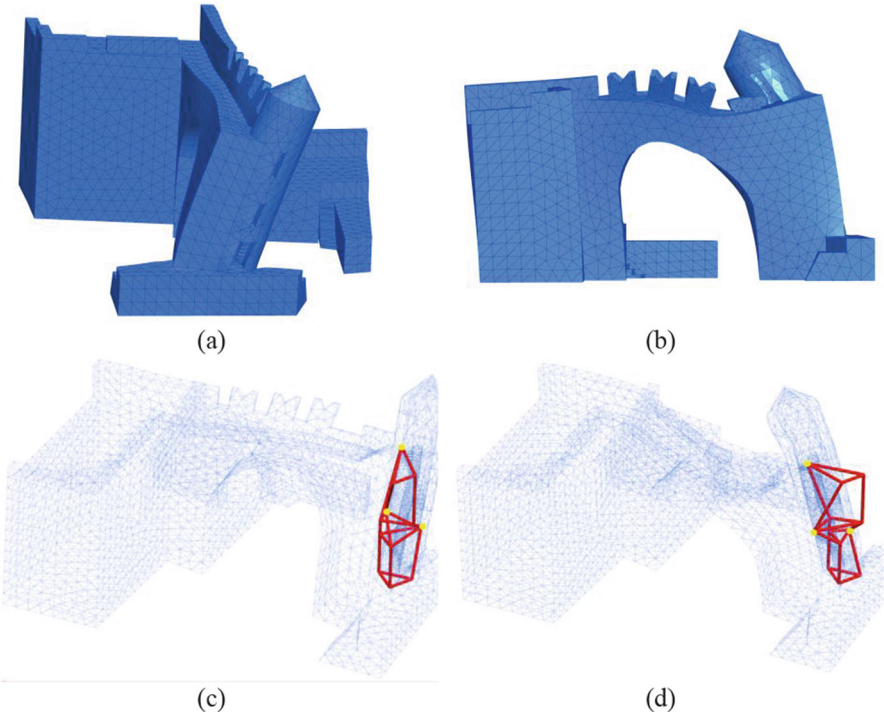

Fig. 4 (**a**) The first and (**b**) second mode shapes of the calibrated model and (**c**) the first and (**d**) second mode shapes' correlation with the test results

Table 1 Frequency values of the test and calibrated model and ADF of the first natural modes

Mode number	Test frequency (Hz)	Calibrated model frequency (Hz)	ADF (%)
1	5.981	5.982	0.023
2	9.253	9.251	0.024

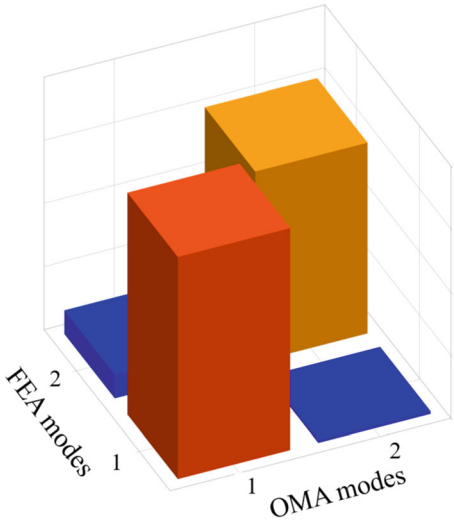

Fig. 5 An MAC matrix of the calibrated model

Table 2 Base and calibrated material properties and spring interface stiffness

Component	Property	Base value	Updated value
Tower	Elastic modulus (GPa)	1.001	3.03
	Density ($\frac{kg}{m^3}$)	2200	2183.76
The rest of the model	Elastic modulus (GPa)	1.001	2.08
	Density ($\frac{kg}{m^3}$)	2200	2008.09
Spring interface	Stiffness per area ($\frac{GPa}{m}$)	0.39	0.38

The updated material properties of two components of the structure and the stiffness of the assigned springs before and after calibration are presented in Table 2. The updated elastic modulus, a crucial material property affecting structural behavior, underwent significant changes. This emphasizes the importance of calibrating numerical models based on OMA. Specifically, the tower component's elastic modulus is more than three times greater than the value calculated using the empirical equations. Therefore, the structural performance is underestimated, and the structure exhibits lower initial stiffness when subjected to wind or seismic loads. Additionally, it was observed that the tower component's elastic modulus exceeded that of the rest of the structure, indicating its greater stiffness, which is against the initial assumption. Furthermore, the spring interface stiffness experienced minimal change, indicating its negligible impact on the structure's modal properties.

6 Conclusions

A holistic methodology was employed for developing a simulation-based digital twin of a cultural heritage asset. The case study is Naillac tower, which is the remnant of the older stone masonry tower built in 1400 AD that collapsed due to

an earthquake in the eighteenth century. The corner tower, originally constructed to accommodate the staircase leading to the main tower, along with the arch and a portion of the fortification, was chosen for modeling. The 3D geometric documentation was conducted using digital cameras, drones, total stations, and 3D laser scanners. Subsequently, a 3D model was constructed from the gathered data. Following this, a 3D finite element (FE) model of the case study was created, applying base material properties and boundary conditions. Concurrently, operational modal analysis (OMA) was executed using accelerometer sensors to capture the first two natural frequencies and corresponding mode shapes. Lastly, the material properties of the numerical model components were adjusted based on the OMA findings. The main findings of this research study are outlined as follows:

- The absolute difference in natural frequency (ADF) values for both modes **are less than 0.03%, and** the modal assurance criterion (MAC) values for the first and second modes are more than 75%, which shows a good correlation between the OMA and the numerical analysis results.
- The updated elastic modulus, crucial for structural behavior, showed significant changes, highlighting the need for OMA-based model calibration. The elastic modulus of the tower component exceeds three times the value estimated by empirical equations. Consequently, this leads to an underestimation of structural performance, resulting in reduced initial stiffness when the structure is subjected to wind or seismic forces.
- The elastic modulus of the tower surpasses the value of the rest of the structure contrary to the initial assumptions.
- Spring interface stiffness remains minimally affected after the calibration process.

1 Introduction

The ongoing effort to limit emissions in the construction industry is now focusing on the embodied energy in building materials to introduce renewable and bio-based alternatives, such as engineered wood products (EWP), to building products traditionally made with concrete, steel, or aluminium. One such substitution is a façade system bearing frame structure commonly made in aluminium. While increasing the sustainability of source material performance requirements must still be met, and the minimum 35 years of service life should be ensured to qualify as carbon removal according to the new European certification scheme [1]. While certain system elements, that is insulated panels and glass panels attached to the timber frame, can be exchanged after 20–25 years [2], the structure should withstand at least two

service lives and approach the typical building design service life of 100 years. The infill/insulation, sealing, and cladding elements that are subject to ever-increasing energy-efficiency and air and moisture tightness requirements should be installed allowing easy disassembly as specified in the standard ISO 20887:2020 [3]. Overall sustainability of the hybrid timber–aluminium façade system was shown to be superior to the aluminium-based system [2] via Life-Cycle Assessment including end-of-life scenarios of landfilling, recycling, and reuse. The benefits of the most preferable scenario, that is reuse, are subject to the uncertainties connected to the delayed realization and technical and economic feasibilities. To ensure the durability of the structural glulam façade frame with an accepted reliability level, real environmental loads should be considered and possibly adapted to include climate change scenarios. Wood exposed to moisture fluctuations over time can develop fungi, and rot and lose its functional properties. Timber can be effectively protected over many decades by providing proper façade insulation and ventilation based on good practice, as well as introducing predictive inner climate control via sensors. Especially challenging weather conditions can be experienced in Scandinavia, where high humidity and short dry seasons require climate-conscious adaptations of building solutions. Furthermore, coastal locations are exposed to high wind loads that lead to unavoidable fatigue-induced damages over longer periods. Fatigue in wood is a complex research field, where material anisotropy and typical huge variations of static mechanical properties hinder the development of universally applicable rules while accurate quantification of environmental and operational loads poses further challenges. Fatigue life is usually understood as the number of load cycles N at a given load amplitude S leading to the mechanical failure, where damage accumulates with every cycle and reaches value 1 at ultimate failure. Different fatigue lives for common wood failure modes found in literature and standards are shown in Fig. 1.

Load cycles differ in amplitude, frequency, form, direction, and distribution on the structure. Dynamically applied load, that is wind on facades is difficult to

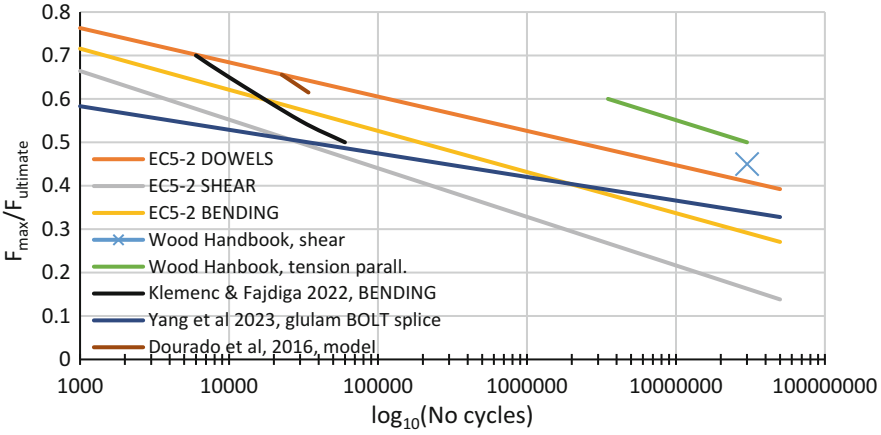

Fig. 1 Fatigue life curves for timber in literature [4–6] and EC5-2

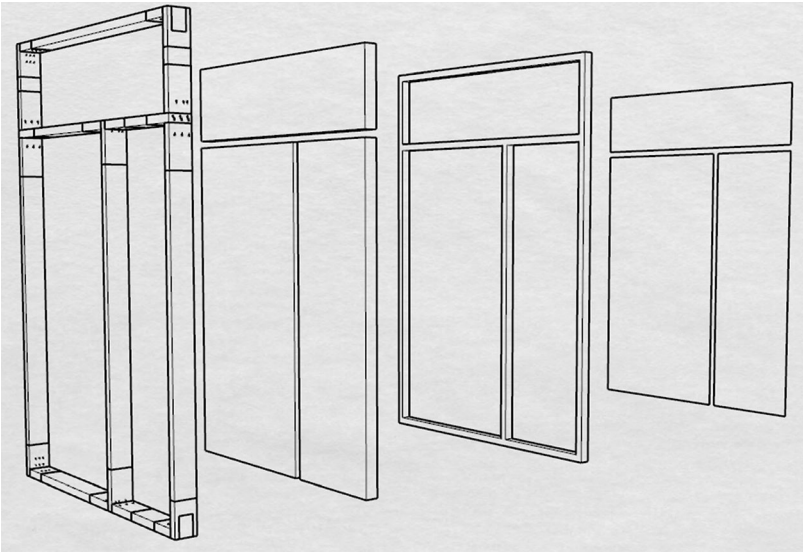

Fig. 2 Elements of the façade system from the left: timber frame, insulation, aluminium frame, and glass pack/metal panels

quantify due to varying directions and particular aerodynamic conditions in the area. Increased exposure to high wind loads can lead to decreased service life and premature damage. Damage in wood due to various cyclic loads is underdeveloped research area. Non-linear damage accumulation models require multitude long-duration cycling experiments for a given wood species. However, linear damage accumulation model of Palmgren-Miner was found to exhibit sufficient accuracy for timber roof-to-wall connections subjected to wind load [7]. This article presents the methodology of evaluating fatigue life of façade timber frame under wind loads and its practical application for three locations in Norway (Oslo, Trondheim, Tromsø) based on 3 years of wind observations (2021, 2022, 2023). The frame and façade system build-up is depicted in Fig. 2.

2 Methodology

To ensure the successful reuse of façade elements, the capacity to withstand several environmental loads must be sufficient. Most critical loads include cycling moisture and temperature changes and wind loads. The considered hybrid timber–aluminium façade system was already assessed as safe against mould development in Nordic climates [8, 9]. This study is devoted to the mechanical performance only and assumes sufficient biological decay resistance of timber frame over the 100-year period and proper maintenance and regular inspection or monitoring.

2.1 Experimental Tests of Timber Frame Connections

Experimental static mechanical tests were performed on the internal screw connections of the frame depicted in Fig. 3. The connections are loaded vertically, in the plane of the glulam frame and represent gravity loads. Three- and four-point bending tests were performed for L-joint and T-joint, respectively. Strain gauges were used to apply the load at the speed of 0.1 kN/s. Force and displacement data were logged.

L-joint consists of a 150 × 150 × 10 mm L-bracket and nine 45-degree inclined screws of 5 mm diameter and 50 mm length. T-joint features three rows of four 5 × 140 mm screws connecting three timber members at 45-degree to the wood fibre direction.

2.2 Numerical FEM of Experimental Tests of Joints

The finite element method was used to simulate the mechanical behaviours of the connection under the conditions of the laboratory test. Continuum 3D elements with eight nodes reduced integration and a general size of 5 mm were used. Mesh sensitivity was investigated to provide sufficient accuracy within reasonable

computation time. The discretization of the models is shown in Fig. 4. The wood material model is elastic orthotropy with nine parameters listed in Table 1.

Steel was modelled as elastic isotropic with $E = 210$ GPa, and $\nu = 0.3$. Screws are modelled without thread as a smooth shank of the screw core diameter and tied to wood.

2.3 Wind Load Model

Wind load calculations were carried out according to EN-1991-1-4 2005. The rules apply for buildings up to 200 m high. Basic wind velocity is obtained from the meteorological station (Oslo, Blindern) using API Frost as max wind velocity values in 10-min intervals at 10 m height above the ground and hourly mean velocity for reference, see Fig. 5.

Wind action on the façade is represented by the equivalent surface pressure q_p:

$$q_p(z) = \left[1 + \frac{k_r \cdot v_b \cdot k_l}{v_m(z)}\right] \cdot 0.5 \cdot \rho \cdot {v_m}^2(z), v_m(z) = k_r \cdot \ln\left(\frac{z}{z_0}\right) \cdot c_0(z) \cdot v_b \quad (1)$$

where in the function of height z in the coastal area with terrain category 0, where v_b is the base wind speed, see EN 1995-1 for details.

$$v_b = c_{\text{dir}} \cdot c_{\text{season}} \cdot v_{b,0} \quad (2)$$

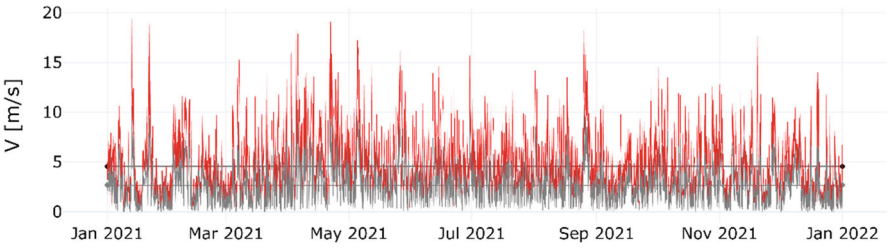

Fig. 5 Wind speed at 10-min temporal resolution (red—maximum peak, grey—mean) observed at Oslo-Blindern in 2021

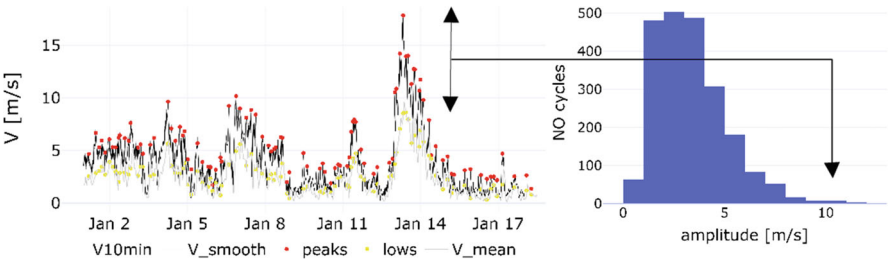

Fig. 6 Wind speed peaks (Oslo) identified from 10 min maximum values shown for 1 week (top) and amplitude histogram for all peaks during one year of data

where c_{dir}, c_{season}, are directional and seasonal wind factors, respectively. Wind load has a non-constant amplitude and requires handling damage accumulation from different cycles. Cycles are extracted from maximum wind time series using smoothing function (Savitzky-Golay filter within scipy package for Python 3) and peak (extremum) finding algorithm with peak prominence of minimum 1 m/s. The wind observations are available only for maximum and mean values at the highest 10-min resolution so the reference for amplitude estimation is chosen as the mean wind speed for each peak. Peaks and amplitude histograms for 10 amplitude ranges are depicted in Fig. 6.

2.4 Numerical Simulation of the Frame Under Static Equivalent Force

The model of the glulam frame for structural analysis with FEM was created within commercial software ABAQUS, see Fig. 7. The connection models validated with experimental tests for T-joint and L-joint were embedded in the frame model. The frame was fixed by T-plates on the top and horizontal translations are blocked at the bottom beam where bolted locks are attached. Pressure is collected from the frame

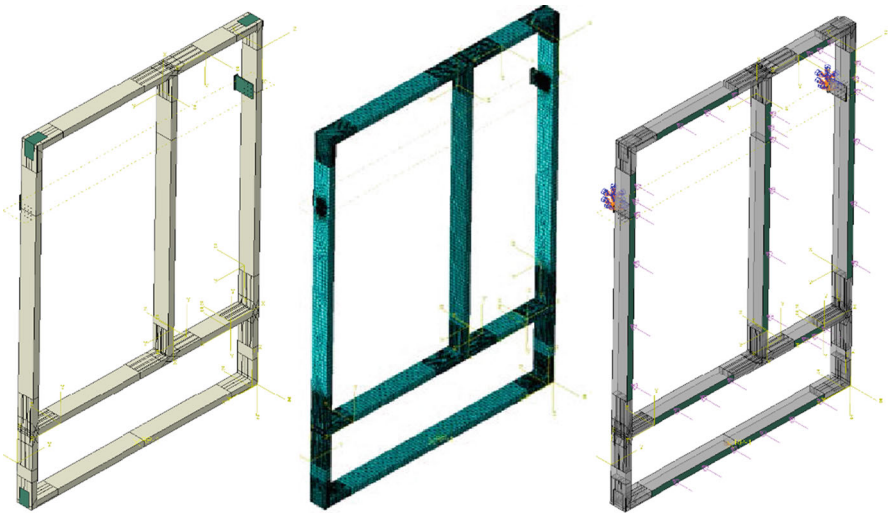

Fig. 7 Geometry, mesh, and boundary conditions of the glulam frame model for FEA

façade surface 2.45 × 3.4 m^2 and distributed over the front frame surface. The weight of the façade panels is not applied, and only the self-weight of timber and steel is considered.

Fatigue verification for timber structures is usually based on a simplified method from EN 1995-2-2, Annex A assuming equivalent constant amplitude fatigue loading. When several different loading amplitudes are present cumulative damage can be evaluated according to Palmgren-Miner theory of linear cumulative damage, see Eq. 3, where D denotes damage, N_{tot} is the total number of cycles, n_i is the stress level of a given load cycle i, and $N_{f,i}$ is the fatigue life corresponding to stress level n_i.

$$D = \sum_{i=1}^{N_{\text{tot}}} \frac{n_i}{N_{f,i}}, D \in <0, 1> \tag{3}$$

Information about damage induced by each load cycle is required and is evaluated by inverting EC5 formula to obtain fatigue life for a k stress level:

$$D \log(N_i) = (1 - k_i) \frac{a(b - R)}{1 - R}, R = \frac{\sigma_{d,\min}}{\sigma_{d,\max}} \tag{4}$$

Stress levels k_i is directly extracted from the wind history as wind peaks ratio to the maximum allowed wind capacity. Coefficients a and b representing the type of fatigue are chosen for dowel-type connections according to Table A.1 in EC5-2 (EN 1995-2-2). R is defined as a ratio of minimum to maximum design stress applied in the load cycle. Fatigue material factor is not accounted for.

3 Results

3.1 *Experimental and Numerical Results for Timber Frame Connections*

Force–displacement curves from connections experiment and simulation show good agreement in the elastic range, see Fig. 8. L-connection experiences slip, not captured by the simulation but measured at around 0.26 mm. The slip is caused by the presence of the L-shaped, 15 × 15 × 1 cm steel plate connecting frame corner elements.

3.2 *Numerical Simulation of Timber Frame and Fatigue Service Life Estimation*

The final maximum basic wind speed for building height 12 m (third story) was 19.4 m/s and corresponds to the pressure of around 6.8 kPa. Under this statically applied pressure, the frame timber members reach 28% capacity in compression perpendicular to the grain around the T-plate bolts, see Fig. 9.

The central T-joint is the most strained connection in the frame and perpendicular to grain compression stresses are at 3 MPa and 83% capacity. L-joint has the largest value of longitudinal shear stresses with 30% capacity (see Table 2), while compression perpendicular to the grain is at 22%, see Fig. 9. Stresses in steel elements under maximum load are depicted in Fig. 10. Mises stress hypothesis was used to estimate stress level in T-brackets, L-joint, and T-joint. Most stressed steel elements are bottom bolts and the bottom part of the T-bracket that transfer most of the load of the timber frame hanging on them. However, the level of stress at just below 160 MPa was found to be below 50% of the ultimate tensile strength limit for the most typical carbon steel of grade S235, namely 360 MPa. Such a low level of stress allows us to assume that load in steel elements is below the endurance limit for fatigue defined in Eurocode 3, part 1–9 (EN 1993-1-9).

Maximum deformations of 4.8 mm occur in T-joint as shown in Fig. 11.

The wind speed at which the frame is at 100% of local static perpendicular to grain compressive stress capacity is set at 19.4/0.83 = 23.5 m/s. Additionally, to account for the higher dynamic elastic modulus, the maximum wind speed was increased by 20% to 28.2 m/s. The value was based on the literature findings, where a different mean ratio between dynamic and static modulus of elasticity for wood was found, that is 1.07 [10], 1.1 [11], 1.13 [12], 1.22 [13], and 1.28 [14]. All identified load cycles are considered for total damage evaluation without assuming fatigue endurance limit. Cumulative linear damage for four consecutive years 2020–2023 in three Nordic cities is summarized in Table 3. Based on those damages, the predicted service life due to mechanical fatigue failure in the frame is estimated for each location at over 100 years for both Oslo and Trondheim and at 32 years for Tromsø.

Overview of load cycles due to wind for a given year is shown in Fig. 12.

4 Discussion

4.1 Discussion of Results

Service life due to damage accumulation in timber frame under wind exposure is estimated as non-critical for Oslo (Blindern) and Trondheim (Voll) observations assuming a height of 12 m above the ground. Tromsø location has a decidedly smaller service life, at 32 years. The main factor is the presence of several high peaks in wind speed compared to the estimated frame capacity of 28.5 m/s. For the more exposed locations with direct seaside locations, and stronger winds design changes are recommended, for example symmetric geometry or stiffening elements. Furthermore, experiments on the out-of-plane load response of both T-joint and L-joint would improve the estimation of capacity and service life.

4.2 Limitations of the Research

This work makes several limiting assumptions. Only static structural analysis is performed, and no dynamic effects and time-dependent material properties are accounted for in the simulation. Moisture-induced stresses, damage due to moisture cycles, and coupled moisture-mechanical stress fields were not considered. Wind loads are collected from 10 min frequency data of maximum wind speeds. Thus, actual number of cycling and real minimum wind speed for accurate amplitude estimation is not known. Wind direction was not accounted for to decrease the real pressure on the façade, which is a conservative assumption. The positive stiffening effect of façade panels was not included, and fatigue of steel T-plate connectors and screws was not studied in detail due to the assumed endurance limit at the expected stress level. Additionally, the cumulative damage was obtained based on linear theory, and the progressive increase in the damaging effect of similar cycles was not considered. The influence of the accumulated damage and duration of load can be substantial factors for fatigue life assessment. However, no sufficient data for the wood performance under different sequences of short-term loading are available in the standards and literature to allow for a non-linear damage accumulation model with a sufficient confidence level. Thus, the focus of future research within timber engineering should be damage development and accumulation under cycling loading if carbon removal goals in timber construction are to be achieved.

5 Conclusions

Structural analysis of the glulam frame supporting a novel modular façade system in the Nordic wind conditions was performed to predict fatigue service life to ensure the long-term sustainability of replacing aluminium/steel with glulam. The finite

element model of the frame was calibrated using laboratory mechanical tests of the T- and L-joint with screws and brackets. Continuum models of both timber and steel were used to increase the precision of modelling complex stress states for the identification of failure modes. Linear damage accumulation calculation is shown for 4 years between 2020 and 2023 in Oslo, Trondheim, and Tromsø locations in Norway. Key conclusions from the paper are listed:

- The critical role of the major wind load events with speed over 20 m/s on the fatigue life and damage in timber frame is observed.
- Design alternation, that is introducing symmetrical geometry, re-designing, or reinforcing joint is recommended to limit the load level in the critical location.
- The most critical failure mode was identified as local perpendicular to grain compression in wood in the T-joint.
- The predicted service fatigue life for the façade system is estimated at 32 years for Tromsø and over 100 years for Oslo and Trondheim.

Acknowledgements This research was funded by the EEA Norway Grant nr LT-INNOVATION-0002: 'Developing a more environmentally friendly automated façade system that is integrated into the building's control systems'. Experimental tests were performed in 2022.

1 Introduction

Steel-reinforced concrete (RC) bridge decks are now widely adopted for bridges. Despite their numerous benefits, the steel reinforcement within the concrete is vulnerable to corrosion over the bridge's service life, highlighting a key factor in the bridge deterioration [1]. This issue is particularly notable in colder climates where deicing salts are employed, where the degradation of bridge decks is primarily attributed to the corrosion of steel [2]. Initiation and propagation are the two common stages of steel corrosion. In the first stage, the ions accumulate on the rebar surface due to water and aggressive agents' penetration, leading to a set of electrochemical reactions which results in the initiation of the second stage and the formation of rust [3]. The first stage was investigated by Shafei et al. [4] through developing a stochastic framework using finite element models and various sources of uncertainty. Corrosion effects on the durability of RC structures have been

concerning for engineers and decision makers, as the cost of repair and rehabilitation can be significant [5]. Battelle-NBS, a benchmark study in 1975, showed a total of $70 billion corrosion cost (4.2% of the gross national product (GNP)) in the United States. The estimated corrosion cost increased to a total of $300 billion in 1995, which was estimated to increase even further to about twice considering the indirect costs of corrosion. Accordingly, the cost of corrosion in the infrastructure sector covered 16.4% of the total annual cost of corrosion for the industry sectors. A study conducted by Virmani [6] reported that 15% of the bridges had deficiencies majorly due to corrosion of steel, indicating 37% corrosion costs of highway bridges out of all the corrosion costs of the infrastructure sector.

Khatami and Shafei [7] investigated the deterioration of RC bridges in the Midwest due to environmental factors like temperature, humidity, and deicing salts. The authors developed a computational model to predict corrosion initiation times based on regional climate data. The study quantified climate condition effect of both crack width and the duration needed to reach durability thresholds. Shi et al. [8, 9] also studied the chloride penetration in concrete mixture with shrinkage-compensating cement, showing that increasing the dosage of the agent increased chloride penetration.

The production of carbon-intensive materials is a major contributor to the considerable greenhouse gas emissions. Cement and steel were reported to be responsible for 8% and 7% of global carbon dioxide (CO_2) emissions, respectively. Thus, a movement toward decarbonization of the construction industry can be a beneficial step in reducing greenhouse gas emissions. Several approaches have been proposed to decrease the carbon emissions of cement and steel production including using alternative fuels, carbon-capturing, energy efficiency of cement, or alternative materials [10]. The development of fiber-reinforced polymer (FRP) bars in recent years has provided the opportunity for decreasing the use of steel rebars in RC structures. FRP bars consist of extremely fine polymer bars embedded in a matrix. Discrete fibers of various types have also been used in concrete mixtures to enhance the mechanical properties [11–13]. The polymer reinforcement is not susceptible to corrosion while providing high strength-to-weight ratio, high tensile strength, and light weight compared to the conventional steel bars. Four widely-known FRP materials are glass (GFRP), carbon (CFRP), basalt (BFRP), and aramid (AFRP). The low manufacturing cost and easy availability of the glass fibers make them one of the most popular FRP materials. Research has shown that raw material supply is the main contributor to the energy use and environmental impact category results of GFRP structures, followed by the minor contribution of raw material transportation (less than 10%) and manufacturing (10% of greenhouse gases and 15–20% of the energy use). Utilizing the FRP bars in the concrete structures increase their durability and service life, decreasing the need for repair and rehabilitation, which can lead to significant carbon emission and material waste. Thus, the hidden costs of repair and rehabilitation during the service life of a structure are lower than that of a steel-reinforced structure, making FRP bars feasible alternatives despite the higher initial cost [5, 14, 15].

Several researchers studied and analyzed the use of FRP materials in RC structures in terms of sustainable metrics, environmental impacts, and costs. Daniel [16] showed that a GFRP bridge required less than half of the energy input in comparison with bridges of other traditional materials. The sustainability of a GFRP bridge deck in comparison with a composite (steel concrete) bridge was analyzed by Mara et al. [17] in terms of life cycle, maintenance, and construction process, indicating a reduction of 20% in carbon emission in case of a GFRP deck. Maxineasa et al. [18] showed that glass fibers had less negative environmental impacts on global warming, human health, and ozone depletion potential compared to carbon fibers. Barker [14] studied the feasibility of GFRP, CFRP, and AFRP as alternatives to the conventional steel in RC structures. The FRP materials were compared considering the energy requirement and greenhouse gas emissions during the construction followed by sustainable metrics within the service life and also recyclability. The study showed that GFRP minimized the energy requirement and CO_2 emissions, as it was produced at a lower temperature compared to steel. The life-cycle assessment of the design stage study of a GFRP-reinforced bridge and a conventional steel-reinforced bridge were studied by Cadenazzi et al. [19], reporting lower acidification, global warming, eutrophication, and photochemical oxidant creation for the GFRP bridge compared to the steel one. Garg and Shrivastava [5] compared the steel rebars with CFRP, BFRP, and GFRP bars in reinforced concrete beams both environmentally and economically. The results of the study showed 43% and 46% less CO_2 emission and energy consumption for GFRP-reinforced beams compared to the steel-reinforced beams, respectively, providing an environment friendly option in terms of carbon footprint (Fig. 1).

Preinstorfer et al. [20] evaluated the mass-related global warming and material cost of a broad range of concrete structures including a rail platform barrier, a retaining wall and a bridge reinforced with conventional steel and GFRP bars. The parametric design study linked the mass of longitudinal rebars to the properties of global warming. The results showed slightly more sustainable solutions for GFRP-reinforced structures for global warming. As a protective alkaline environment was not required due to non-corrosiveness of GFRP bars, an optimized concrete mix with less clinker amount could provide the same performance. The optimized mix resulted in 31% lower mass-related global warming factors compared to the steel bars. Another study by Sbanieh et al. [10] showed that using GFRP bars instead of steel reinforcement decreased CO_2 emissions by almost 23%. Ji et al. [21] compared the sustainability of GFRP, CFRP, BFRP, and steel bars for carbon emission based on both weight and volume of FRP bars. Accordingly, the weight-based factors of steel bars were slightly lower than those of GFRP bars; however, from a volumetric aspect, the carbon emission factors of the GFRP bars were lower than those of steel as the density of GFRP bars were lower.

From another perspective, the use of concrete consumes significant amount of fresh water, crushed stones, and river sand. Also, the long transportation distance of crushed stone to the marine environment increases the cost and pollution. The non-corrosive properties of the FRP bars provides the opportunity for the utilization of seawater and sea sand concrete (SWSSC) in construction, conserving the limited

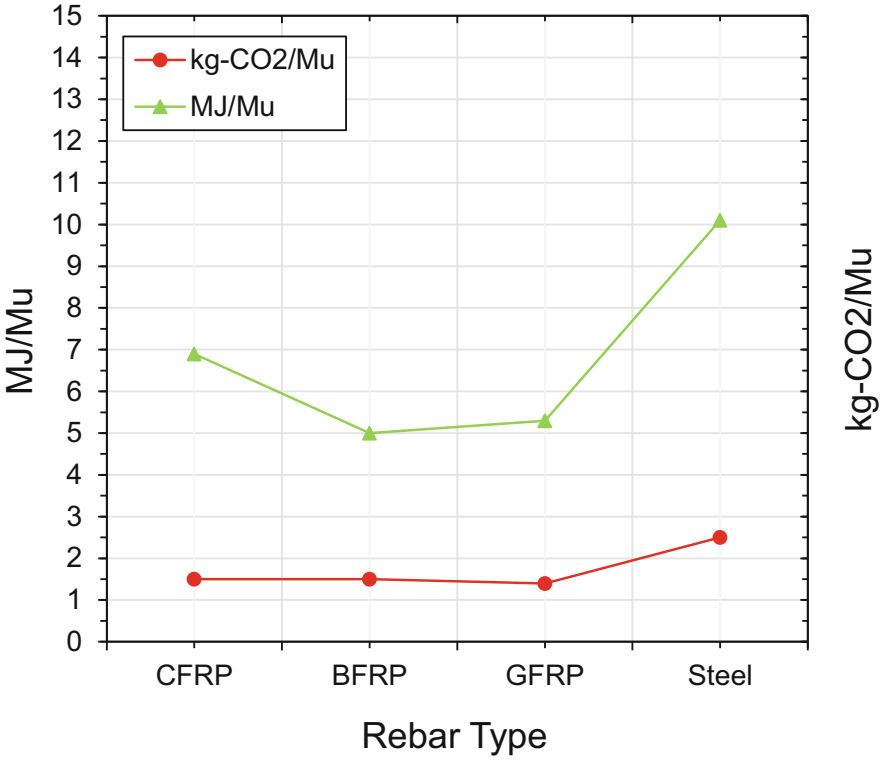

Fig. 1 Carbon emission and energy use of different rebar types [5]

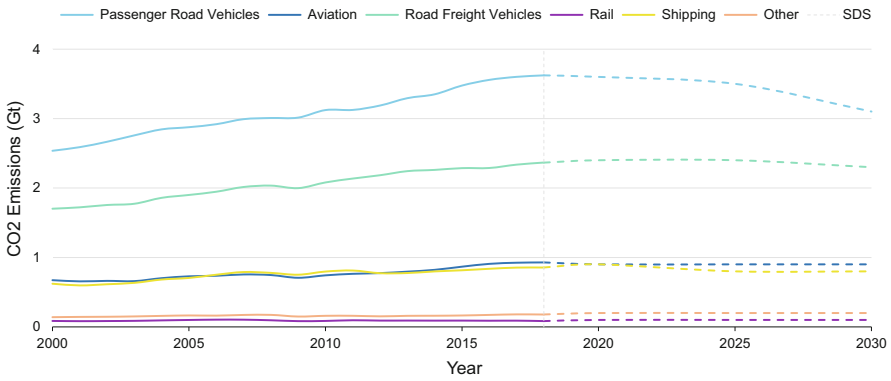
source of river sands and fresh water while decreasing the transportation distance of the aggregates. Dong et al. [22] performed a life-cycle cost assessment (LCCA) of GFRP/CFRP-reinforced and also steel-reinforced concrete beams in marine environments. The LCCA included the production, transportation, construction, service life and end of life categories. The results showed that SWSSC had considerably lower environmental impacts in all the categories with reduction rates ranging from 26.3% to 48.6% compared to the conventional concrete.

Given the substantial freight activity across the US infrastructure and transportation network, road freight vehicles contribute significantly to CO_2 emissions in the transportation sector, ranking second only to passenger road vehicles (Fig. 2). Thus, options with lower freight activities provide opportunities for substantial decarbonization. Considering the lower weight of GFRP bars compared to steel bars, GFRP-reinforced structures decrease the environmental burdens in longer transportation distances as the weight of GFRP makes it possible to use fewer trucks saving several freight distances per project [22].

In this study, various aspects of the performance of a GFRP-reinforced bridge deck are compared to the counterpart aspects of a steel-reinforced bridge deck under similar environmental conditions and traffic loads. The bridges were instrumented



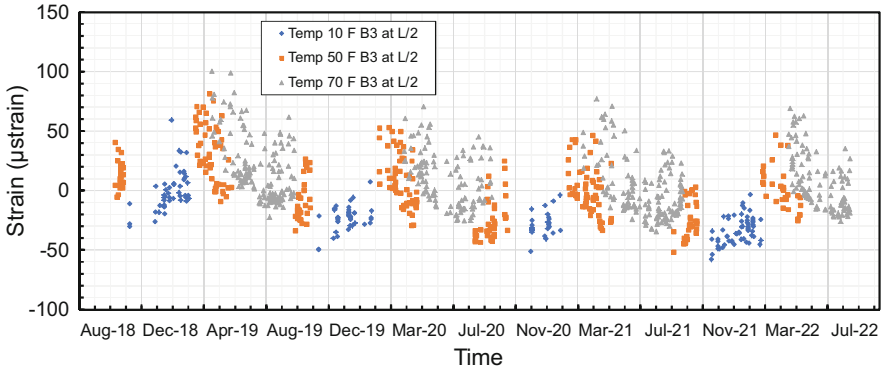


Fig. 2 Transport sector CO_2 emissions over time [23]

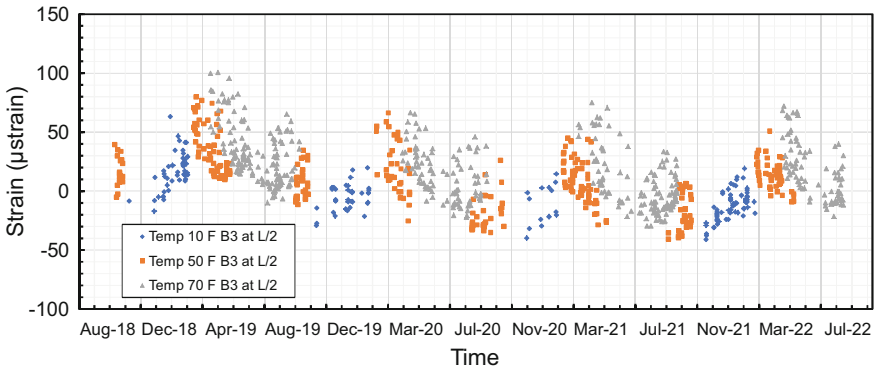
using various sensors and monitored over the years. The strain data was collected and analyzed to find the seasonal patterns and also anomalies in the structural response of the bridge decks. The results of the experimental tests of the GFRP bars were also examined to compare the mechanical properties of the GFRP bars with steel bars. A life-cycle cost analysis was also performed to evaluate the financial aspects of using GFRP in bridge decks instead of steel reinforcement. The results of the study sheds light on the viability of using GFRP-reinforced bridge decks instead of steel-reinforced bridge decks in terms of structural performance, long-term bridge response, and the total cost, while providing the bridge engineering community with a more durable and sustainable option that causes lower environmental impacts.



2 Long-Term Health Monitoring

Two bridges in Minnesota with similar properties were selected to study the structural performance of a GFRP-reinforced deck and a conventional steel-reinforced deck in comparison with each other. Each bridge was instrumented with vibrating wire strain gauges at several sections. The strain and temperature values at all sensor locations were collected for a period of over 48 months. The collected data was analyzed for maximum strains, seasonal variations, and abnormalities in the bridge deck's behavior. As the cracking tensile strain of concrete is considered to be 100–-120 μstrain, the maximum strains extracted from the collected data was used to find the potential cracks in concrete decks.

Figure 3a shows the collected data for three temperatures of 10, 50, and 70 °F at the mid-span of the steel-reinforced bridge. The gauge was positioned on the bottom reinforcement mat of the deck close to the longitudinal axis of the bridge. The figure shows that the average compressive strain at 10 °F increased at the bottom center gauge. Under a temperature of 50 °F, the strain values generally decreased in every

(a)

(b)

Fig. 3 Strain values of the bottom center gauge of the bridge decks at 10, 50, and 70 °F. (**a**) Steel-reinforced bridge deck. (**b**) GFRP-reinforced bridge deck

subsequent fall and spring season, trending mostly to compressive strains. However, the strains increased every subsequent fall. On the other hand, the strains decreased over the summer and generally over the years at 70 °F at mid-span. The figure shows scattered strain values with variations for different seasons with various temperatures.

The strain time history of the bottom center sensor of the GFRP-reinforced bridge deck at temperatures of 10, 50, and 70 °F is illustrated in Fig. 3b. The figure shows a decreasing trend over the years at 10 °F at mid-span. At 50 °F, the strains showed an overall decreasing pattern with an increase every spring at mid-span. At 70 °F, the strains show a decreasing trend over each spring and the subsequent summer with a peak of tensile strains close to the beginning of each spring to lower tensile or even compressive strains more through the subsequent fall.

The figures show similar behaviors of the GFRP- and steel-reinforced bridge decks with respect to low, medium, and high temperatures across the seasons. Accordingly, both bridge decks reacted to cold weather with majorly compressive

strains, indicating that the reinforcing bars were mainly in compression as the concrete contracted. The strain values in both bridges covered similar ranges, with the steel-reinforced deck showing a slightly steeper decreasing slope over the years. Similar strain ranges and generally decreasing average strains were observed in different seasons at medium and high temperatures, too. The trends show that the high tensile strains occurred as the concrete expanded in warm seasons.

3 Laboratory Tests on GFRP Bars

In order to gain a better understanding of the mechanical properties and strength of the GFRP bars utilized in the construction of the GFRP-reinforced bridge deck, a series of laboratory material characterization tests was conducted. Four samples of the GFRP bars employed in the bridge construction project under study were subjected to testing. These specimens underwent tension until failure while measuring force, displacement, and strain. The collected data facilitated the development of stress–strain curves, enabling comparison of the tensile properties of the specimens with reference values obtained from prior GFRP tensile tests.

The GFRP bars utilized had a nominal diameter of 0.625 inches and an effective diameter of 0.67 inches, with each piece being cut into 28-inch segments. One longitudinal strain gauge was installed on each 28-inch specimen. Displacement rate was determined according to ASTM D7205 [24]. The specimens were loaded in tension until failure, with force, strain, and displacement being measured.

The stress–strain curves for the four GFRP test specimens are depicted in Fig. 4, demonstrating consistent mechanical properties across all tests. Stress increases linearly until reaching maximum load, followed by sudden failure marked by multiple glass fibers snapping simultaneously, necessitating a sudden decrease in load by the testing machine to maintain a constant displacement rate.

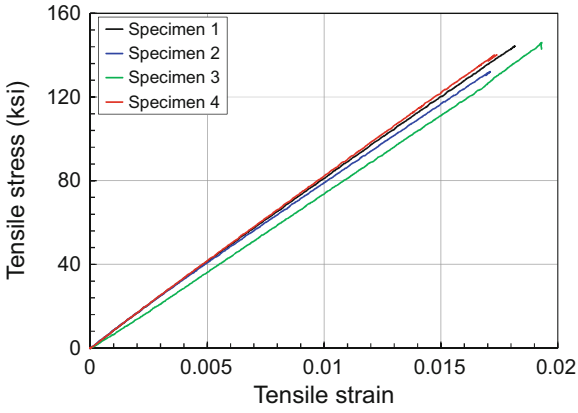


Fig. 4 Stress–strain curve of the four GFRP specimens tested in this study

4 Life-Cycle Cost Assessment

An important aspect of using GFRP reinforcement as an alternative in reinforced concrete bridge decks is the economic viability of manufacturing, construction, and service life of the material. A life-cycle cost analysis was conducted to compare the GFRP-reinforced bridge deck cost to that of the steel-reinforced bridge deck during the estimated service life. The study evaluated the cost of using GFRP and conventional steel in bridge decks in three categories including the initial cost, the cost of repair and rehabilitation, and the cost of reconstruction of the deck at the end of the service life of the bridges.

As the GFRP bars consist of fine glass fibers in a resin matrix, the manufacturing process and material composition often results in a higher initial cost compared to the conventional steel, which is widely available and commonly used. As such, the manufacturing and the production of the GFRP bars could cost 1.7 times more than those of conventional steel. Moreover, the construction costs associated with GFRP bars could increase by up to 20% when compared to those of steel bars. Thus, the initial costs of working with GFRP bars might be an unfavorable factor that prevents utilizing such bars in bridges. However, the main advantage of employing the alternative reinforcement is to protect the reinforcement against corrosion, which is a major reason for the bridge deck degradation especially in the cold regions. Therefore, the bridge deck's durability and service life increase, reducing the need for frequent repair and rehabilitation like the steel-reinforced bridge decks in corrosive environments. Also, the reconstruction cost of the GFRP deck was considered to be approximately 10% higher than that of the steel-reinforced deck. Thus, despite the higher initial manufacturing cost, total construction cost, and also deck reconstruction cost of the GFRP-reinforced deck, the LCCA showed that the advantages of utilizing the GFRP bars in decreasing the repair and rehabilitation needs and the associated costs can affect the economic viability of a GFRP-reinforced bridge deck. As such, utilizing the GFRP bars could decrease the life-cycle cost of a bridge deck by more than 20% with a similar service life period. In the meantime, using GFRP bars also increase the durability of the bridges, providing a larger life span that could decrease the life-cycle cost of the bridge deck even further by 37%. Therefore, the life-cycle cost analysis showed that the GFRP-reinforced bridge deck could be a superior choice economically. The benefits can be further realized when reducing the carbon footprint is also taken into consideration.

5 Conclusions

In this study, the GFRP bars were investigated as an environmentally friendly alternative to the conventional steel reinforcement in bridge decks. The GFRP reinforcement is non-corrosive, providing more durable concrete bridges with larger life spans. The study compared the long-term behavior, mechanical properties, and life-cycle costs of two similar bridge decks, one reinforced with GFRP and the other

reinforced with conventional steel. The GFRP bars decrease the need for the production of carbon-intensive materials such as steel and cement, reducing the carbon footprint and the environmental impacts of the construction industry. Besides, the light weight of the GFRP bars compared to the steel bars decreases the required transportation distance, reducing the carbon emission even further. Increasing the service life of the bridge structures and reducing the need for reconstruction of the bridges at an early age decrease the environmental impacts of the construction process and material waste. Thus, GFRP reinforcement shows superior characteristic as a promising alternative to the steel bars in bridge decks in terms of environmental friendliness while providing satisfactory structural performance.

1 Introduction

During the past decade, there have been ongoing discussions of how to decrease the global CO_2 emissions output. The building sector is responsible for a significant portion of such emissions so the shift toward sustainable construction materials and systems is required [1]. These alternative sustainable solutions must also be efficient to gradually replace the traditional ones. An example of such a solution is the hybrid timber–concrete floor system. The aim to combine different materials in construction systems or elements is to create a hybrid system that maximizes the advantages and minimizes the disadvantages that each material inherently has [2]. Timber–concrete floor systems have also shown excellent prefabrication capabilities and can be classified as slender in comparison to traditional concrete floors [3]. The use of timber as construction material promotes the application of low-carbon materials, which is vital for modern and sustainable building projects [4].

In addition, several research studies have shown the potential of the timber–concrete composite floor systems (TCC). Fragiacomo and Lukaszewska [5] underlined the importance of the connection between timber and concrete as key in the behaviour of the composite floor system as well as the option to use prefabricated elements when needed. Yeoh [6] examined the ultimate and serviceability short and long-term behaviour of timber–concrete floor systems having three different connection types and developed an analytical model that predicts the strength of potential connection types under different modes of failure. Siddika et al. [7] provided a state-of-the-art review of the available cross-laminated timber–concrete floor systems. These systems have been found to be three to five times stronger than ordinary timber–concrete systems with significant out-of-plane load-bearing capacity. Quang Mai et al. [8] discovered that the bending capacity of a hybrid CLT timber–concrete floor is three to five times higher than the corresponding capacity of a CLT floor and that the natural frequency is 25% higher too.

The scope of this study has been to investigate numerically the properties of a hybrid timber–concrete floor system. The floor system consists of an upper thin concrete floor slab part that is connected to the lower part of transverse and longitudinal glulam beams. Timber and concrete parts are connected using epoxy resin. Plywood panels have been placed between the longitudinal glulam beams, but they do not have any structural contribution. They only act as a framework for the concrete slab during the casting phase. The system has been designed based on the specifications of a test specimen from the experimental campaign by Ferrara et al. [9]. According to this research study, hybrid timber–concrete floor systems have been found to be able to maintain significant flexural capacity with small to moderate deflections when they undergo bending. The test configuration used by Ferrara et al. has been the widely used four-point bending test that has provided a good testing platform.

2 Analysis

The numerical problem has been analysed using the finite element method (FEM). The finite element method is a reliable and versatile method that has been used in complex engineering problems for decades. The philosophy of this method is to examine a complex problem as a summation of the solutions of simpler physical problems [10, 11]. Obviously, the sum of these problems forms an equivalent problem to the original one. The problems are solved using advanced mathematics until a converged solution is reached based on the convergence criteria used in the problem. The applied convergence criteria and root-finding algorithms can vary since these depend on the physical problem and the desired degree of accuracy of the solution [10, 12].

In this research study, a reference model of the hybrid floor system under investigation has been constructed and validated against the experimental results of the reference test specimen. The numerical model has considered both geometric and contact nonlinearities as well as the update of the stiffness matrix after each load iteration. The Newton–Raphson incremental-iterative method has been used to derive the numerical solution [12, 13]. After the first task of the research study had been completed, a series of parameters that influence the structural performance of the floor system were examined. These parameters are the thickness of the concrete slab, the flexural strength class of the glulam beams and the placement of the load. The effect of these parameters on the structural behaviour of the hybrid system has been quantified and important conclusions have been drawn. The presented parametric study together with the reference model, and the available test results from the literature provide an insight into the contribution of each component that composes this hybrid floor system in the overall performance of the system [9, 12, 13].

2.1 Reference Model

For the numerical simulations performed in this analysis, the ANSYS 2023 R2 Student version software package [12] has been used. As described before, the hybrid timber–concrete floor system consists of a concrete slab that is connected by means of adhesion to the underlying grid of glulam beams. The concrete slab has a thickness of 70 mm and covers an area of 2400 × 8000 mm. The external longitudinal beams have a rectangular shape with cross-section dimensions 800 × 240 mm and the rest of the beams are 100 × 240 mm. The length of the longitudinal beams is 8000 mm. The distance between the external and internal longitudinal beams is 470 mm and between the internal ones is 500 mm. The floor system is pin-supported, and the two pressing line loads are placed symmetrically, 3000 mm from each support [9]. The configuration of the model can be seen in Fig. 1.

The beams and the concrete slab have been simulated using three-dimensional structural element models; SOLID185 and SOLID65 element types have been selected from the ANSYS library, respectively. SOLID 65 is an element commonly used for the simulation of concrete since it provides both cracking and crushing options [12]. Regarding the material properties, the concrete slab is made of strength class C40/50 concrete and the flexural strength of glulam is Gl24h, as in the experiment [9, 13].

The epoxy resin has an important role since it connects the timber and concrete parts thus ensuring a hybrid system formation [9]. For modelling purposes, the resin has been replaced by a pair of contact elements at the timber–concrete interface [13]. The contact elements form a layer between the timber and concrete elements and are placed as surface-to-surface elements. CONTA174 and TARGE170 element types have been used for the contact pairs. The simulation of the connectivity conditions between concrete and timber using a contact pair has been challenging

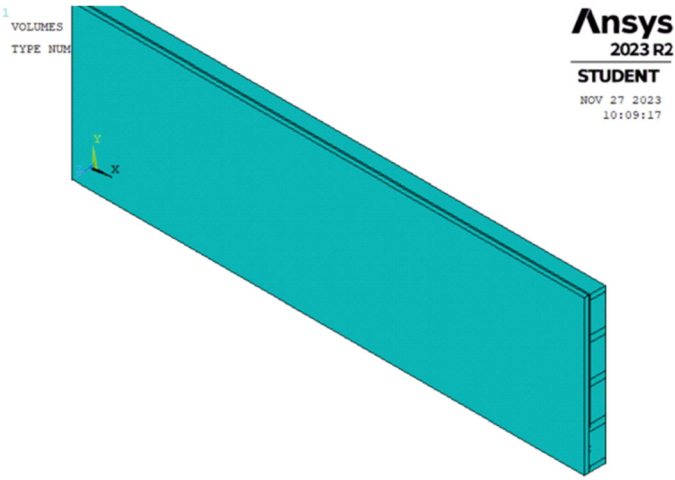

Fig. 1 The hybrid timber–concrete floor system under investigation

Table 1 Examined cases during the parametric study

Parameter	Case	Comments
Thickness of concrete slab	First parametric study-alternative 1	Decrease to 50 mm
Thickness of concrete slab	First parametric study-alternative 2	Increase to 90 mm
Glulam strength class	Second parametric study	Increase to GL30h
Load placement	Third parametric study	Loads placed at 2 m from the supports

due to necessary conversion of the experimental connectivity conditions to numerical factors. Therefore, selecting the values of several factors to some extent relied on the test and trial method, which is a limitation of the model. The Coulomb friction coefficient has been set equal to 0.3, and the 'bonded always' contact option has been used [13–15].

2.2 Parametric Investigation

After the verification of the reference numerical model by comparing its results to the experimental findings, the next step has been to perform a parametric study. The scope of this study has been to investigate, understand, and quantify the effect of certain parameters on the structural performance of the hybrid floor system. The examined parameters and the corresponding cases are presented in Table 1.

3 Results and Discussion

The numerical results from the parametric study and the reference model are presented in the following Figs. 2, 3, 4, 5, 6, 7, and 8. Emphasis has been placed on three findings, the distribution of the von Mises stresses (see Fig. 2), the

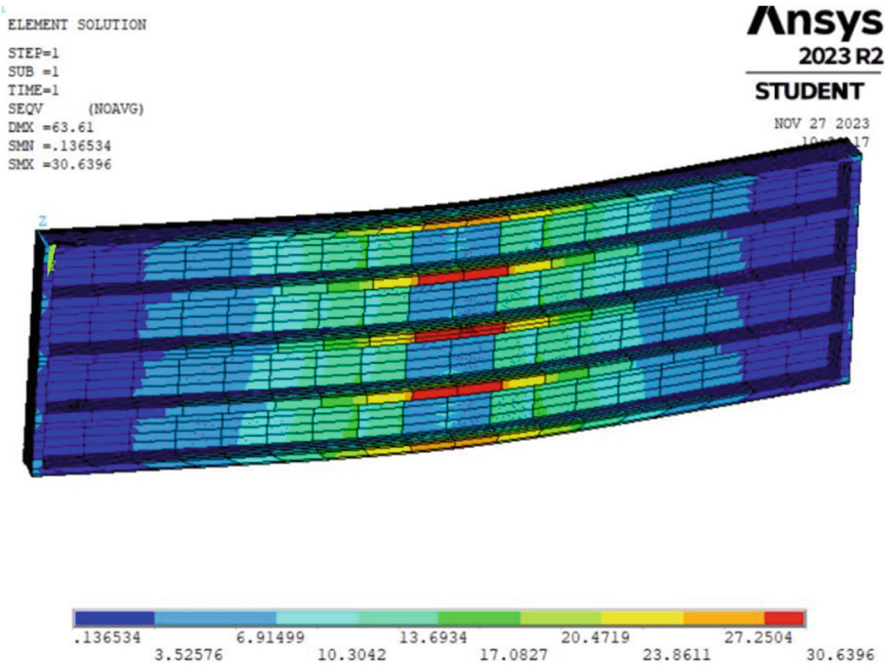

Fig. 2 Von Mises stress distribution of the reference model

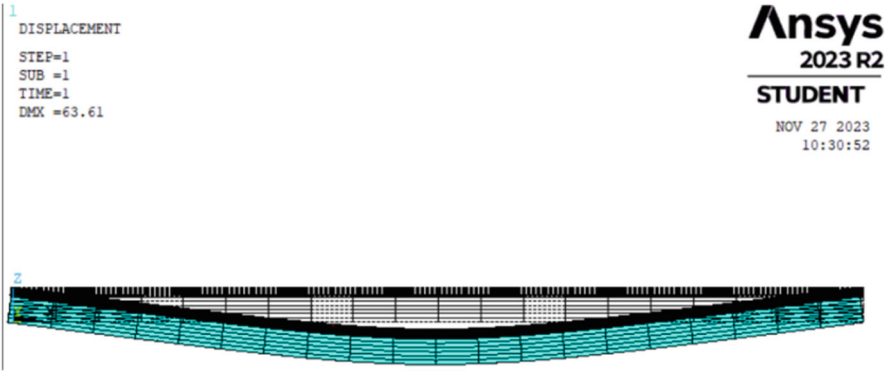

Fig. 3 Maximum deflection of the reference model

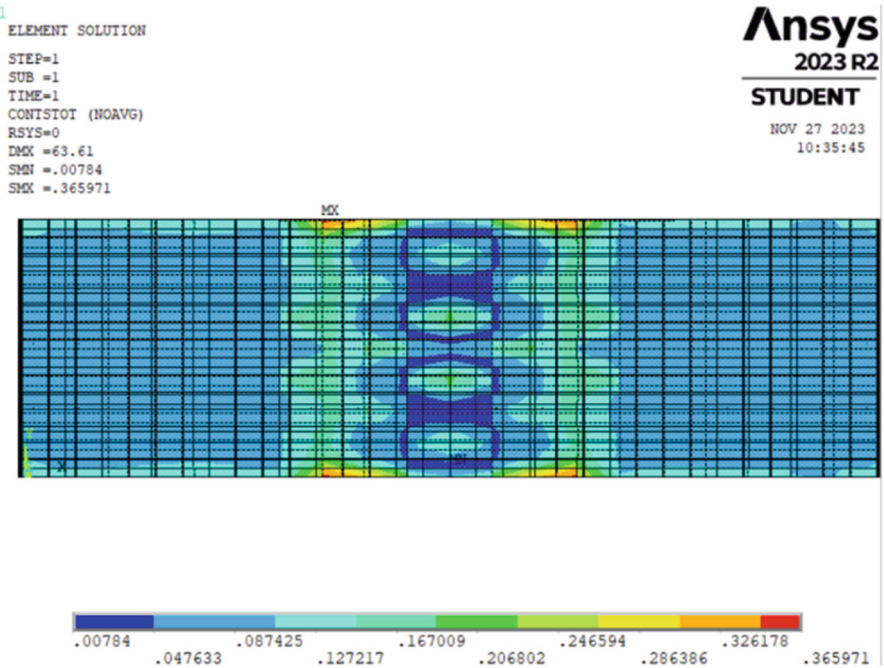

Fig. 4 Contact element stress distribution of the reference model

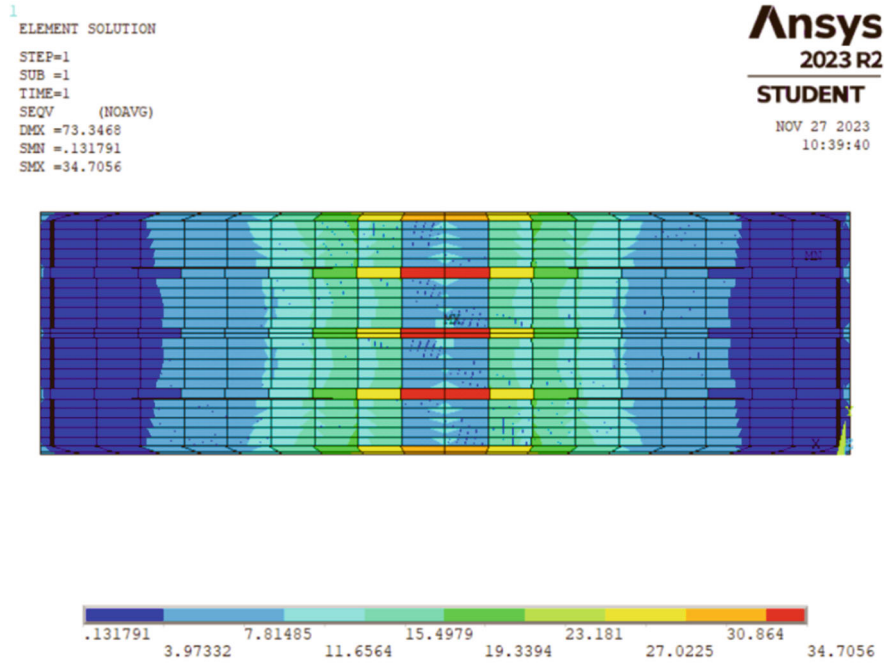

Fig. 5 Von Mises stress distribution of the first parametric study-alternative 1

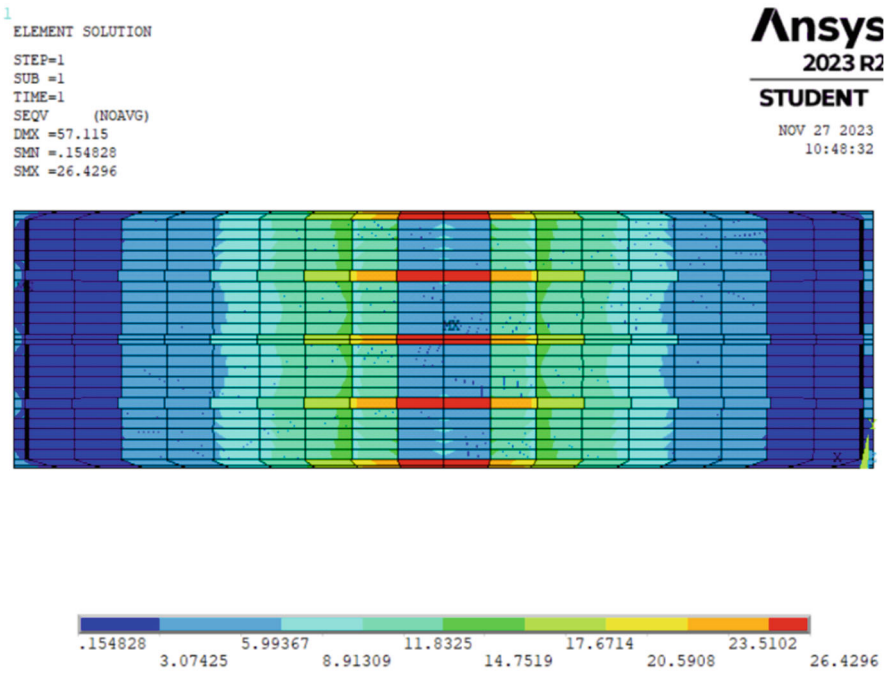

Fig. 6 Von Mises stress distribution of the first parametric study-alternative 2

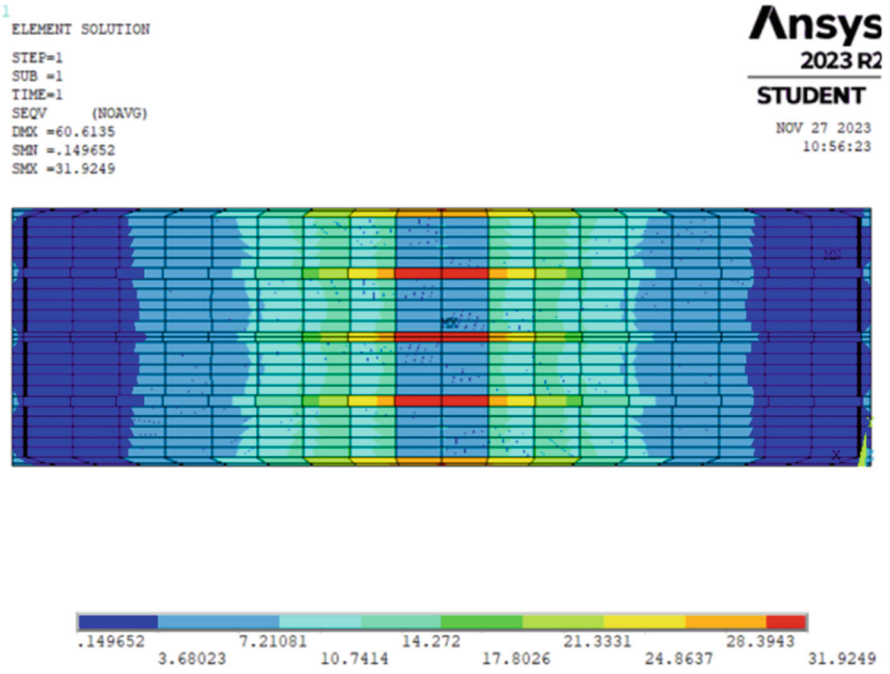

Fig. 7 Von Mises stress distribution of the second parametric study

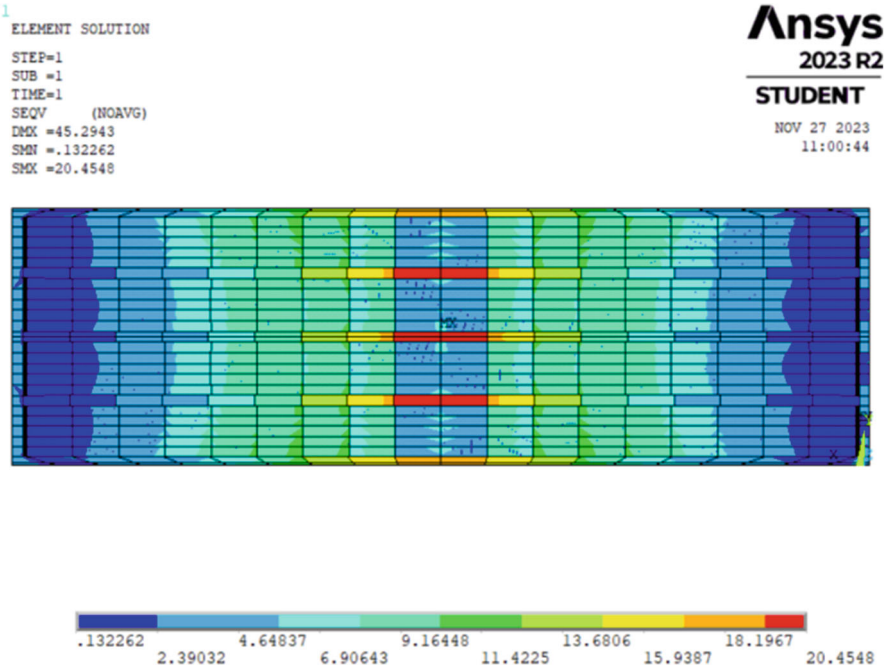

Fig. 8 Von Mises stress distribution of the third parametric study

maximum deflection at the mid-span of the floor system (see Fig. 3), and the contact stresses developed at the timber–concrete interface (see Fig. 4).

The maximum deflection of the reference model has been found to be equal to 63.61 mm, which is very close to the 63.6 mm measurement during the experiment [9]. The third parametric study has produced a lower value of the mid-span deflection of 45.29 mm, whereas the first parametric study-alternative 1 produces a higher of 73.35 mm.

Contact stresses have been detected throughout the interface of the slab, but their maximum values have been developed close to the load application areas. The third parametric study has produced a lower value of contact stresses equal to 0.25 MPa whereas in the reference model the value is 0.37 MPa. The higher value has been detected in the first parametric study-alternative 1, and it is equal to 0.41 MPa.

The shape of the von Mises stress distribution has remained the same as in the reference model (see Fig. 2) throughout the parametric study but the values vary (see Figs. 5, 6, 7, and 8), depending on the parameter under examination. The contour plot appears to have a rather symmetric shape with the peak stress values near the midpoint of the span.

The von Mises stresses have been found to have greater values in the case where the concrete slab has a decreased thickness, as shown in Fig. 6 in comparison to Fig. 5. There is a drop of about 24% in the developed maximum stress.

In Fig. 7, where a higher quality glulam grade is used the von Mises stresses appear to be quite close in value to the reference model (see Fig. 2) with a maximum value of around 31 MPa.

In Fig. 8, the placement of the load closer to the end supports has a significant effect on the reduction of the magnitude of the von Mises stresses. The maximum value in this case is 20.45 MPa.

4 Conclusions

The presented and proposed numerical simulation has managed to produce quite accurate results and provide further knowledge on the structural performance of hybrid timber–concrete floor systems. As aforementioned, the numerical results of this study have been verified against experimental ones and are in close agreement.

The parametric study has determined the effect of different parameters on the structural behaviour of the hybrid floor systems. Obviously, an increase either in the thickness of the concrete slab or in the strength class of timber has a positive contribution to the floor system. However, the effect of the thickness of the concrete slab has been found to be more significant than the effect of the strength class of the glulam beams. This must be connected to the higher stiffness of the concrete part in comparison to the timber one.

The effect of the load placement has been proven to be the most profound, both in the calculated maximum deflection and stress. This case has produced the lowest values of stress and deflection out of every case. The long span of the floor is believed to have contributed to this outcome.

The long-term and post-failure behaviour of the components used in the construction of the hybrid floor system has not been examined in this study.

Overall, hybrid timber–concrete floor systems have been proven to be a sustainable and efficient alternative to traditional floor systems. The numerical analysis of hybrid floor systems is challenging, but it can be considered as an effective tool when designing such systems.

1 Introduction

Buildings constructed on sloping terrain are inherently susceptible to premature damage in the event of an earthquake due to the horizontal and vertical irregularities present resulting from the construction of foundations at varying levels following the hill profile. Further, extremely high seismicity of Indian Himalayan region, mostly categorized under high seismic zones in Indian standard IS 1893 (2016) [1], i.e. zones IV and V, gravely intensifies the associated seismic risk. The consequences of the combination of the inherent seismic vulnerability of such buildings and the extremely high seismicity of the Indian Himalayan region have proven to be disastrous as evident from the aftermath of past earthquakes. The extremely complex seismic response of buildings constructed on sloping terrain gets further exacerbated upon incorporating URM infills as partitions in those buildings due to the complex interaction between the frame and infill elements. However, openings in the form of doors and windows are integral parts of URM infill panels to accommodate the

functional requirements. To accurately assess the seismic response of such buildings, it is necessary to consider the infill-frame interaction alongside the effects of functional openings on the overall strength and stiffness of infill panels. Extensive efforts have been put forth towards the understanding of the inelastic response of such buildings under the effects of seismic excitations over the past decade [2, 3]. However, most of the scientific studies have been undertaken either on bare frames without considering the effect of infill-frame interaction or on fully infilled frames without considering the presence of openings. The aim of the present study is to acquire a deeper understanding and shed light on the effect of functional openings in infills on the dynamic properties that govern the seismic response in terms of the fundamental period of vibration and modal mass participation ratios considering the fundamental mode of vibration. Influence of various opening ratios prevalent in India for various combinations of doors and windows on the failure mechanism of the overall structure is also investigated. The present study will provide key insights into the expected structural damage and damage in infills which will be crucial for developing sustainable earthquake-resistant design strategies for buildings constructed on sloping terrain.

2 Description of Analytical Models

A generic mid-rise unreinforced masonry (URM) infilled RC building as shown in Fig. 1a with a plan dimension of 25.6 × 15 m prevalent in the Indian scenario is considered for the parametric study. Two simple vertical structural configurations prevalent in towns and cities of the Indian Himalayas are considered, viz., split-foundation (Fig. 1b) and step-back (Fig. 1c).

All the considered buildings are situated on soil type I in seismic Zone IV of IS 1893 (2016) and are designed and detailed as Special Moment Resisting Frames (SMRFs) following the guidelines of IS456 [4], IS1893 [1], and IS13920 [5]. To assess the seismic response, three-dimensional analytical models of the considered buildings are developed using the software package SAP2000 [6]. Dead and imposed loads are applied on individual structural elements as per recommendations of IS 875 [7] and IS 875 [8], respectively. Strong column-weak-beam design is considered by limiting the ratio of the moment capacity of columns to beams to a minimum of 1.4. The details of the material properties and resulting section sizes are listed in Table 1.

The presence of infill panels significantly alters the overall response of RC frames under seismic excitation [9–12] and should be considered for accurate estimation of seismic response. A number of techniques are available to incorporate the interaction of infill and frame elements [13]. In the present study, the action of infill panels under seismic excitation is modelled using single eccentrically braced diagonal struts with geometric properties as per IS 1893 (2016). A wide range of sizes of openings for doors and windows are observed throughout India. The area of opening for windows expressed as a percentage of overall size of infill panel ranges from 5.7% to 29.4%

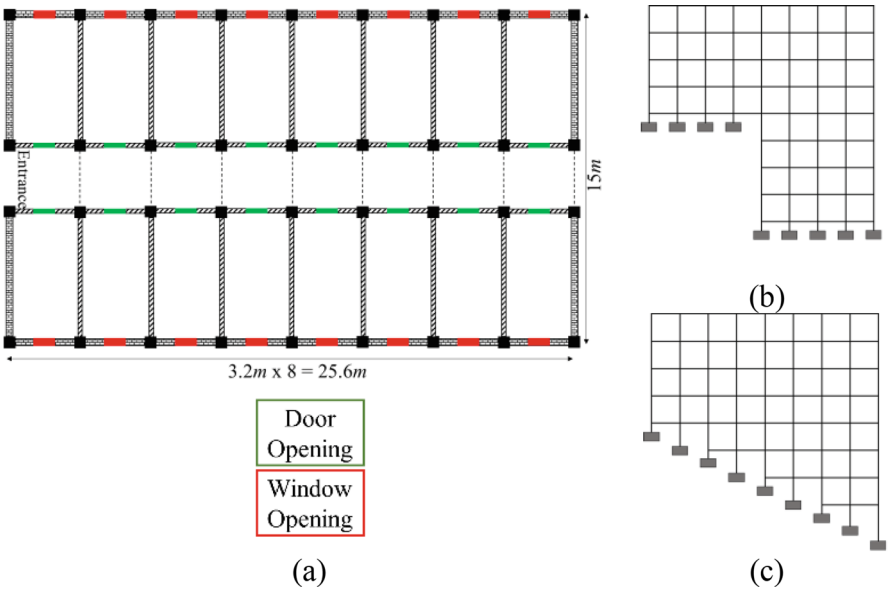

Fig. 1 (**a**) Plan; (**b**) elevation with split-foundation (SF); (**c**) elevation with step-back (SB) foundation

Table 1 Material properties and design details of the considered buildings

Description	Specification
Grade of concrete	M40
Grade of steel reinforcement	Fe500
Size of beam sections	300 × 400 mm
Size of column sections	350 × 350 mm
Size of section of 1.1 m short columns in split-foundation building	350 × 350 mm
Size of section of 1.1 m and 2.75 m short columns in step-back building	600 × 600 mm
Size and spacing of transverse reinforcements	8 mm @ 100 mm c/c

and in the case of doors, it ranges from 19.06% to 30.49% [14]. Considering the functional requirement of the considered buildings, the location of doors and windows are placed systematically as shown in Fig. 1a. Further, possible combinations of door type (D1, D2, and D3) and window type (W1, W2,..., and W11) are considered resulting in opening combinations ranging from W1D1 to W11D3 resulting in a total of 66 buildings with openings and percentage openings of doors and windows were varied systematically from 20% to 30% and 5% to 30%, respectively (Table 2). A number of literature is available regarding the effect of opening on the overall strength and stiffness of the infill panels [15–19]. Kurmi and Haldar [20] showed that the strength and stiffness modifiers proposed by Decanini et al. [15] had the least deviation from experimental results and was easy to use for parametric study, hence, is considered for the present study.

Table 2 Dimensions of prevalent openings and combinations of doors and windows considered

Combination of doors and windows	Width of window (m)	Height of window (m)	Width of door (m)	Height of door (m)	Door opening ratio (%)	Window opening ratio (%)

To model the inelastic deformations of beam elements, plastic moment hinges are provided at both ends of the beam as per ASCE-41 [21]. In the case of the columns, fibre-interacting P-M-M hinges are provided at each end. In addition, shear hinges, with capacities estimated as per ASCE-41 [21], are provided in each column to check the probability of shear failure of column due to shear forces developed due to

strut action of infill panel under seismic excitation. All the probable failure modes of infill panels identified by Haldar [13] have also been considered. Accordingly, axial hinges are provided at the middle of each diagonal strut as per ASCE-41 [22] accounting for bed-joint failure mode of the infill panel.

3 Results and Discussion

Seismic response of buildings is characterized by a number of parameters such as fundamental period of vibration, mode shape, and modal mass participation ratio. The imparted alteration in the strength and stiffness of infill panels due to the presence of functional openings combined with the inherent structural irregularities arising from step-back and split foundation can have a significant impact on the overall seismic behaviour and consequent global failure of buildings constructed in hilly regions. The effect of variation in the opening ratio on the parameters that govern the seismic behaviour in terms of the fundamental period of vibration and modal mass participation ratio is discussed in the following sections.

3.1 Period of Vibration

The fundamental period of vibration is an important dynamic property that determines the seismic response of buildings and largely depends on the mass and stiffness properties of the considered buildings. Depending on the characteristics of the seismic excitation, buildings with varying dynamic properties will respond differently. The variation in the fundamental period of vibration of the buildings with opening ratio considering various combinations of doors and window openings are plotted in Figs. 2 and 3. In Fig. 2, the trend of variation in the fundamental period of vibration is plotted for considering specific door opening but varying the window opening ratio. The observed variations are almost completely linear with minor deviations and the trendlines are completely parallel to each other in the direction across the slope of the terrain (Fig. 2a, c). The variation in the fundamental period of vibrations among buildings with varying door opening ratio but same window opening ratio (like W1D1, W1D2 and W1D3) remains almost constant with increase in window opening ratio. An almost completely linear variation is also observed in the direction along the slope of the terrain, but the trendlines were not parallel to each other. In this direction, the variation in the fundamental period of vibrations among buildings with varying opening ratio of doors but same window opening ratio increases as the opening ratio of windows increases and is maximum between W11D1, W11D2, and W11D3 in both step-back and split-foundation buildings (Fig. 2b, d). Figure 3 shows the overall variation in the fundamental period of vibration for all considered combinations (W1D1–W11D3) including the case of fully infilled (FI) building without any functional openings in the infill panel. The

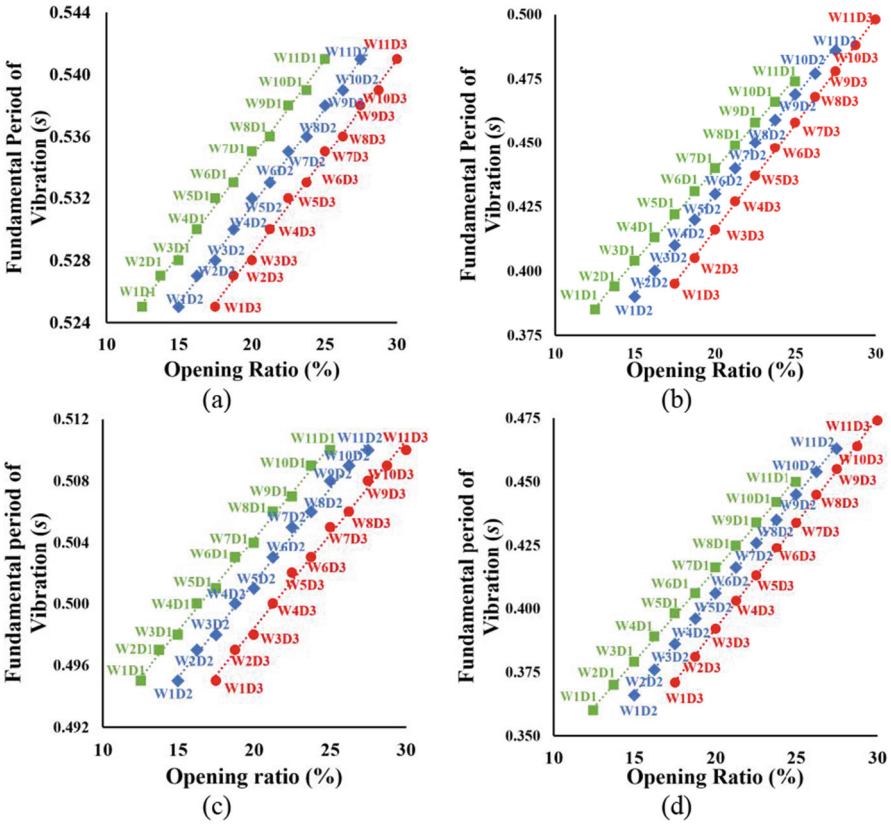

Fig. 2 Variation of period of vibration with opening ratio in the direction across the slope for (**a**) split-foundation and (**b**) step-back building; and along the slope direction for (**c**) split-foundation and (**d**) step-back building with trendlines for varying window opening but fixed door opening

variation of the fundamental period of vibration as a function of the opening ratio can be established using regression relationships using Eqs. (1) and (2) for split-foundation buildings in the direction across and along the slope, respectively. Similarly, for step-back buildings, Eqs. (3) and (4) can be used to describe the same in the direction across and along the slope, respectively.

$$T = 0.0002a^2 + 0.00004a + 0.522 \tag{1}$$

$$T = 0.0001a^2 + 0.0019a + 0.345 \tag{2}$$

$$T = 0.0002a^2 + 0.00004a + 0.492 \tag{3}$$

$$T = 0.0001a^2 + 0.0019a + 0.319 \tag{4}$$

where T is the fundamental period of vibration in s and a is the opening ratio in percentage.

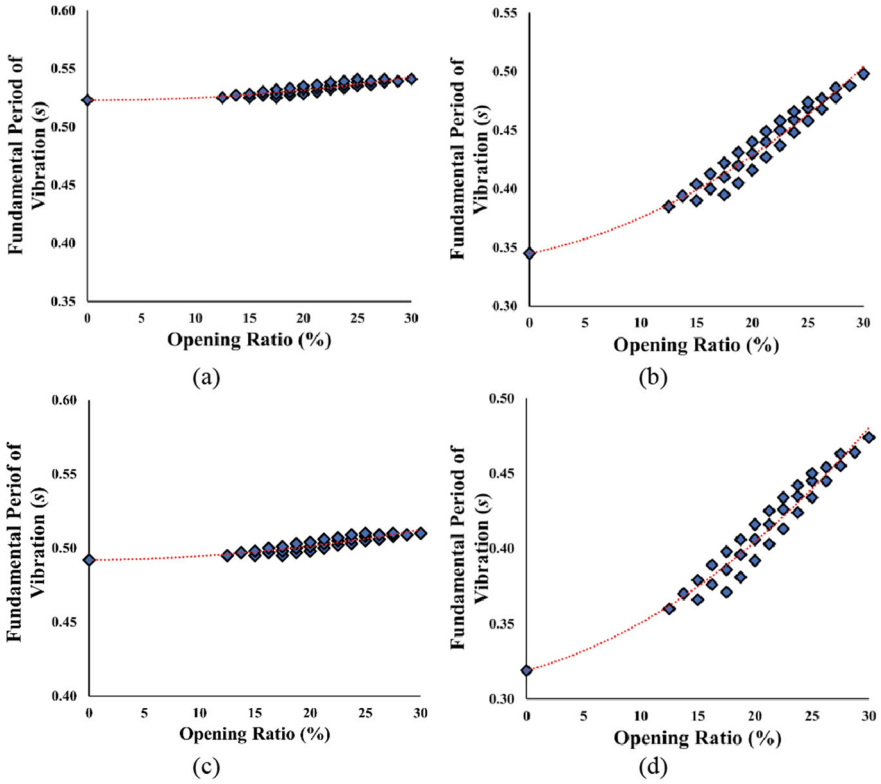

Fig. 3 Variation of period of vibration with opening ratio in the direction across the slope for (**a**) split-foundation and (**b**) step-back building; and along the slope direction for (**c**) split-foundation and (**d**) step-back building

In the direction along the slope of the terrain, a comparatively larger variation is observed in the fundamental period of vibration in both considered building typologies (i.e. step-back and split-foundation). The higher variation is a direct result of the presence of openings in the infills along the direction of slope thereby reducing the overall stiffness particularly in this direction. Conversely, the insignificant change in the fundamental period of vibration can be attributed to the lack of any functional openings in the infill panels in this direction.

3.2 Modal Mass Participation Ratio

In addition to the fundamental period of vibration, the mode shape and the modal participation ratio are another important dynamic property that determines the overall seismic response of buildings. Buildings with a very high modal mass ratio

in the fundamental mode of vibration tend to vibrate very close to their fundamental mode during seismic excitation. The seismic evaluation of such buildings can be achieved using simple traditional non-linear capacity spectrum-based approaches with reasonable accuracy. However, buildings with comparatively lower modal mass participation ratio of fundamental mode shape will have a highly complex and irregular response due to the contribution of higher mode shapes on the overall seismic response. In the case of such buildings, complex and computationally expensive non-linear dynamic approaches need to be undertaken to evaluate the seismic response. The variation of the modal mass participation factor with the opening ratio is listed in Table 3. The observed modal mass participation of the fundamental mode of vibration in fully infilled buildings (both SF and SB) is lower than 85–90%, which is generally considered a minimum for the determination of the overall seismic response of buildings. This indicates a significant contribution of the higher modes of vibration (in translation and rotation, due to the torsional irregularity of hill buildings) on the seismic response of the considered buildings.

The modal mass participation ratio further reduces in both along and across the slope directions with an increase in the opening ratio ranging from 1–4% for a 1.5% opening ratio to 8–10% for a 30% opening ratio as compared to their fully infilled counterparts. It could be observed that the reduction in modal mass participation ratio is higher in the direction across the slope of the terrain resulting from the torsional irregularity of the building in this particular direction.

3.3 Assessment of Damage Under Seismic Excitation

Due to the significant contribution of higher modes of vibration on the seismic response of all considered buildings as listed in Table 3, a simple non-linear time-history analysis is considered to assess the non-linear response of the buildings under seismic excitation. The 1976 Friuli earthquake is considered for this purpose due to its moderately high ground motion parameters (6.5 Mw and 0.35 g PGA). Both components of the considered ground motion are applied simultaneously since all considered buildings have torsional irregularity resulting from the construction of foundations at varying levels.

Figure 4 shows the displacement history record at the roof of the respective buildings in the direction along the slope of the terrain. It could be observed that the decrease in the overall stiffness of the buildings due to the presence of functional openings results in an increase in the displacement response of both split-foundation and step-back buildings. Moreover, the displacement response of the respective buildings increases with an increase in the opening ratio as shown in Fig. 4. It could be observed that the displacement response of W11D3 was 62.2% higher than FI, while in the case of W1D1, it was 33.36% higher for split-foundation buildings. Similarly, for step-back buildings, the maximum displacement at the roof was 62.72% and 25.69% higher for W11D3 and W1D1, respectively, when compared to their FI counterpart. The damage observed in the split foundation buildings is

Table 3 Modal mass participation ratio of fundamental mode of vibration

Designation	Opening ratio (%)	Modal mass participation ratio (%)			
		Split-foundation building		Step-back building

shown in Fig. 5 for varying opening ratios in infill panels. It can be observed that the damage in the structural elements (beams and columns) remains largely the same with an increase in the opening ratio. Collapse of all the considered split-foundation buildings is caused by a combination of shear and flexural failure of the short columns just above the uppermost foundation level. However, the extent of damage

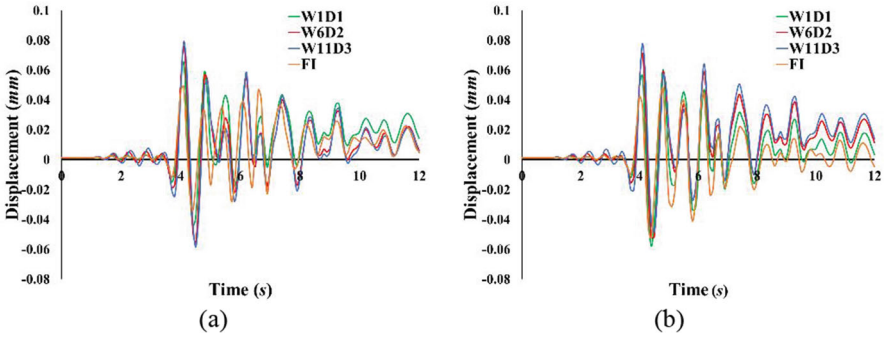

Fig. 4 Displacement response history at roof of building with (**a**) split-foundation; and (**b**) step-backs

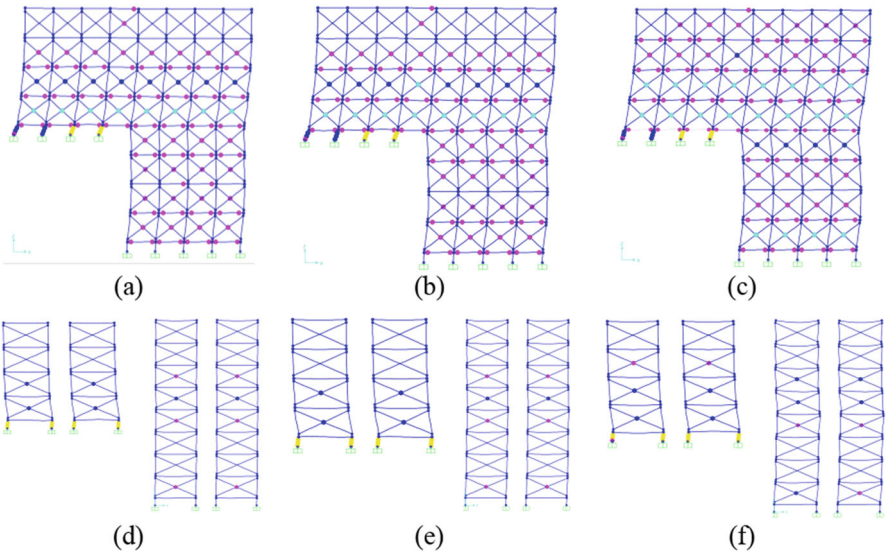

Fig. 5 Damage pattern observed in split-foundation buildings in the direction along the slope of the terrain (**a**) W1D1, (**b**) W6D2, (**c**) W11D3; and across the slope of the terrain (**d**) W1D1, (**e**) W6D2, (**f**) W11D3

in the infill panels increases significantly in both along and across the slope directions as a consequence of the reduction in strength and stiffness of the infill panels. Similarly, in the case of step-back buildings, the collapse is caused by a combination of shear and flexural failure of the 1.1 m short columns closest to the uppermost foundation level (Fig. 6). An increase in the extent of damage in infill elements can be observed in with an increase in the opening ratio. Thus, the extent of earthquake losses will increase considerably with an increase in the percentage area of openings in infill panels under moderately large seismic excitation.

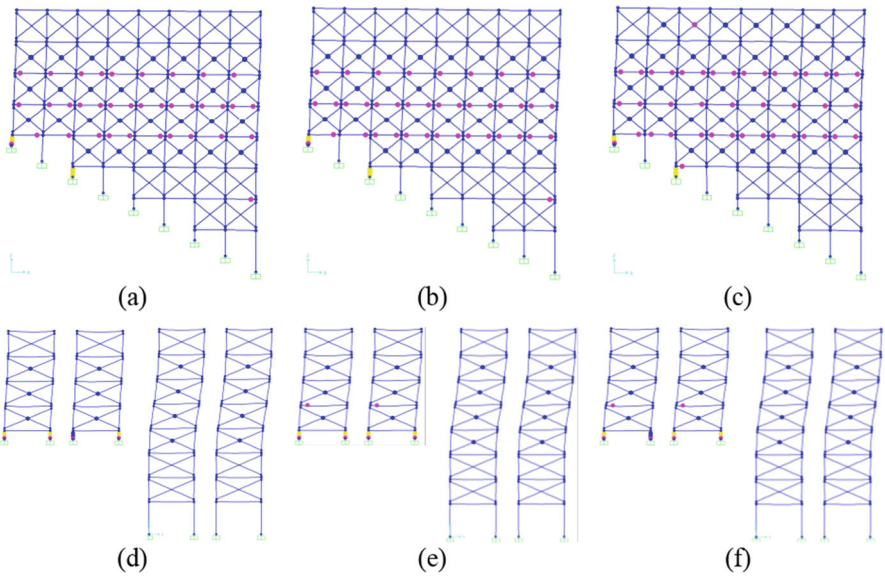

Fig. 6 Damage pattern observed in step-back buildings in the direction along the slope of the terrain (**a**) W1D1, (**b**) W6D2, (**c**) W11D3; and across the slope of the terrain (**d**) W1D1, (**e**) W6D2, (**f**) W11D3

4 Conclusion

The dynamic properties of buildings constructed on sloping terrain considering various opening ratios relevant to Indian construction practices have been compared in the present study. It was found that the fundamental period of vibration increases considerably in the direction along the slope of the terrain with an increase in the opening ratio while an insignificant variation was observed in the direction across the slope due to the fact that openings in the form of doors and windows were present in the infill panels along the direction of slope. With an increase in the opening ratio, a reduction in the modal mass participation ratio in the fundamental modes and contribution of higher modes of vibration has been observed both for split-foundation and step-back buildings. Non-linear dynamic evaluation of the 66 numbers of considered buildings with various doors and window openings combinations showed the displacement response of the considered buildings increases with an increase in the opening ratio. The maximum displacement at the roof of the buildings increased by 33.36–62.2% and 25.69–62.72%, depending on the opening ratio, for step-back and split-foundation buildings, respectively, compared to their fully infilled counterparts. As the opening ratio increases, the extent of damage in the infills also increases due to the reduction in the strength and stiffness of the infill panel. For the comparison purpose, all the 66 considered buildings are subjected to 1976 Friuli earthquake (6.5 Mw and 0.35 g PGA) due to its similarity in expected

seismic hazard in the Indian Himalayan region. However, large variation exists in ground motion parameters such as amplitude of vibration, frequency content and duration of ground motion. Therefore, in order to minimize the subjectivity and to incorporate the variability in ground motion parameters, a large number of time-history analyses considering multiple earthquake records need to be performed which is out of the scope of the present study. Due to the highly non-linear and complex seismic response of URM-infilled RC buildings constructed on sloping terrain, a comprehensive seismic vulnerability assessment is required to develop proper earthquake design standards and disaster mitigation policies to reduce the expected seismic risk in the towns and cities of the Indian Himalayan region.

1 Introduction

Representation of seismic hazards is always challenging for structural engineers as it can be done in many ways, such as hazard curves, uniform hazard spectrum (UHS), and peak ground acceleration (PGA). Among the many options, two of the most widely used representations use UHS and hazard curves. While UHS represents the seismic hazards in terms of spectral coordinates corresponding to a fixed probability of exceedance (POE) at all spectral periods, hazard curves are constructed for each

spectral period, providing POEs of different amplitudes of spectral ordinates. Current code provisions use UHS as the basis for estimating design demand. However, using UHS offers good safety against the hazards corresponding to different return periods. Still, it fails to control the collapse risk for the structures subjected to any hazard in its lifetime. This question of collapse risk is answered by representing seismic hazards in terms of the risk-targeted response spectrum (RTRS), which will be discussed in the subsequent sections.

2 Risk-Targeted Response Spectrum

A structure might be exposed to different levels of seismic hazards in its lifetime, any of which can lead to its collapse. The hazard and the conditional probability of collapse in itself is not deterministic, i.e., it brings an element of uncertainty with itself. With this uncertainty associated with the hazard and the conditional collapse probability, there is always a risk associated with the collapse of structures. This risk of collapse is estimated using the hazard and the fragility curves, as discussed in [1]. A structure constructed using conventional UHS rarely yields a uniform risk of collapse of structures. However, suppose the design demand is set to result in a uniform risk of collapse in the structures with different spectral periods at a given site. In that case, there is better control over the performance of structures. A response spectrum constructed using those design demand values as spectral ordinates corresponding to the respective spectral periods is called an RTRS. The iterative adjustment of the design demand values is illustrated in [1].

RTRS depends on the targeted risk value, the type of structure for which the fragility curve is estimated, and the hazard curve. Since the hazard at a location is governed by the geological activities beneath the earth's surface, which humans cannot control. So, the targeted risk value is attained by adjusting the fragility curve of the structure, which is a function of the structure's type and capacity. In this work, masonry structures are the point of focus.

3 Literature Review

Numerous researchers have previously done seismic risk estimation for various structures. Luco et al. [2] drew a comparison between the seismic design maps available during that period and the risk-targeted seismic design maps. The study was done for the Conterminous United States (US). They adjusted the 10^{th} percentile collapse capacity value in the structure's fragility curve to achieve the targeted risk value by keeping the other factors constant until the target collapse risk was achieved. For the first step in iteration, they assumed the 10^{th} percentile collapse value to be equal to the hazard value corresponding to a return period of 2475 years.

A similar study was done by [3] to develop risk-targeted seismic design maps for the regions of France. They found that applying the targeted-risk methodologies for the design hazard estimation did not yield significant variation in the already existing seismic hazard maps, which is opposite to what was found for similar studies in the US. The target annual collapse probability they chose (10^{-5}) was also on the lower side when compared to the target value selected for the US.

A slightly new aspect of the study was explored by [4], where they performed disaggregation of the mean annual collapse risk. They found out that the fragility curve's lower half contributes the highest to the annual collapse risk despite having a low conditional collapse probability. This implies ground motion intensities associated with those fragility values are pivotal in increasing the collapse risk.

The conclusions of [4] also highlight the need for several ground motions for the fragility curve estimation, as they found that these values were very sensitive to slight perturbation if a small number of ground motions were used. Their proposed method suggests building the fragility curve using only two intensity levels. Thus, a greater number of ground motions can be used for the non-linear time history analyses (NLTHA) for these two intensity levels rather than using small number of ground motions for all the intensity levels.

4 Methodology of Collapse Risk Estimation

The estimation of collapse risk associated with a structure requires meticulous effort. It mainly depends on two contributors, i.e., the site hazard curve and the collapse fragility curve of the structure. The methodology is briefed here and can be studied in detail from [1].

- Obtaining the hazard curve for the selected site followed by converting the probabilities in, say, '*T*' years (in general, 50 years) to the annual probabilities. Alternatively, the hazard values can only be estimated as annual probabilities at the start.
- Next, the conditional collapse probabilities of the structure, represented by the fragility curve, are estimated. Various methods of non-linear time history analyses, such as incremental dynamic analysis or multiple-stripe analysis, can be used for this purpose.
- The multiplicative integration (convolution in some texts, as in [3, 5]) is done by dividing the hazard and the fragility curves into numerous small segments to increase the accuracy of numerical integration. This yields the annual collapse risk associated with the structure.
- The collapse risk in the structure's lifetime can be obtained using the annual collapse risk and assuming its temporal distribution as the Poisson process.

5 Iterative Procedure to Achieve Targeted Risk

The collapse risk value estimated in the previous section is the initial risk value. Achieving the target collapse risk value requires the above procedure to be performed iteratively until the target is met. The median value of the fragility curve (μ) is slightly changed at the start of each new iteration, keeping all other values the same as the previous iteration. The step at which the criteria of collapse risk are met, and the value of that step is reported as the RTRS value. The following subsections describe how the hazard and the fragility values are estimated in this study for calculating collapse risk, followed by the procedure to develop RTRS.

5.1 Hazard Estimation

Two methods used for estimation of seismic hazard are deterministic seismic hazard assessment (DSHA) and probabilistic seismic hazard assessment (PSHA). DSHA quantifies the seismic hazard for a site by a single value that is obtained from the maximum of all the values due to the nearby occurring faults, thrusts, lineaments, etc. On the other hand, PSHA estimates the hazard in terms of the value and its probability of occurrence. PSHA considers uncertainty in all the three elements of the hazard estimation, namely, source model, attenuation relationships, and the local site effects. Appropriate contribution by each of the models or the attenuation relationships are provided by assigning proper weightages.

For this study, PSHA is used to obtain the hazard at a few selected locations in the northern Himalayas using the computational tool by [6]. The source models and the attenuation relationships are taken from [7], who converted the input data from [8] in the desired format executable by the computational tool OpenQuake. The logic tree for the source model is kept the same as [8]. The attenuation relationships used for the hazard estimation in this study are listed below.

5.2 Fragility Curves

A fragility curve for a structure is the plot of failure exceedance probability against the demand values for which the structure is being designed. The computation of fragility curves is a computationally extensive task which requires a lot of time. Performing these computations for different buildings at different places takes a lot

of work. Instead, a lognormal assumption of the curve by taking the 10^{th} percentile collapse capacity as the demand hazard value corresponding to a return period of 2475 years simplifies the job significantly, as discussed in [2].

The assumption of the 10^{th} percentile collapse capacity is taken from the conclusions of the FEMA-funded ATC-63 project. After testing the structures of several structural and architectural types under maximum considered earthquake (MCE) ground motions, they found that about 10 per cent of the structures collapsed, thus assuming the 10^{th} percentile capacity of the structure to be equal to the MCE level demand value. Although these values are average for structures constructed of different materials, the same has been assumed for the masonry structures in this chapter for simplicity.

5.3 Developing RTRS

As discussed in the preceding section, the 10^{th} percentile collapse value forms the basis for the estimation of the median value for the fragility curve. The multiplicative integration of the hazard and the fragility curves yields the associated annual risk, which is further used to obtain the collapse risk in the structures' lifetime, assuming the temporal distribution as Poisson process. Now, the target risk is achieved by iteratively adjusting the 10^{th} percentile value, which changes the fragility curve's median value until the target is met. Once the targeted risk value is attained, the corresponding 10^{th} percentile value of the fragility curve in the latest step is reported as the risk-targeted value. This calculation is repeated to obtain the risk-targeted values for different spectral periods. The response spectrum constructed using these values is called RTRS for the selected target risk and structure type. For this study region, the targeted risk of 1 per cent in 50 years is chosen.

For the risk calculation while estimating the RTRS values and the collapse risk of the masonry structures in the upcoming section, the intensity measure (IM) used to obtain the hazard curve is the spectral acceleration (Sa) at the structural time period. Calculation of the RTRS requires determining the risk-targeted hazard value at each spectral period, and the hazard curves used for the calculation of those values correspond to the respective spectral period. The engineering demand parameter (s) (EDPs) such as peak inter-storey drift ratio or beam column joint rotation can be used such that it differentiates between the collapse and non-collapse cases clearly.

6 Risk Calculation for Masonry Structures

As discussed in Sect. 1, the structures designed for the code provisions yield non-uniform collapse risks across different spectral periods and locations. The results of collapse risk assessment (shown in Table 2) using the actual masonry structures' fragility curves of [13], supports the claim made above. Several stone

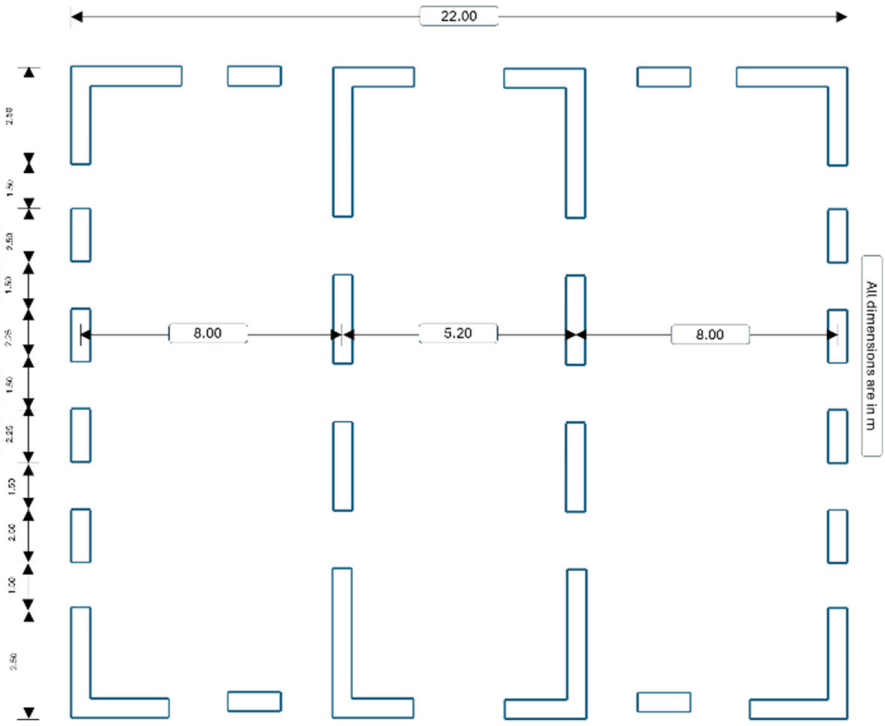

Fig. 1 Plan of the considered stone masonry building

masonry structures comprising different storey heights and aspect ratio of the openings (*h/l*) along with flexible and rigid diaphragms are compared based on associated collapse probability conditioned to MCE level hazard. The schematic plan of the masonry building is shown in Fig. 1 for reference. Also, the risk of collapse of structure due to the exceedance of any hazard level in the structure's lifetime is estimated. The collapse risk related to the exceedance of any hazard level can be obtained using the multiplicative integration of the hazard and fragility curves. However, the conditional collapse probability associated with the exceedance of MCE level hazard can be obtained using the fragility curves of [13]. For the collapse risk estimation from the annual likelihood of collapse in the structures' lifetime, the temporal distribution is assumed to be Poisson process, which is correct for seismic events.

The mean and the standard deviation values of the lognormal fragility curves are taken from Table 5.1 of the work done by [13]. The values in the tables are normalized regarding effective spectral acceleration. So, to obtain the actual median capacity of the structures, the values obtained from the table are multiplied by the effective behaviour factor given in Table 3.1 of [13], which is further multiplied by the DBE to MCE conversion factor of [14] to obtain the median capacity of the structures. A similar conversion is done with the x-axes of the fragility plots from

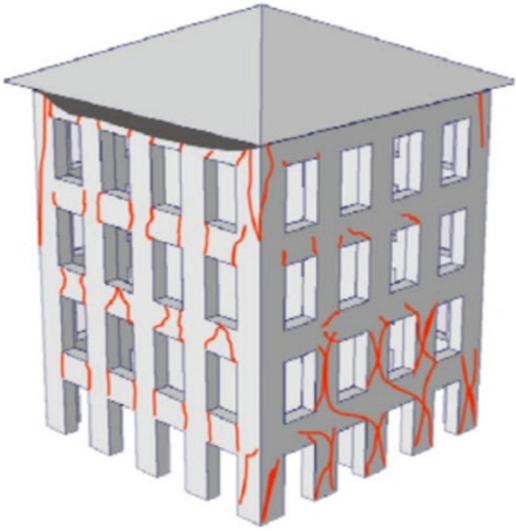

Fig. 2 Damage Grade 5 of the masonry structure. (Taken from [13])

[13], and the conditional collapse probability corresponding to the MCE demand value, estimated using PSHA, is obtained. The standard deviation values are adopted as in Table 5.1 of [13]. These values are also mentioned in Table 2 of this work. The structural period of the structures is obtained using the empirical equation given in [14].

Similarly, the hazard values are obtained, as discussed in Sect. 5.1 of this chapter. The hazard curve for Mandi is considered for this comparison of collapse risks. The parameters of the fragility curves are taken for the damage grade 5 (DG5), as mentioned in [13]. The damage measure considered by them is the percentage of the damaged masonry of the entire surface area of the masonry walls under non-linear biaxial failure criterion. The structure whose 50 per cent or more area of the walls got damaged under the biaxial state of stress is classified as DG5. Figure 2 shows the damage state of the masonry structure listed under DG5. It is assumed that of all the illustrated damage states, DG5 is nearest to the collapse of the structure. The risk values thus obtained for different buildings are tabulated in Table 2 of this work. Due to the absence of certain fragility curves in [13], the conditional collapse probability values associated with the exceedance of MCE level hazard for those buildings are unavailable (N.A.) in Table 2.

7 Results

For the locations tabulated in Table 1, all in the northern Himalayan region, a comparison of the UHS and the RTRS values is made. All the listed locations lie in the Indian states of Himachal Pradesh and Uttarakhand. The upcoming

Table 1 Selected locations for the comparison of UHS and RTRS

Selected locations	Longitude	Latitude
Mandi	76.93°E	31.71°N
Shimla	77.17°E	31.10°N
Roorkee	77.88°E	29.85°N
Dehradun	78.03°E	30.32°N
Uttarkashi	78.44°E	30.73°N
Nainital	79.45°E	29.39°N
Chamoli	79.56°E	30.29°N
Almora	79.64°E	29.59°N
Bageshwar	79.77°E	29.84°N
Pithoragarh	80.22°E	29.58°N

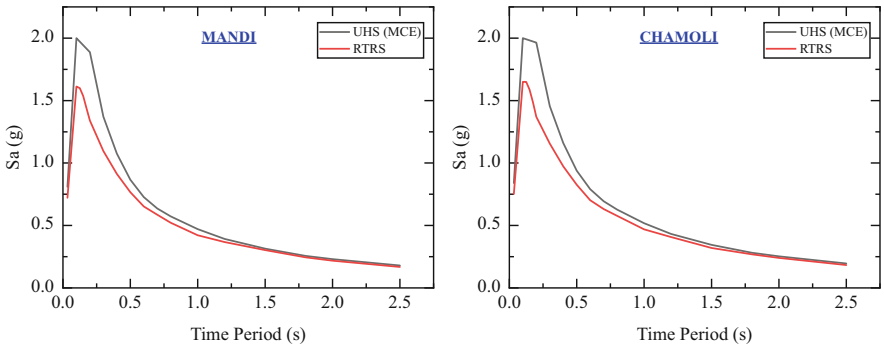

Fig. 3 UHS vs. RTRS for Mandi and Chamoli (Zone V)

subsections discuss the comparison of the UHS and the RTRS values. For the UHS plot, the seismic hazard values correspond to a hazard level with a return period of 2475 years. The RTRS values for the same region are obtained for a chosen targeted collapse risk value of 1% in 50 years and compared.

7.1 Locations of Zone V

According to the Indian code provisions of [14], Zone V is the zone with the highest seismic activity in the country. Among the selected locations for this study, the UHS and RTRS for the regions in Zone V are compared in Figs. 3 and 4. Evidently, for all the areas in Zone V, the design demand value must be decreased to achieve the targeted risk value. The difference between UHS and the RTRS values is significant for the small structural periods. For larger periods, the difference between the values is minimal.

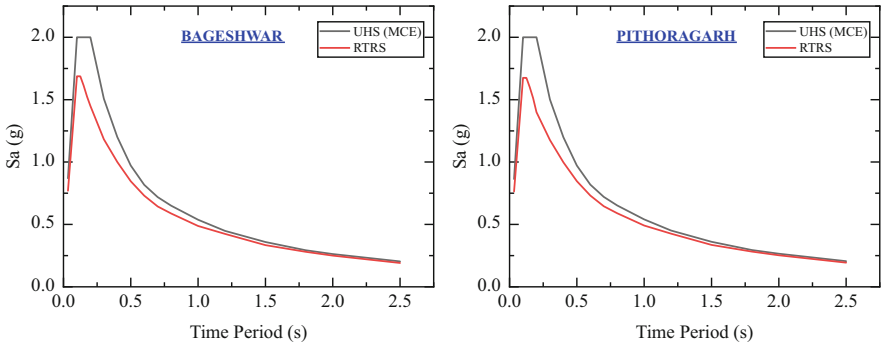

Fig. 4 UHS vs. RTRS for Bageshwar and Pithoragarh (Zone V)

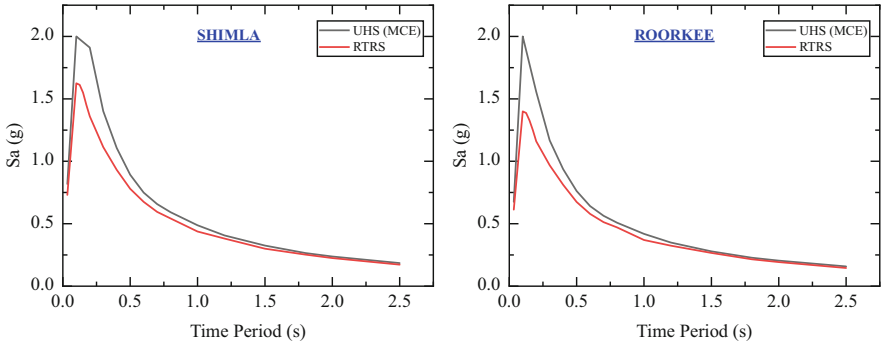

Fig. 5 UHS vs. RTRS for Shimla and Roorkee (Zone IV)

7.2 Locations of Zone IV

A comparison of the UHS and RTRS for the regions lying in Zone IV (less seismicity than Zone V), according to [14], is plotted in the Figs. 5, 6, and 7. Similar to the results obtained for Zone V, the RTRS values are also lower than UHS for the MCE level hazard. For the regions of Roorkee and Nainital, the reduction is larger than that of the other regions of the same seismic zone. For the larger structural periods, the trend remains the same as is the case for the locations of Zone V.

7.3 Collapse Risk Variability

The collapse probability conditioned to the exceedance of MCE level hazard is larger than 10% for all the cases discussed in Table 2. However, the conditional collapse probabilities suggest that structures with rigid diaphragms are safer than those with flexible diaphragms.

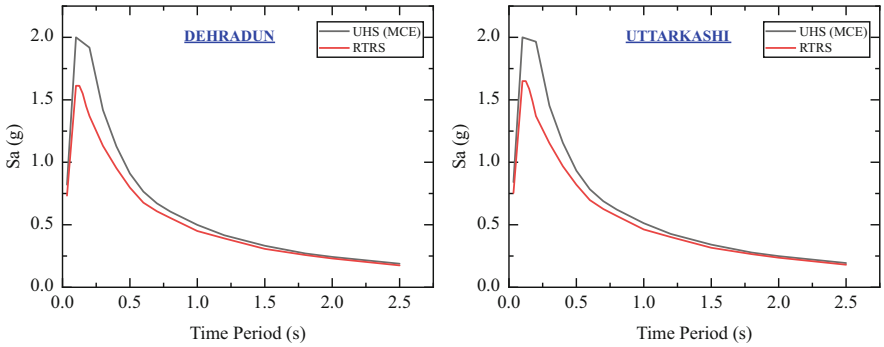

Fig. 6 UHS vs. RTRS for Dehradun and Uttarkashi (Zone IV)

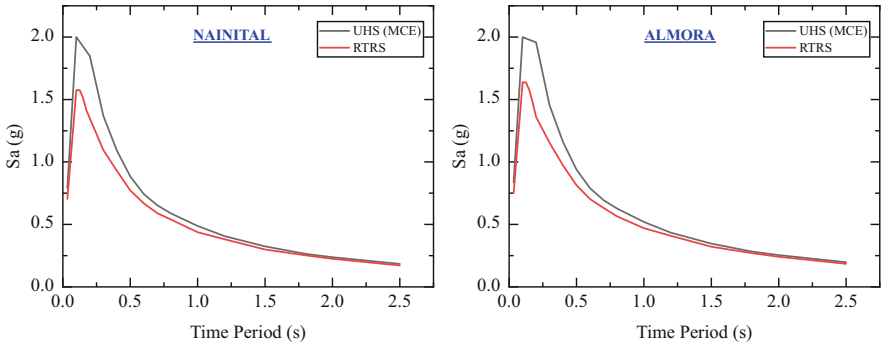

Fig. 7 UHS and RTRS for Nainital and Almora (Zone IV)

For a change in the aspect ratio of the opening (*h/l*), the collapse risk varies from 2.24% to 3.75% for the 2-storey buildings with flexible diaphragms. This value ranges from 2.16% to 4% for the 6-storey building. The collapse risk varies from a minimum of 2.16% to a maximum of 3.55% with number of stories in buildings with flexible diaphragms and an opening aspect ratio less than unity. These values vary significantly when the structures with different diaphragm types, i.e., flexible or rigid, are studied. For the structures with an opening aspect ratio greater than unity, the collapse risk for the 2-storey building with flexible diaphragms is 3.75%. This value is 1.53% for the structure with rigid diaphragms.

8 Conclusions

For all the locations of the study region, RTRS values are lower than UHS values. This is because the current code provisions for determining design demand are conservative, i.e., current provisions overestimate the design hazard values.

Table 2 Risk of exceedance of damage state for different masonry structures

Diaphragm	*h/l*	Fragility parameter	2-storey	4-storey	6-storey
Flexible	≥1.0	μ	1.86	1.26	0.90
		β	0.71	0.75	0.69
		Collapse prob. conditioned to (MCE) (%)	56	60	60
		Collapse risk (%)	3.75	4.00	4.00
	<1.0	μ	2.40	1.32	1.38
		β	0.66	0.70	0.70
		Collapse prob. conditioned to (MCE) (%)	N.A.	60	N.A.
		Collapse risk (%)	2.24	3.55	2.16
Rigid	≥1.0	μ	2.80	2.80	2.08
		β	0.63	0.63	0.65
		Collapse prob. conditioned to (MCE) (%)	20	15	20
		Collapse risk (%)	1.53	0.79	0.96
	<1.0	μ	4.48	3.44	2.24
		β	0.61	0.64	0.64
		Collapse prob. conditioned to (MCE) (%)	N.A.	20	N.A.
		Collapse risk (%)	0.40	0.48	0.81

Fragility parameters and specifications obtained from [13]

However, this practice does not ensure the level of safety against collapse. On the other hand, designing for RTRS provides a targeted safety level with optimal cost. This way, RTRS also contributes to the sustainability of the masonry structures. Knowing the collapse risk beforehand estimates the minimum performance level the structure will likely provide at the exceedance of a particular hazard level.

The conditional collapse probability (shown in Table 2) being higher than the values (10 per cent) obtained from the conclusions of the ATC-63 Project is because the masonry structures discussed in this study are not code-compliant, hence show a higher risk of collapse. Also, variability in the collapse risks obtained for the actual masonry structures highlights the need for RTRS to estimate the design demand, which ensures that the structures are designed to achieve a uniform (targeted) risk of collapse in their lifetime. Designing for RTRS will help in better planning and emergency preparedness in case of the occurrence and the exceedance of a hazard level.

9 Limitations of the Study

Although it is attempted to make this study as general as possible, due to the assumptions taken, this study has several limitations, as discussed below.

- The assumption of the 10^{th} percentile collapse value of the fragility curve as MCE demand value for masonry structures is only sometimes valid, as the value was an average of the values of the structures of all material types.

- For simplicity, the local site conditions were assumed to be the same for the entire region, which is a possible source of error.
- The standard deviation values selected for the lognormal fragility curves are based on previous studies. Application of the values determined for the structures constructed of a particular material to the same type of structure will yield better results.
- Owing to the complex nature of the procedure, its implementation in practice requires significant simplification and adjustments to existing codes and standards.

1 Introduction

The long-term performance of reinforced concrete (RC) bridges is significantly affected by corrosion, especially in aggressive chloride environments. Corrosion may cause serviceability issues, such as staining, cracking, and spalling of concrete, and seismic performance issues, namely strength and ductility decay or confinement degradation. These issues are amplified given that bridges play a key role in transport infrastructure networks and their functionality is vital for the operation of the whole system [1, 2]. The impact of corrosion on the seismic behavior of RC bridges is experimentally investigated through an accelerated corrosion procedure. Experimental testing is cost-intensive, and due to the time-dependent nature of corrosion, the process is accelerated in the laboratory. In recent years, numerical methods are employed in many researches to simulate the corrosion in RC bridges and take its

time-dependent nature into account. The accuracy of the models is highly dependent on the accuracy of the material models [3].

With the development of big data techniques, machine learning (ML) has shown significant advantages in prediction and categorization in the field of engineering. ML is the specific area of artificial intelligence that allows computers to learn from data and solve a given task. Salami et al. [4] compared the performances of different ML techniques to optimize the predictive modeling of corrosion initiation time. Zhu et al. [5] used artificial neural network in conjunction with Kohonen self-organized mapping to model the chloride threshold in RC. Most recently, Xu et al. [6] estimated multilevel capacity of bridges with the aid of the ML. The trained ML models could also accurately identify the flexure and shear failure modes. In another recent work, Xi et al. [7] conducted a reliability analysis on the basis of ML considering realistic nonuniform corrosion.

Chloride contamination is the primary cause of corrosion in RC bridges. Researchers have studied the effect of corrosion on RC bridges through experimental and numerical methods. Corrosion is a time-dependent phenomenon. Thus, its process is accelerated in the laboratory to be able to take its effect into account, which is costly and accompanied by some amount of error. However, numerical methods make it possible to implement nonlinear dynamic analysis and derive seismic fragility curves of corroded RC bridge piers over time. With the evolution of computational algorithms, ML-aided numerical methods are developed to recognize or predict patterns in data. In this paper, numerical models of RC bridge piers are built in OpenSees [8] platform. The geometric, loading, and material properties of the piers are randomly chosen. Each model is nonlinearly analyzed under random ground motion records scaled to design-based earthquake (DBE) and maximum considered earthquake (MCE) spectra. Prior to the analyses, corrosion is allocated to the models by degrading the mechanical properties of steel and concrete. The percentage of the corrosion is considered as a stochastic parameter. Maximum drift ratios are stored at each analysis to build the database. Using the created database, different ML algorithms are compared to find the most accurate one. *R*-squared (R^2), mean absolute error (MAE), mean squared error (MSE), and root mean squared error (RMSE) metrics are considered as the criteria for tracking the efficiency of the models. Bayesian search is employed as the algorithm for tuning the hyperparameters.

2 Corrosion-Induced Degradation

Morphology of corrosion in RC structures is categorized into two types: (i) uniform and (ii) pitting. Uniform corrosion is caused by concrete carbonation while penetration of chlorides induces pitting corrosion. Figure 1a and b depict schematic illustrations of uniform and pitting corrosions. Both cases are characterized by a reduction in the mechanical properties of the steel. Yield and ultimate strengths, elastic modulus, and ultimate strain of reinforcing steels are proven to be reduced

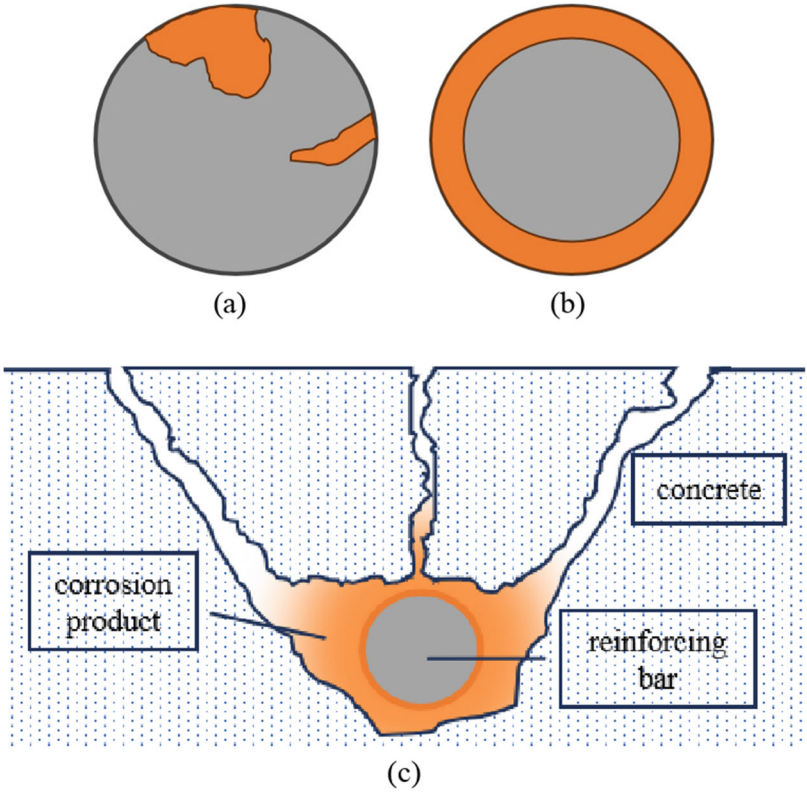

Fig. 1 Corrosion of reinforcing steel: (**a**) pitting corrosion, (**b**) uniform corrosion, (**c**) cracking, and spalling of concrete due to the steel corrosion

when corroded. For analytical and numerical purposes, decay equations have been proposed in various researches [9–11] that take the corrosion-induced degradation into account, as

$$f_{\mathrm{y}} = \left(1.0 - \alpha_{\mathrm{y}} Q_{\mathrm{corr}}\right) f_{\mathrm{y0}} \tag{1}$$

$$f_{\mathrm{u}} = \left(1.0 - \alpha_{\mathrm{u}} Q_{\mathrm{corr}}\right) f_{\mathrm{u0}} \tag{2}$$

$$E_{\mathrm{s}} = \left(1.0 - \alpha_{E} Q_{\mathrm{corr}}\right) E_{\mathrm{s0}} \tag{3}$$

$$\varepsilon_{\mathrm{u}} = \left(1.0 - \alpha_{\varepsilon} Q_{\mathrm{corr}}\right) \varepsilon_{\mathrm{u0}} \tag{4}$$

where $f_{\mathrm{y}}, f_{\mathrm{u}}$, E_{s}, and ε_{u} are residual yield and ultimate strengths, elastic modulus, and ultimate strain of the corroded steel, respectively, $f_{\mathrm{y0}}, f_{\mathrm{u0}}$, E_{s0}, and $\varepsilon_{\mathrm{u0}}$ are initial yield and residual strengths, elastic modulus, and ultimate strain of the intact steel, respectively, Q_{corr} is the corrosion percentage, and α are corresponding empirical coefficients for which different values are reported. In the present study, α_{y} and α_{u}

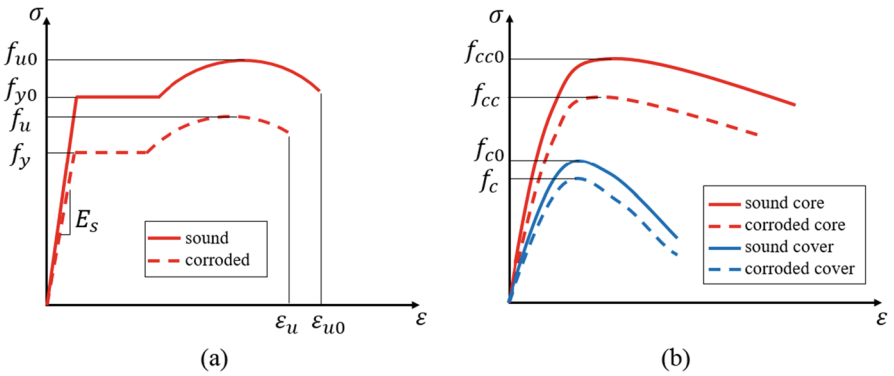

Fig. 2 Mechanical properties of corroded components: (**a**) reinforcing steel and (**b**) core and cover concrete. (Adapted from Xu et al. [6])

are determined to be 0.5 from the work of Du et al. [9], $\alpha_E = 0.75$ is adopted from the study by Lee and Cho [10], and α_ε is taken as 3.0 according to Cairns et al. [11].

During the corrosion process, rusted steel undergoes volumetric expansion leading to cracking and even spalling of the cover concrete, which in turn reduces the compressive strength of the concrete as shown in Fig. 1c. Coronelli and Gambarova [12] proposed the following equation to calculate the compressive strength of the corroded concrete:

$$f_c = \frac{f_{c0}}{1 + K\frac{\varepsilon_1}{\varepsilon_{co}}} \tag{5}$$

where f_c is the residual compressive strength of concrete after corrosion, f_{c0} is the compressive strength of sound concrete, K is the bar roughness and diameter coefficient that has been suggested to be taken as 0.1 for medium-diameter ribbed longitudinal bars [13], ε_{co} is the strain at peak compressive strain, and $\varepsilon_1 = 2\pi(\upsilon_{rs} - 1)Xn_{bars}/p_0$ is the smeared tensile strain in the cracked concrete in which $\upsilon_{rs} = 2$ is ratio of volumetric expansion of oxides with respect to sound material [14], X is the depth of the corrosion attack, n_{bars} is the number of the compressive bars, and p_0 is the perimeter of column section. The stress–strain relationships of sound and corroded reinforcing steel and concrete are illustrated in Fig. 2.

3 Numerical Method and Verification

To have an accurate simulation of an RC bridge pier, it is needed to take three main issues into account [15]; (i) correct simulation of plasticity in the pier, which matches with the actual behavior, (ii) considering buckling and low-cycle fatigue fracture in the nonlinear behavior of reinforcements, and (iii) considering bar slippage (strain

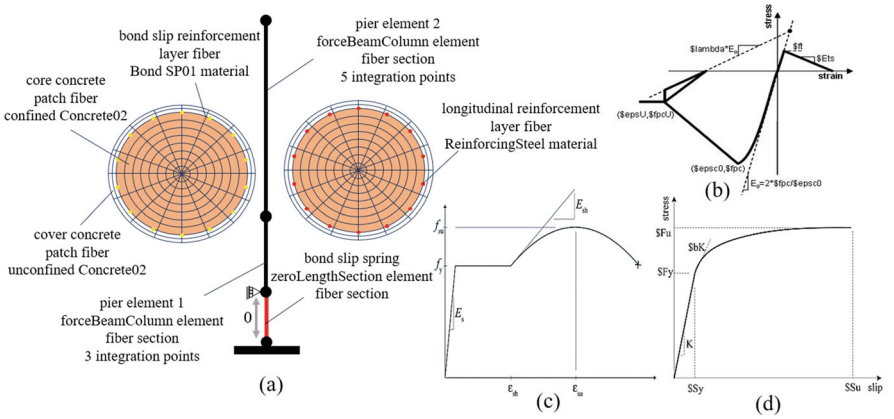

Fig. 3 Numerical modeling method: (**a**) OpenSees model, (**b**) Concrete02 material, (**c**) ReinforcingSteel material, and (**d**) Bond SP01 material

penetration). Hence, nonlinear analyses of RC bridge piers are conducted in OpenSees platform, in which it is possible to accurately consider the aforementioned behaviors.

Nonlinearities may develop anywhere along the pier during an earthquake loading Therefore, a force-based beam-column element is employed in this study, which has distributed plasticity along the element. The pier is modeled with two elements. The first element's height is $6L_b$ in which L_b is buckling length of longitudinal bar. It is modeled with three integration points to ensure that the distance to the first integration point is equal to the buckling length of longitudinal bar as shown in Fig. 3a. The remaining height of the pier is modeled with another element with 5 integration points. The fiber section allocated to both elements consists of cover concrete, core concrete, and reinforcement fibers. Concrete02 material (Fig. 3b) is adopted for cover and core concrete fibers. The confinement effect is accounted for using the method proposed by Chang and Mander [16]. Reinforcing steel material is employed for reinforcement fiber, which is capable of modeling compression buckling and low-cycle fatigue effects as shown in Fig. 3c.

At intersections such as column-to-footing connections, the bond-slip associated with strain penetration typically occurs along a portion of the anchorage length. To account for this effect, a ZeroLengthSection element with a fiber section consisting of cover and core concrete fibers and reinforcement fiber with Bond SP01 material (Fig. 3d) is placed at the intersection between the column and footing. The ZeroLength Section element used at the bottom of piers is depicted in Fig. 1a with yellow layer fibers.

In addition to the modeling issues of the RC piers, mentioned in the previous paragraphs, substructure mass effects are usually ignored during the design and analysis procedures. It means that the seismic performance of the pier is not included in the evaluation of the seismic performance of the whole pier system

[17]. Therefore, the contribution of the substructure mass is considered in the modeling of the RC piers of the present paper by allocating the pier mass using the element mass density property in the force-based beam-column elements. Furthermore, a lumped mass is applied to the topmost node of the pier to account for the deck mass. The conventional damping value of 5% is assigned to the piers through Rayleigh damping model [18].

The RC bridge pier models of the present study are adopted from antecedent research by Su et al. [19]. In the mentioned research, ten specimens with different reinforcement grades and concrete strength were cyclically loaded, half of which had circular a cross-section and the other half had rectangular a cross-section. The circular specimens are selected, numerically modeled using the described method, and quasi-static analyses are conducted according to the specified loading protocol. Prior to the lateral loading, gravity loading is applied to the models using load control to the specified values. Base shear and top node displacement values are stored and compared to the results from the mentioned experiment in Fig. 4. It is clearly seen that the modeling method is capable of simulating the nonlinear behavior of RC bridge piers with reasonable accuracy.

4 Results

The corrosion effects are applied to the circular RC pier models using the degradation equations. The parameter Q_{corr} is considered to be a stochastic parameter. Therefore, Eqs. (1)–(4) get a random nature due to their dependency on Q_{corr}. In this way, the variable nature of environmental conditions of different regions is taken into account, improving the generalization of this study. The generality of the study is further boosted by accounting for different pier designs through giving a random nature to the aspect ratio of the pier, H/B , initial diameter of the longitudinal bars, d_{b0}, and axial load applied to the pier, W. The main properties of the concrete and the steel, namely initial compressive strength of concrete (f_{c0}) and initial yield strength of steel (f_{y0}), are also randomly selected to consider the variable nature of the materials. Table 1 summarizes the stochastic parameters considered for this study. At each analysis, a random value is assigned to each stochastic parameter according to their respective distributions, and the model is analyzed under a randomly selected ground motion adopted from the records introduced in FEMA P695 [20]. All the ground motion sets including far-field and near-field records are chosen, constituting 100 ground motion records. The ground motions are scaled to the DBE and MCE spectra according to provisions of ASCE/SEI 7-16 [21].

The ML algorithms chosen for this study are in the supervised learning class. Supervised learning is used when the labeled data is available. Data collection is one of the main challenges in implementing artificial intelligence processes, due to the lack of relevant, accurate, and high-quality data. In the present research, the labeled data required for the database is created through a randomized experiment with the stochastic parameters tabulated in Table 1. This way of data creation is computationally extensive and time-consuming. However, the result is a well-structured and accurate database that leads to high-performance predictive models. To create the database necessary for the ML algorithms, 1000 analyses are conducted for each seismic level, constituting 2000 data for the database. The entire dataset is randomly divided into a training set (70%) and a testing set (30%). The workflow of the ML and the hyperparameter optimization is depicted in Fig. 5.

The codes of linear regression (LR), decision tree (DT), random forest (RF), and XGBoost algorithms are developed to build the predictive models. The training set is used for data fitting of the models, and the testing set is used for validating the

W	Lognormal	500 (kN)	0.1
f_{c0}	Normal	43 (MPa)	0.13
f_{y0}	Normal	450 (MPa)	0.12
Ground motion	Uniform	50.5	0.57

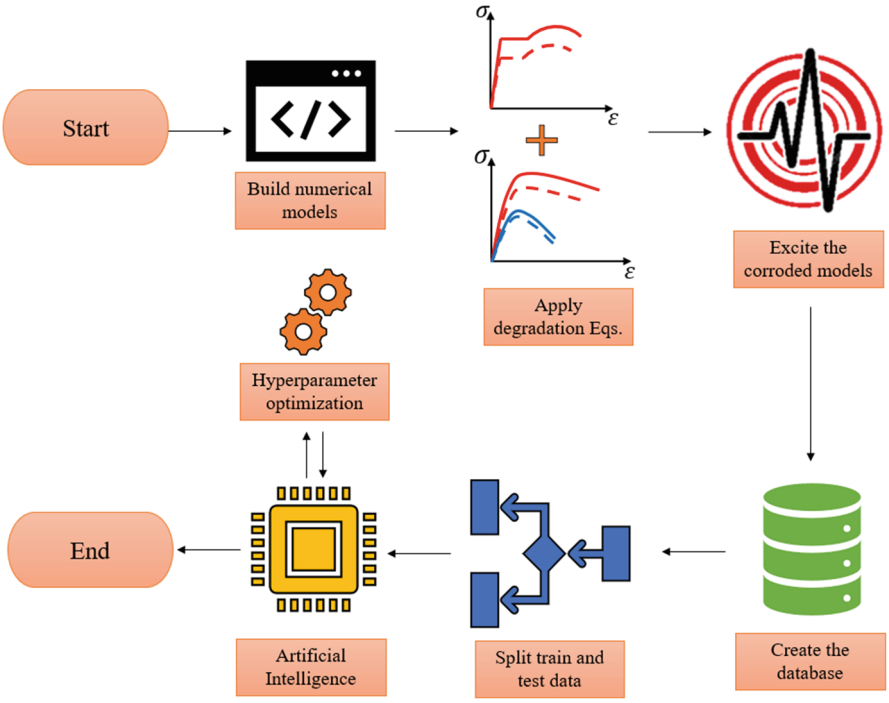

Fig. 5 Flowchart of the ML and hyperparameter optimization

models. The parameters tabulated in Table 1 are taken as feature variables, and the maximum drift experienced during the excitation, $\delta_{\max}$, is the output taken as the target variable in this study. The maximum drift is calculated as the ratio of the maximum lateral displacement to the pier height. All the dataset components are numeric values except for the seismic level which is a categorial data, consisting of two categories; (i) DBE and (ii) MCE. One-hot encoding technique is used to convert categorical variables to numeric values by creating a binary column for each category, indicating whether the category is present or not.

Every algorithm comes with additional hyperparameters that need to be configured to avoid problems such as overfitting, underfitting, convergence, etc. Hyperparameter optimization (HPO) algorithms are proposed to tackle these problems. The goal is to find $\boldsymbol{x}^* \in \text{argmin}_{\boldsymbol{x} \in \boldsymbol{X}} f(\boldsymbol{x})$, in which $f: \boldsymbol{X} \rightarrow \mathbb{R}$ is the function that maps from the hyperparameter space $\boldsymbol{x} \in \boldsymbol{X}$, and $\boldsymbol{x}^*$ is the set of hyperparameters with the best performance. The most commonly used HPO algorithms are grid search, randomized search, and Bayesian search. While grid search investigates every possible combination of hyperparameters, randomized search tests a random combination of hyperparameters, and thus it is less time-consuming. However, these two algorithms do not consider the past results. Bayesian search improves the performance of the optimization by considering the previously selected hyperparameters

Table 2 The explored hyperparameters and their ranges for ML algorithms

Algorithm	Hyperparameters	Range
LR	N/A	N/A
DT	max_depth	[1 ... 21]
	min_samples_split	[2 ... 11]
	min_samples_leaf	[3 ... 26]
RF	n_estimator	[25 ... 100]
	max_features	[1 ... 21]
	max_depth	[2 ... 11]
	min_samples_split	[3 ... 26]
XGBoost	eta	[0.01, 0.2]
	min_child_weight	[1 ... 6]
	max_depth	[2 ... 11]
	min_samples_split	[3 ... 26]

when determining the next set. Hence, Bayesian search is utilized in this study. The explored hyperparameters and their ranges in the HPO process are summarized in Table 2.

The hyperparameters of LR algorithm are not too much in number, and those that it has cannot be tuned. Consequently, HPO is not applied to LR. In tree-based algorithms, max_depth (maximum depth) is the most important hyperparameter that indicates how big the tree can grow. Complex patterns cannot be learned provided that max_depth is set to be too low while the models with large max_depth value are prone to overfitting. Thus, HPO is needed for max_depth. The two remaining hyperparameters, min_samples_split (minimal number of samples required to divide a node) and min_samples_leaf (minimum number of samples required to form a leaf node), are also decisive factors in avoiding the overfitting issue. In RF algorithm, along with max_depth and min_samples_split, two more hyperparameters, n_estimator (the number of trees to consider) and max_features (maximum number of features provided to each tree), are explored. If the n_estimator is too low, the performance of the model will be weak. And if it is a very large number, it will increase the computational complexity of the model without any increase in the performance of the model. The same trend is true for max_features. In XGBoost, the conservativeness of the model can be adjusted by the eta (features weight) and min_child_weight (minimum sum of instance weight needed in a child).

The observed maximum drifts and the predicted ones for both training and testing sets are plotted in Fig. 6. Lines corresponding to absolute errors of ± 0.1 and ± 0.2 are also plotted. The scatters illustrated in Fig. 6 are accompanied by histograms of the observed and predicted values on the plot margins. It is seen that LR and DT models have a considerable number of data points with absolute errors that exceed ± 0.01 and ± 0.02 while the number of the same data points in RF and XGBoost models is much lesser, showing the capability of these algorithms in training accurate models.

The accuracy and performance of the models are compared in Fig. 7. The predictive model developed by the LR algorithm provides the lowest accuracy in the testing dataset with $R^2 = 0.53$, MAE $= 0.0026$, MSE $= 1.4 \times 10^{-5}$, and

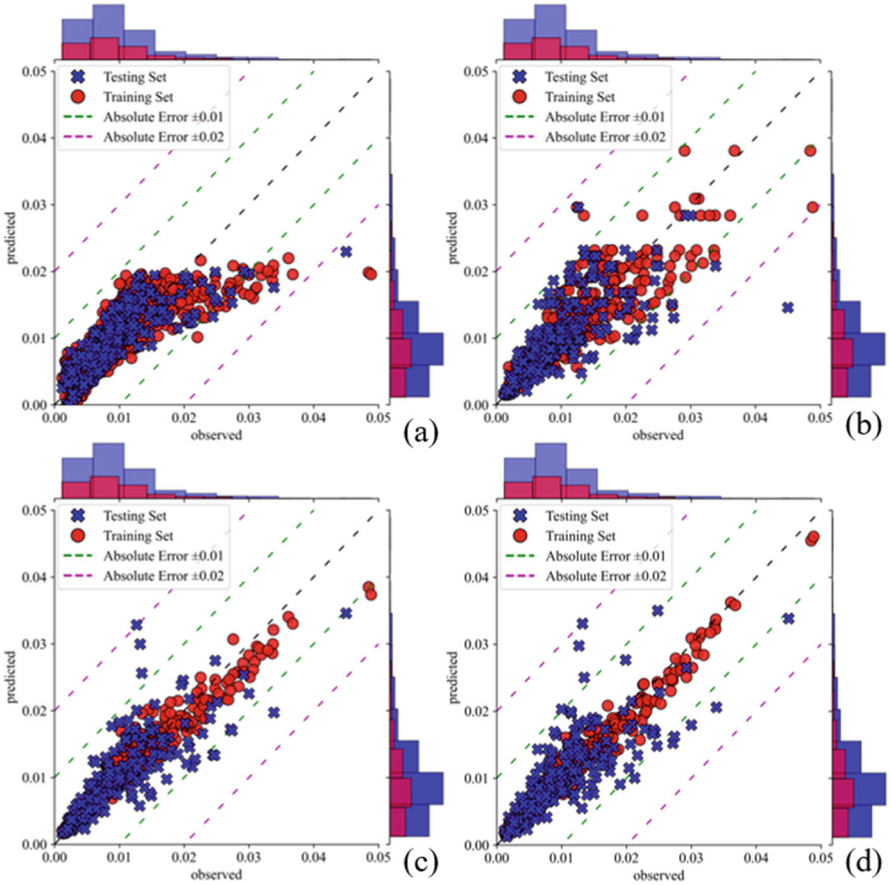

Fig. 6 Observed-predicted scatters of different ML models: (**a**) LR, (**b**) DT, (**c**) RF, and (**d**) XGBoost

RMSE = 0.0036. The weakness of LR in measurement of maximum drift of corroded RC bridge piers indicates the nonlinear nature of the database. Tree-based models yield more accurate predictions. Among them, DT with $R^2 = 0.7$, MAE = 0.0024, MSE = 1.1×10^{-5}, and RMSE = 0.0033 is the least accurate one. However, according to its performance seen in Figs. 6 and 7, the HPO has helped avoid overfitting of the model. The accuracy of the predictions is further increased by using the RF algorithm. The RF model has $R^2 = 0.73$, MAE = 0.002, MSE = 8×10^{-6}, and RMSE = 0.003. According to the metrics in Fig. 7, XGBoost algorithm with $R^2 = 0.8$, MAE = 0.0015, MSE = 5×10^{-6}, and RMSE = 0.0028 yielded the most accurate predictions among all other models. According to Fig. 6, all the predicted data points from XGBoost algorithm have absolute errors of less than ±0.02.

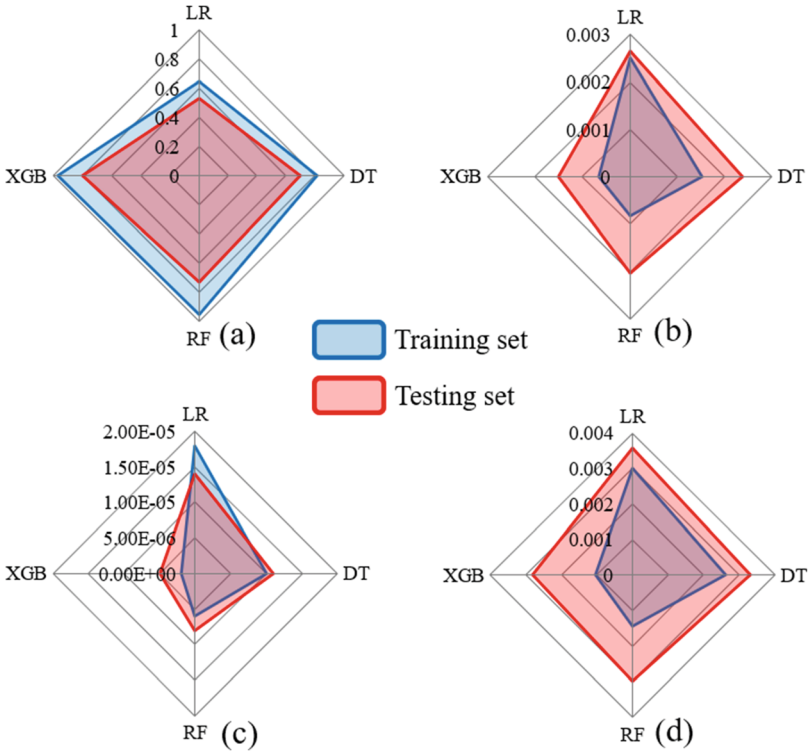

Fig. 7 Performance comparison of different ML models: (**a**) R^2, (**b**) MAE, (**c**) MSE, and (**d**) RMSE

5 Conclusion

Different ML algorithms are utilized in the present study to predict the maximum drift of corroded RC bridge piers. The database is built by developing numerical models of bridge piers whose mechanical properties have deteriorated due to corrosion. To improve the generality of the study, the key parameters affecting geometry, design, material, and environmental conditions are randomly chosen. The models are trained with 70% of the database and are tested with the remaining 30%. Bayesian search algorithm is also employed to tune the hyperparameters of the ML algorithms to obtain the best performance of them. The major findings of this study are as follows:

- Due to the nonlinear relationship between the features and the target, the LR model showed a weak performance in predicting the maximum drift of corroded RC bridge piers.
- Tree-based models, namely DT and RF, provided more accurate predictions; about 35% more accurate than the linear model. It indicates that tree-based algorithms map nonlinear relationships quite well.

- Among tree-based models, RF performed slightly better. The reason lies in the ability of the RF algorithm to avoide the overfitting of the model.
- The closeness of the performances of the DT model and the RF one indicates the significance of the HPO in avoiding the overfitting of the model.
- The comparison of the metrics used in this study exhibited that XGBoost model has the highest accuracy. The accuracy of this model is 50% and 15% higher than the linear and tree-based models, respectively.

1 Introduction

Understanding material behaviour lies at the core of structural engineering. Engineers seek to predict how different types of materials react to different kinds of load actions. The beam element is an essential structural element that can experience compression, flexure (bending), torsion, tension, or a combination of these actions. Understanding how a reinforced concrete (RC) beam resists bending loads serves as the fundamental principle for designing a plethora of structures. When a load is imposed on an RC beam, it undergoes bending, experiencing both tension and

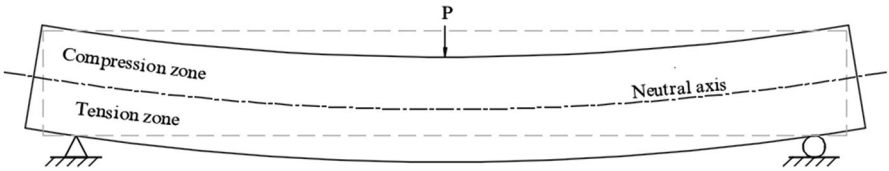

Fig. 1 RC beam in flexure

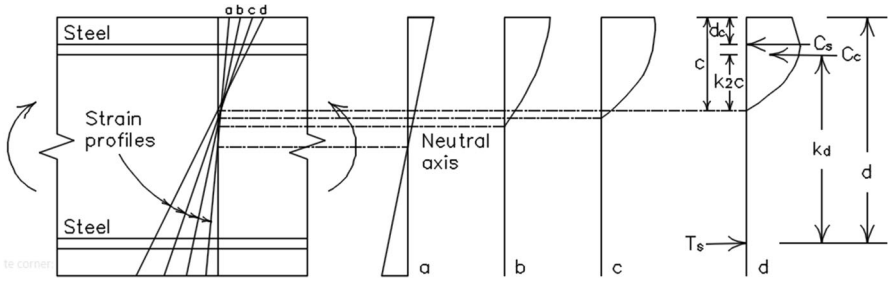

Fig. 2 Stress and strain distribution in an RC section under bending

compression. The distribution of these forces within the beam is contingent on the direction of application of the load. When a point load is applied to the top of an RC, the top of the beam undergoes compression while the bottom experiences tension, as depicted in Fig. 1.

These two zones are separated by a plane that experiences zero stress due to bending called the neutral axis. The position of this neutral axis within the beam cross-section shifts based on the distribution and magnitude of applied loads. Typically, steel reinforcement in the form of circular bars is incorporated within RC beams to better support the loads applied. As the applied load induces stress in the RC beam, corresponding stains occur. Figure 2 presents the stress profile and strain distribution for a doubly reinforced RC section under bending [1]. The compression stress blocks a, b, c and d correspond to the strain profiles a, b, c and d. When an RC beam undergoes bending, compressive stresses are borne by the concrete and reinforcement in the compression zone, while the reinforcement in the tensile zone primarily carries tensile stresses. Concrete, possessing minimal tensile capacity, resists only limited tensile forces in the tension zone before it cracks.

The flexural response of a beam describes how the beam deflects under loading. The typical moment-deflection curve of an RC beam, particularly with an under-reinforced or balanced section, is characterized by three main stages (Fig. 3). In the first stage, the beam undergoes elastic deformation from the initial loading until the concrete in tension cracks. During this stage, both the concrete and the tension reinforcement resist the tensile forces until concrete cracking occurs. Beyond this point, it is assumed that the concrete in tension ceases to contribute to the beam's flexural capacity, and the tension steel reinforcement bears all tensile stress. Some discontinuity occurs between stage one and stage two owing to the change of beam

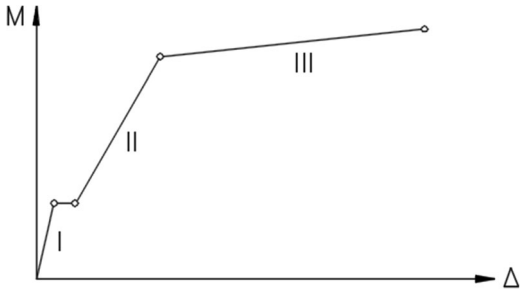

Fig. 3 Typical load–deflection curve of an RC beam

properties from the loss of concrete's tensile strength. As the beam loading continues, stage two begins after the concrete cracks and ends with the yielding of the tension reinforcement. In stage three, there is a more pronounced change in slope, and since the internal steel reinforcement used is a highly ductile material, plastic deformation occurs where the beam continues to rotate. The beam does not support significantly higher loads at this stage but experiences considerable deflections until reaching its ultimate moment capacity. Assuming the shear strength of the beam exceeds its flexural strength, the beam eventually fails beyond this point through steel rupture or concrete crushing or their combined action.

The flexural capacity of an RC beam can be assessed through experimental testing in a laboratory setting but can also be determined via analytical and numerical methods. With knowledge of concrete and steel material behaviour and how they interact in a beam system, mathematical formulations can be done to determine a beam's flexural capacity. This analytical method is well established in literature [1–4] and is based on the following assumptions: (1) Plane sections perpendicular to the bending axis before bending remain plane after bending, (2) The constitutive model (stress–strain relationship) of concrete and steel is known and used to compute the stress in concrete and steel (3) Internal forces within the beam are in equilibrium with external loads at that section (4) there is equal strain in the concrete and reinforcement at the same level. More advanced numerical techniques like finite element (FE) analysis with computer software packages like ANSYS [5], ATENA [6], Abaqus [7], DIANANFEA [8] and NX Nastran [9] can also be used to effectively model RC beams and simulate their reactions to various types of loads. Numerical modelling is usually done alongside experimental investigations to determine the structural behaviour of materials. Increasing knowledge and software capacity has made the numerical modelling of complex RC behaviour possible.

Consequently, various types of concrete beams with distinct characteristics and configurations can be modelled and analysed using these software packages, resulting in significant savings in both time and cost compared to conducting physical experiments [10]. This present study aims to predict an RC beam's flexural response using analytical and numerical methods. The two methods used are validated with results from an experimental program conducted in an existing study [2].

2 Methodology

A case study from an existing study was considered. The chosen beam was analysed using numerical and analytical approaches. The results were subsequently compared with the existing experimental results. An RC beam of 1840 × 120 × 240 mm with a 25 mm concrete cover, two 10 mm rebars at the tension side of the beam and two 8 mm rebars at the compression side was considered. Shear links of 8 mm were provided in 80 mm centres. The beam schematic with loading points shown is presented in Fig. 4. The steel reinforcement had a yield strength of 540 MPa, and the cylinder concrete compressive was 50 MPa.

2.1 Material Constitutive Models

The constitutive model for the concrete and the steel reinforcement is illustrated in Fig. 5. The model for concrete, as proposed by Hognestad [11], is characterized by two curves: an ascending parabolic branch defined from Eqs. 1 to 3 and a descending branch. The concrete elastic modulus and tensile strength are derived from Eqs. 4 and 5 [12]. For the numerical analysis, the first point of the curve was made to satisfy Hooke's law as required by ANSYS, and the second point of the curve defined the extent of the elastic region (30% of the ultimate compressive stress) [13]. The

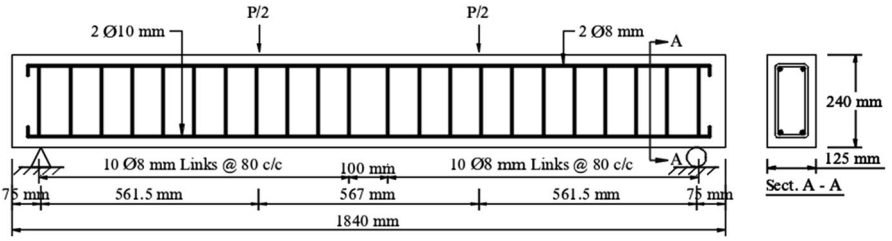

Fig. 4 Beam reinforcement details

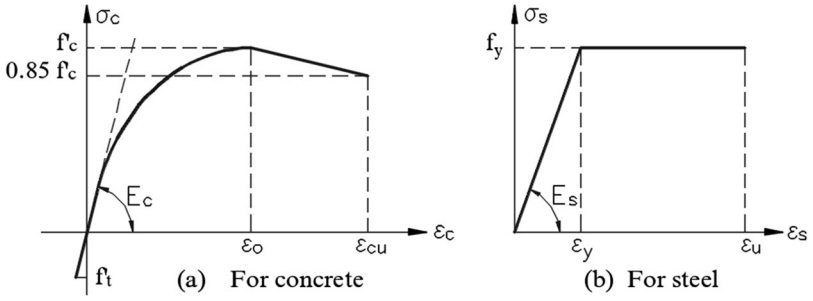

Fig. 5 Stress–strain relationship (**a**) for concrete and (**b**) for steel

following points of the curve leading to the ultimate compressive strength were derived from Eq. 2. The descending branch of the curve was ignored in the FE material model to avoid convergence issues.

$$f_c = f'_c \left[2\left(\frac{\varepsilon_c}{\varepsilon_0}\right) - \left(\frac{\varepsilon_c}{\varepsilon_0}\right)^2 \right] \qquad 0 \le \varepsilon_c \le \varepsilon_0 \tag{1}$$

$$f_c = f'_c - 0.15 f'_c \left[\frac{\varepsilon_c - \varepsilon_0}{\varepsilon_{cu} - \varepsilon_0} \right] \qquad \varepsilon_c > \varepsilon_0 \tag{2}$$

$$\varepsilon_0 = \frac{2f'_c}{E_C} \tag{3}$$

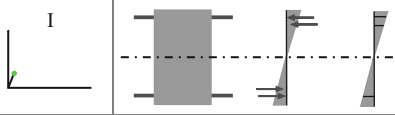
$$E_c = 4730 \times \sqrt{f'_c} \tag{4}$$

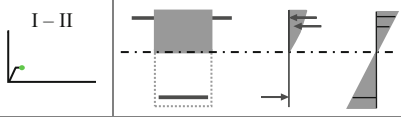
$$f_t = 0.7 \times \sqrt{f'_c} \tag{5}$$

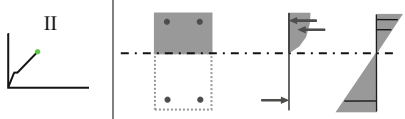
where

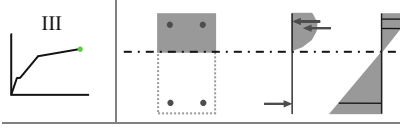
f_c = stress at concrete strain (ε)
f'_c = Cylinder compressive stress
f_t = Splitting tensile concrete stress
ε_c = strain at concrete stress (f)
ε_0 = strain at f'_c
E_c = Concrete Modulus of elasticity

The tension and compression behaviour of the reinforcing steel is assumed to follow an elastic-plastic model, as determined by Eqs. 6 and 7. Here, f_s and ε_s are the stress and strains in the reinforcing steel, respectively, while f_y and ε_y denote the yield stress and strains in the reinforcing steel. E_s is the reinforcing steel modulus of elasticity.









$$f_s = E_s \varepsilon_s \qquad \varepsilon_s < \varepsilon_y \tag{6}$$

$$f_s = f_y \qquad \varepsilon_s \ge \varepsilon_y \tag{7}$$

2.2 Analytical Approach

The analytical approach to determine the behaviour of the RC beam was done by using force equilibrium and strain compatibility equations; the various points of the load–deflection curve were guided by Toutanji et al. [14]. For the start of the beam loading just before the tension steel yields, the neutral axis was calculated from the first moment of area of the transformed area. Different moments of inertia are calculated before the tension concrete cracking and the different stages after. Force

Table 1 Stages of RC beam flexural behaviour

Stage	Section—stress block–strain profile	Neutral axis depth and moment	Curvature and deflection
I		$\frac{\sum Ay}{\sum A} = 0$ $M = \frac{f_t I}{y_b}$	$I = \sum\left(I_i + A_i d_i^2\right)$ $\varnothing = \frac{M}{E_c I}$ $\Delta = \frac{M}{24E_c I}\left(3L^2 - 4a^2\right)$
I – II

III			

equilibrium is used for section analysis from the point concrete enters its plastic behaviour after the tension steel yields. Table 1 presents the parameters for the section analysis, stress block, strain profiles, moment, curvature and deflection formulas for the different stages of the RC beam loading. The sectional strain relationships are used alongside these expressions to calculate the neutral axis depths and corresponding moments.

L is the clear span of the beam, a represents the distance from the beam edge to the load point, $P/2$, y_b is the distance from the centroid of the transformed section to the bottom of the section, C_c is the concrete compressive force, C_s is the compression steel compressive force, T_s is the tension steel tensile force, c is the depth of the neutral axis, d_c is the depth of the compression steel and k_{c2} is the distance between the centroid of the compression force in concrete and the neutral axis as shown in Fig. 2.

2.3 Numerical Approach

The numerical modelling was done using the ANSYS FE analysis software. The software considers the nonlinear behaviour of structures under gradual loading with the concept of load steps. It adjusts the model's stiffness matrix after each load step to incorporate the nonlinear alterations in the structure's stiffness due to the nonlinear behaviour of the constituent materials [15]. The software updates the

Table 2 Material properties used in the ANSYS model

Material	Element type	Material properties

Steel plates	Solid185	Linear isotropic	EX—200,000 MPa	PRXY—0.3	

stiffness matrix using Newton–Raphson equilibrium iterations. With each load step, the difference between the forces applied to the model and the element stresses is computed, known as the out-of-balance load vector. The program then checks if there is convergence. If the convergence criterion is not fulfilled, an iterative process continues, re-evaluating the out-of-balance load vector and updating the global stiffness matrix until convergence is reached [16].

Table 2 presents the various material elements used to numerically model the concrete, steel reinforcement, support and load application plates and the mechanical properties assigned to them. The FE beam was modelled with the exact dimensions and material properties as the experimental beam to represent the physical condition accurately. The concrete and steel materials were modelled with similar equations used in the analytical model: multilinear isotropic relationship (Eqs. 1–3), elastic modulus (Eq. 4), uniaxial cracking stress (Eq. 5) and uniaxial crushing stress (experimental case study). The shear transfer coefficients represent the crack face condition of concrete, and the values range from 0 to 1. 0 represents the complete loss of shear transfer (smooth crack), while 1 signifies no loss of shear transfer (rough crack) [15]. These values were chosen from existing literature [5] and adjusted to ensure convergence.

The loading and support distances and conditions of the FE model were also made to be identical to the experimental beam. Two 20 mm thick steel plates were modelled with the beam to serve as the beam support and the loading point. These plates distribute stress more evenly, preventing stress concentrations and averting

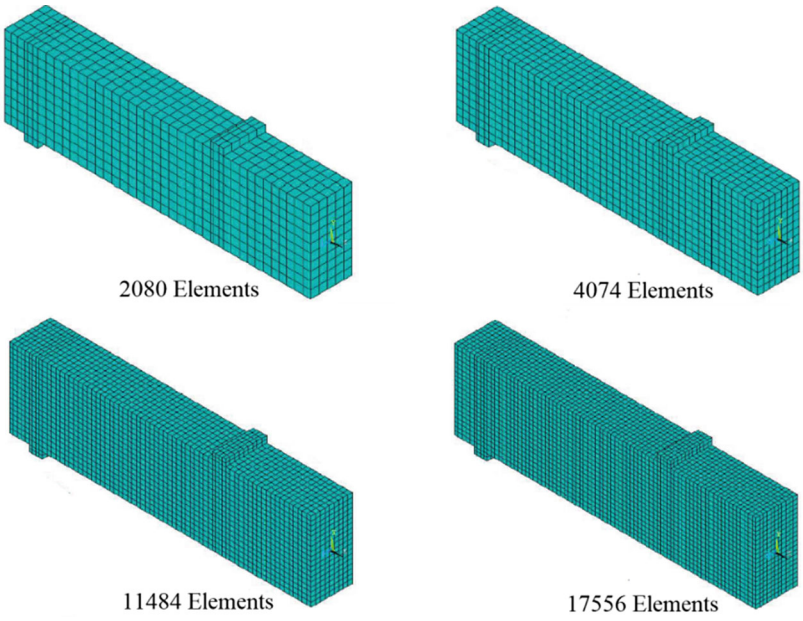

Fig. 6 Beam FE models with different mesh densities

premature beam failure. Given the symmetric nature of the beam, only half of it was modelled to reduce computation time and disk requirements. A plane of symmetry was established at the mid-span, effectively restricting its movement in the direction perpendicular to that plane.

After creating the necessary solid and line elements, the model was meshed (divided into small elements). The mesh density, the number of elements the model is divided into, is critical in obtaining an accurate solution [5]. The mesh density is determined by the mesh size, which is user-controlled in the program; reducing the element size increases the number of elements. In RC models, a coarse mesh may result in a solution that is not sufficiently accurate [15]. Though accuracy typically increases with an increased mesh density, computing time also increases. A mesh sensitivity analysis (MSA) was done to determine a suitable mesh size for the ANSYS beams, one that is not too large to compromise the analysis results but also not too small to maximize the computing process. The MSA process entails increasing the mesh density until further increase has an inconsequential impact on the beam's outcomes. Six identical half beams without internal steel reinforcements were modelled for this process. Beam models with 25 mm, 20 mm, 15 mm, 14 mm, 13 mm and 12 mm corresponded to models with 2080, 4074, 9180, 11,484, 14,030 and 17,556 number of elements. Figure 6 shows four of the six beam models with their corresponding number of elements indicated. An arbitrary 7 kN load was applied to each beam, and the resulting mid-span deflection was measured. The result of the MSA is presented in Fig. 7, which presents the mid-span deflection for

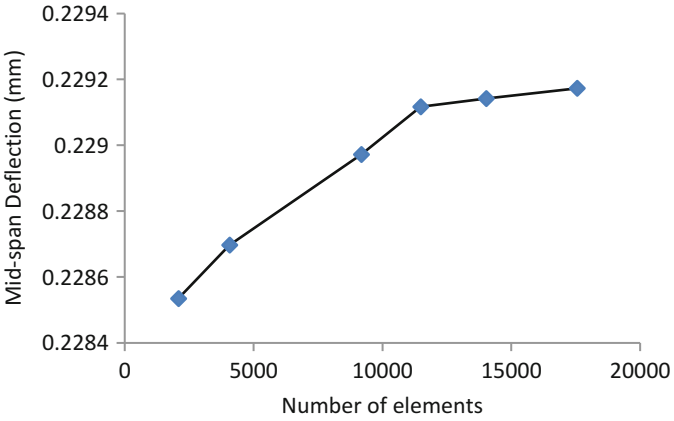

Fig. 7 Deflection at mid-span convergence study

the six beams. The results began to converge in the model with 11,484 elements, corresponding to the 14 mm element size. The 14 mm mesh size was used to model the beam. A finer mesh was also provided at the loading and support locations to prevent stress concentrations.

3 Results

Figure 8 shows the load–defection relationship derived from the analytical formulations presented in this chapter, the numerical analysis done in ANSYS and the case study experimental beam. The three stages of the load–deflection curve are evident from the three curves. The compression concrete cracking load from the experimental, numerical and analytical analysis was 21.68 kN, 22.88 kN and 23.90 kN respectively. The compression yield load and ultimate load derived from the experimental, numerical and analytical analyses are presented in Table 3. The ultimate deflection from the experimental, numerical and analytical analysis was 33.96 mm, 39.77 mm and 35.83 mm, respectively. The percentage difference of the numerical and analytical results with respect to the experimental is also presented. The numerical and analytical curves correlated with the experimental results to a reasonable degree.

4 Discussion

It can be observed from the graph that the numerical and analytical curves were stiffer than the experimental curve. This increased stiffness is because the analytical and numerical models are in perfect conditions with perfect materials. This

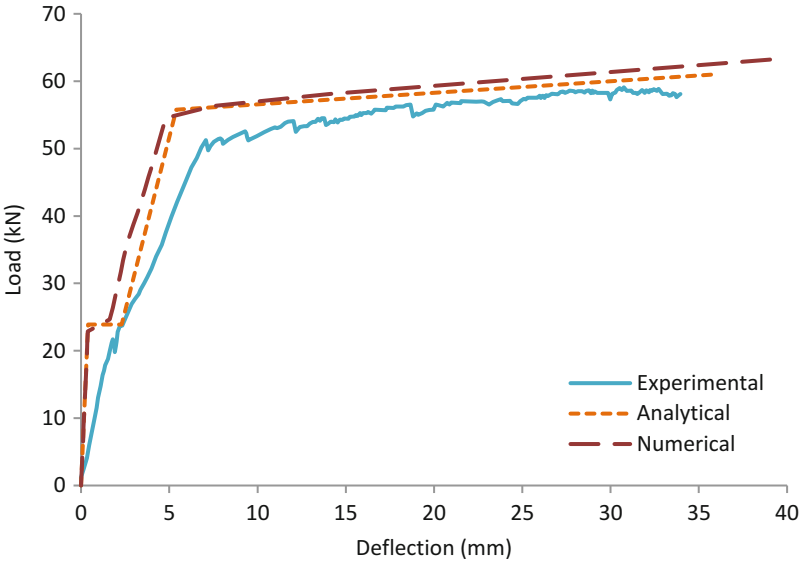

Fig. 8 Load–deflection curves

Table 3 Load–deflection response of control beam

Analysis type	Yield load, P_u (kN)	% Difference	Ultimate load, P_y (kN)	% Difference
Experimental	51.26	–	59.09	–
Numerical	54.56	6.45	63.36	7.22
Analytical	55.78	8.81	61.00	3.22

perfection does not exist in the physical condition. In the physical condition, material imperfections exist, and the bond between the concrete and steel reinforcement could also be imperfect, allowing for slippage. Though these imperfections can also exist when RC beams are used in real-life applications, there could be human error in conducting experimental tests and machine calibration errors with the testing equipment.

It can also be observed that beyond the concrete cracking point, the numerical model is slightly stiffer than the analytical model. This difference can be attributed to the concrete material model adopted in the analytical model. In the true tensile behaviour of concrete, a descending branch known as the tension softening region exists after the maximum tensile stress is reached. However, this region was omitted in the analytical model to simplify the analysis. Similarly, the steel reinforcement also has a strain hardening region when the stress goes from the yield stress to ultimate stress before a slight descent before failure. This region was overlooked in both models. It is essential to recognize that the accuracy of any analytical or numerical model hinges on the precision of the assumptions made. Material models are deliberately simplified to facilitate analysis. Therefore, when developing

analytical or numerical models, it is crucial to understand the implications of the chosen material models, ensuring that they do not compromise the accuracy of the obtained results.

5 Further Considerations

In the research of RC beam flexural behaviour, it is imperative not to rely solely on any single approach in isolation. When conducting physical experiments, it is advisable to complement them with analytical or numerical methods. This helps confirm the results obtained from physical tests, considering the inherent imperfections of physical systems. Likewise, when analytical or numerical analyses are employed, validating the results against existing experimental data is essential. While analytical and numerical models provide ideal conditions often unattainable in real-world settings, their integration can significantly economize both time and costs when exploring various scenarios. Preliminary tests and parametric analyses can be conducted using analytical and numerical modelling techniques, allowing for the variation of different parameters within the system. Parametric analysis, when conducted, will help to identify optimal conditions and configurations before committing to laboratory testing.

It is also important to note that the analytical approach is restricted to specific beam systems characterized by predefined boundary conditions, loading types and beam geometries. As the complexity of the beam system increases, so does the complexity of the analytical formulations required. Conversely, the numerical approach offers an advantage in this aspect. Various beam configurations featuring diverse loading patterns can be effectively modelled and analysed using FE analysis software. Furthermore, an FE model can incorporate intricate phenomena such as bond slip. Though there are advantages to the numerical approach, there is also a cost consideration when acquiring the FE software. While certain software, like ANSYS, offers academic versions, these versions may have limitations regarding the scale of work (size of model) that can be conducted. The numerical analysis also requires computational power and memory; the extent needed depends on the size of the analysis.

6 Conclusion

Analytical and numerical approaches were used to predict the flexural behaviour of an RC beam. The analytical and numerical beam flexural behaviour depicted by a load–deflection curve compared well with the available experimental data. Effective utilization of analytical or numerical approaches necessitates a comprehensive understanding of beam mechanics and the material behaviour of concrete and reinforcing steel. The precision of predictions hinges on the accuracy of material behaviour assumptions.

Experimental, analytical and numerical approaches in determining RC beam behaviour should be used collaboratively. Analytical and numerical methods can save on cost and time but present perfect results from a perfect system. Predefined assumptions and simplified models constrain the analytical approach, while the numerical approach provides a more versatile platform for modelling more diverse beam configurations and accounts for complex phenomena.

1 Introduction

The concept "net zero" entails the attainment of equilibrium between the quantity of greenhouse gases released into the atmosphere and those subsequently withdrawn from it [1]. A zero-carbon transition can boost both productivity and growth [2]. Renewable power could primarily replace fossil fuel-based energy consumption in order to achieve net-zero emissions [3]. Through national-level decisions, the Paris Agreement establishes an international framework with the goal of keeping the average rise in global temperature to well below 2 °C [4, 5]. The environment is significantly impacted by the building industry. Around 40% of global energy use

and greenhouse gas emissions are attributed to it [6]. Also, in terms of geotechnical investigations, it leads to a carbon footprint with the manufacturing and operation of heavy machinery on site as well as in the laboratory. Artificial intelligence (AI), machine learning, deep learning, and artificial neural networks (ANNs) are reshaping data processing and analysis [7] and can be employed as alternatives for laboratory testing.

The main aim is to suggest a technological alternative that decreases the reliance on laboratory testing equipment used for finding C and φ of soil. To this end, ANN, a machine-learning method, is being utilized. By applying this ANN and inputting the index properties of soil, including C and φ, a model is developed through training, testing, and validating its accuracy. Commonly, index properties of soil can typically be determined using basic testing equipment without the need for machinery. Thus, the model is supplied with the index properties as inputs, and it then produces precise values for C and φ. As a consequence, usage of testing machines can be avoided, leading to a reduction in net emissions.

2 Carbon Footprint of Laboratory Testing Equipment

Regarding climate change, greenhouse gas (GHG) emissions, primarily carbon dioxide (CO_2) emissions, are a global concern. Because manufacturing processes require a lot of energy by nature, electricity produced from fossil fuels contributes significantly to global warming [8]. It is widely acknowledged that the comminution of the ore accounts for roughly 70% of the energy used in conventional mining and mineral-processing circuits [9]. Currently, the industrial sector uses over half of the energy consumed worldwide [10]. Global CO_2 emissions from the manufacturing sector are summarized in Fig. 1, which also includes direct emissions for electricity, heat, and buildings. China's industrial growth after 2002, the country that entered the World Trade Organization in 2001, is the reason for the sharp increase [11].

3 Overview of ANNs

An artificial intelligence system is called ANN modeling. It has been successfully used to solve a variety of geotechnical issues [12]. The capacity of ANNs for learning allows them to uncover hidden connections. ANNs do not impose any limitations on the input variables and are capable of learning and modeling latent correlations between inputs and outputs [13]. Although there are numerous types of ANNs, the multilayer feed-forward ANN is the type that is most frequently utilized [14].

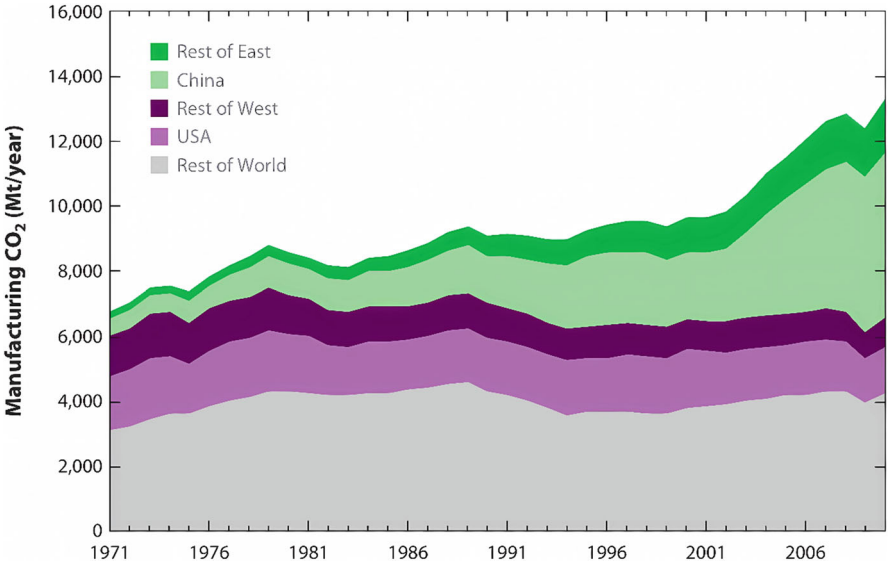

Fig. 1 Carbon dioxide emissions from various regions of the world [11]

3.1 Functioning of Neural Networks

There are three layers in Fig. 2 below: the input layer, the hidden layer, and the output layer. Neurons make up the majority of these layers. All input parameters are contained in the input layer, and goal outputs are found in the output layer. Additionally, the hidden layer is typically used to aid the network's learning process and is positioned between the input and output layers [15]. The summation function, transfer function, and connection weights of the neurons are readily built with the use of parallel computation methods [16].

3.2 Bayesian Optimization Technique

Compared with conventional back-propagation nets, Bayesian regularized artificial neural networks (BRANNs) exhibit greater resilience [18]. The objective function that is often utilized, such as mean squared error (MSE), or E_d in Eq. (1), is modified in the Bayesian approach. A term, E_w, is added to the objective function in Eq. (2) to extend it.

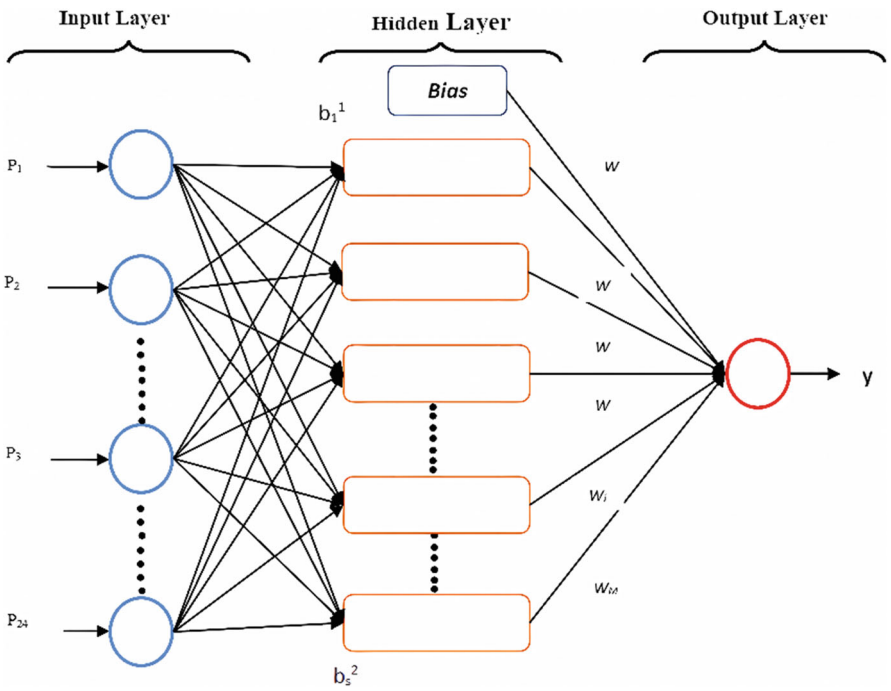

Fig. 2 Architecture of an artificial neural network [17]

$$F = E_{\mathrm{d}} = \frac{1}{N}\sum_{i=1}^{N}\left(e_j\right)^2 \tag{1}$$

$$F = \beta E_{\mathrm{d}} + \alpha E_{\mathrm{w}}, \tag{2}$$

where e_j is the error between the target and observed values, E_{d} is the MSE, α and β are the objective function parameters, whereas E_{w} is the sum of the squares of the network weights [19].

4 Data Used for the Study

4.1 Description of the Dataset

Data were sourced and used in the model's construction from prior research endeavors [20], comprising 11 input parameters and 2 output parameters, namely, C and φ and the remaining input parameters are clearly set out in Table 1.

Table 1 Inputs utilized in the creation of the model

4.2 Characteristics of the Dataset

The statistical properties of all the parameters used for the study are illustrated in Table 2. Also, the correlation among all the input parameters were demonstrated in Fig. 3. The connection between two variables was determined using the Pearson method and depicted using a heat map. The correlation matrix revealed that dry unit weight displayed the highest correlation with cohesion, followed by liquid limit and moisture content. Conversely, the coefficient of uniformity and unit weight exhibited the weakest correlation with cohesion. Similarly, moisture content showed the strongest correlation with the angle of internal friction, whereas the coefficient of curvature demonstrated the weakest correlation.

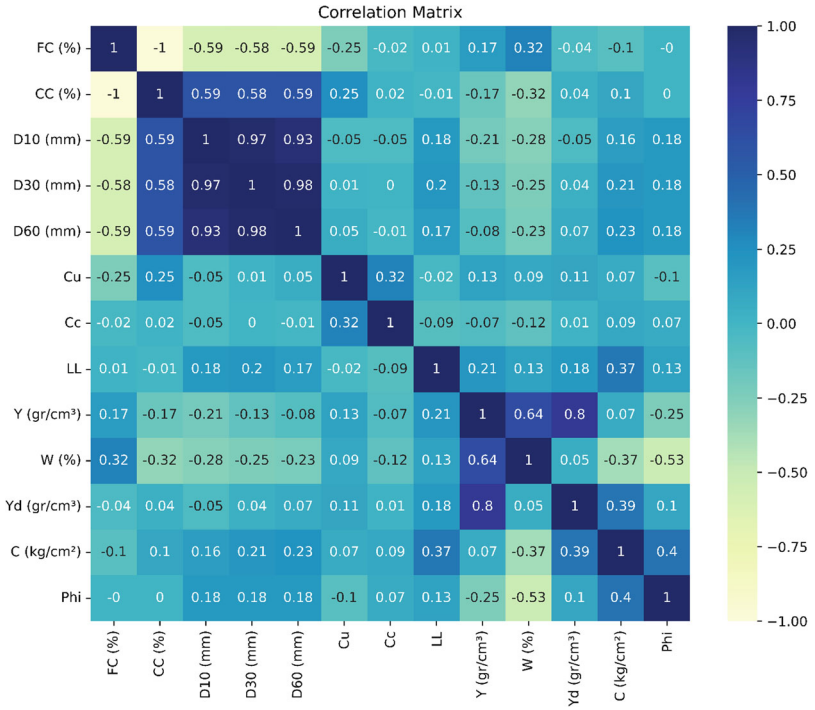

Fig. 3 Correlation among the inputs used for model creation

5 Evaluation Criteria

To assess the precision and resilience of the developed model, five evaluation metrics were employed, namely the root mean squared error (RMSE), the coefficient of determination (R^2), and the mean absolute error (MAE). These metrics are conventionally applied in regression scenarios to gauge the performance of predictive models. The equations corresponding to each metric are as follows:

$$\mathrm{RMSE}\sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(y_i-\hat{y_i}\right)^2} \tag{3}$$

$$R^2=1-\frac{\sum_{i=1}^{n}\left(y_i-\hat{y_i}\right)^2}{\sum_{i=1}^{n}\left(y_i-y_i'\right)^2} \tag{4}$$

$$\mathrm{MAE}=\frac{1}{n}\sum_{i=1}^{n}\left|y_i-\hat{y_i}\right|, \tag{5}$$

where n denotes the total number of observations, y_i stands for the target value, $\hat{y_i}$ for the predicted value, and y_i' for the mean of the target values [21, 22].

6 Results Overview and Interpretation

This section explains how successful the constructed ANNs are using the Bayesian regularization optimization algorithm for predicting the cohesion and φ of soil. In adherence to established methodologies, the training and testing subsets were partitioned in a ratio of 70% to 30% respectively, serving as foundational components for model development and subsequent validation. The database underwent segmentation into distinct training and testing subsets, comprising 62 and 26 samples respectively, to facilitate the model construction process. The assessment of the constructed models' performance ensued through meticulous evaluation, employing various parameters to ascertain their robustness and predictive capabilities.

6.1 Development of the Model

For construction of the model, MATLAB R2018a was employed as the primary computational tool. To ascertain the optimal configuration, encompassing the ideal hidden layer's number and neurons inside each layer, a meticulous trial and error procedure was carried out, guided by a systematic approach. This iterative exploration was performed to ensure the attainment of a model possessing a commendable degree of accuracy. Furthermore, the refinement of ensemble complexity was imperative to optimize the algorithmic space, warranting the inclusion of an optimal number of individuals within the suggested ensembles. As depicted in Fig. 4, the final model has iterations of 178 and the best performance of MSE is 0.026183, attained at 31st epoch. The regression plots associated with data sets for testing, training, and validation are seen in Fig. 5.

6.2 Performance of the Model

Each model's ability to learn is reflected in how well training outcomes work. The results of the testing and training phases of soil cohesion in comparison with original values are depicted in Fig. 6 for cohesion and in Fig. 7 for angle of internal friction of the soil. One way to evaluate how accurate the prediction is by looking at the correlation between the predicted and values. For cohesion, the finalized model had RMSE = 0.293, R^2 = 0.890, MAE = 0.548. Also for the friction angle the model had RMSE = 0.3862, R^2 = 0.819, and MAE = 0.7739. Thus, an ANN with the Bayesian regularization algorithm shows the precise soil shear strength parameter prediction using soil index properties.

3D surface plots of cohesion and φ calculated by RMSE values with respect to each neuron in the hidden layers were given in Figs. 8 and 9 respectively. From both graphs it was observed that the ANN models performed well for up to two hidden

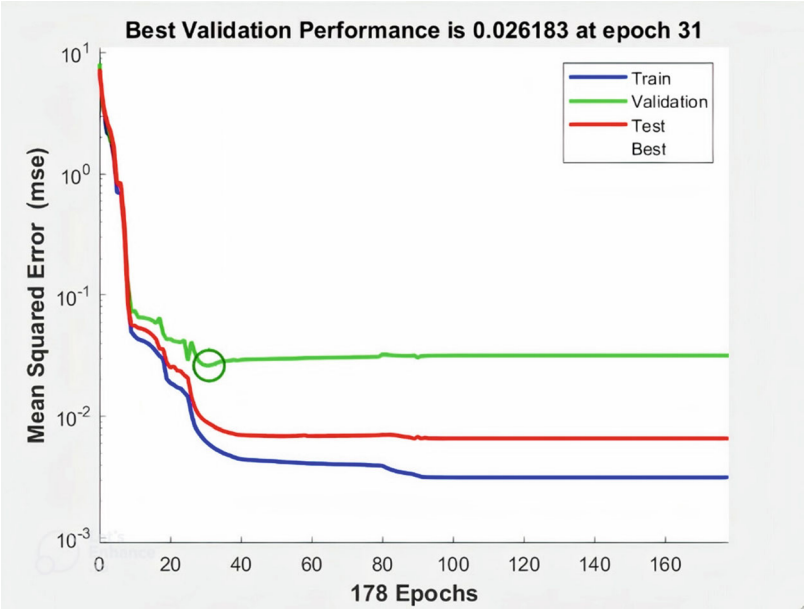

Fig. 4 Performance graph of the final model

layers corresponding to each neuron, as RMSE values close to zero indicate a good model, but from the third hidden layer onward there is an abrupt increase in RMSE values, which is undesirable and indicates low performance. In addition, for cohesion, the performance of the models is good after six neurons in the first two hidden layers, whereas in φ the performance of the models is same for all the neurons in the first two hidden layers.

6.3 Sustainability of the ANN Model in the Long Term

The accuracy and reliability of the initial model for a particular site are undoubtedly good in order to continue; expanding the database with diverse soil data from various sites should be used for testing, training, and validation. With the time-to-time monitoring of performance, data quality, and incorporating the latest optimization techniques improves the generalization and robustness of the model. Incorporating uncertainty analysis techniques enhances the prediction confidence and reveals sources of uncertainty. The traditional method of testing involves more chances of human error and requires high initial capital and time-to-time maintenance, repair, and operational costs are also added, whereas an ANN model initially requires investment in data collection, pre-processing but offers significant cost advantages over time.

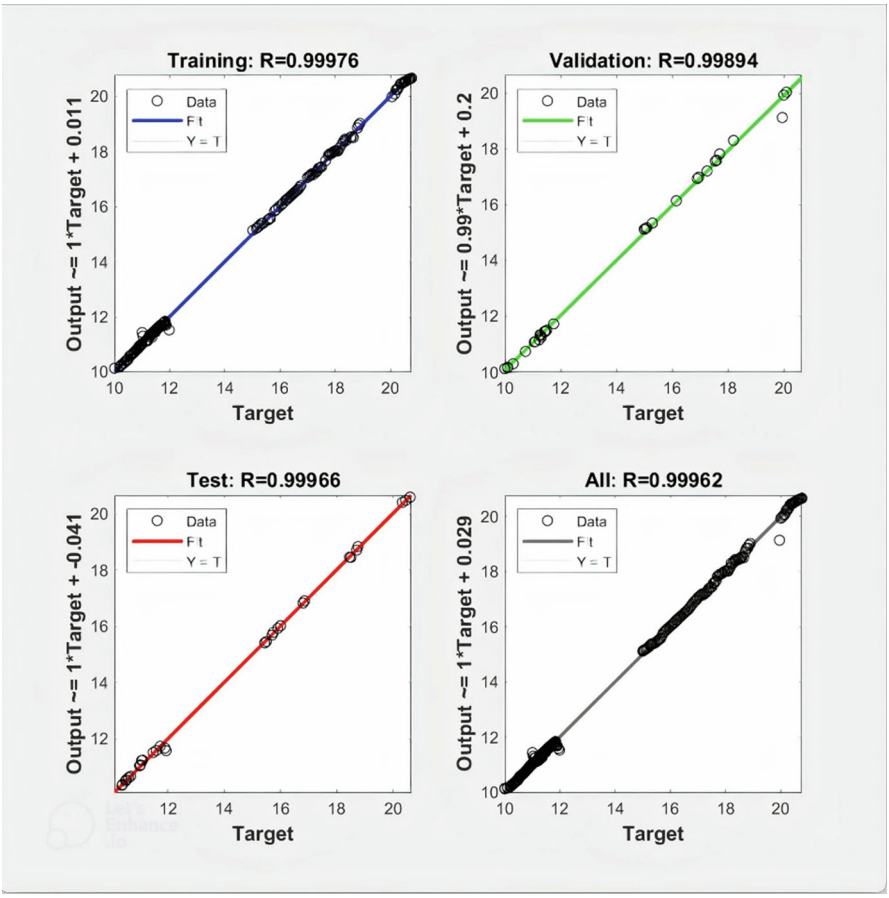

Fig. 5 Regression plots of the testing, training, and validation sets

7 Carbon Reduction Achieved by this Model

For the estimation of carbon reduction, a triaxial machine is considered at our institution. It has a power consumption of 990 W and the time required for testing one sample varies depending on the type of test, with the unconsolidated undrained (UU) test taking 5–10 min, the consolidated undrained (CU) test 26–30 h, and the consolidated drained (CD) test 7–10 days. To obtain the values of C and φ for one particular soil, at least three samples need to be tested. Energy consumption is calculated as

$$\text{Energy (kWh)} = (\text{Wattage (W)} \times \text{operation time of machine (h)})/1000. \quad (6)$$

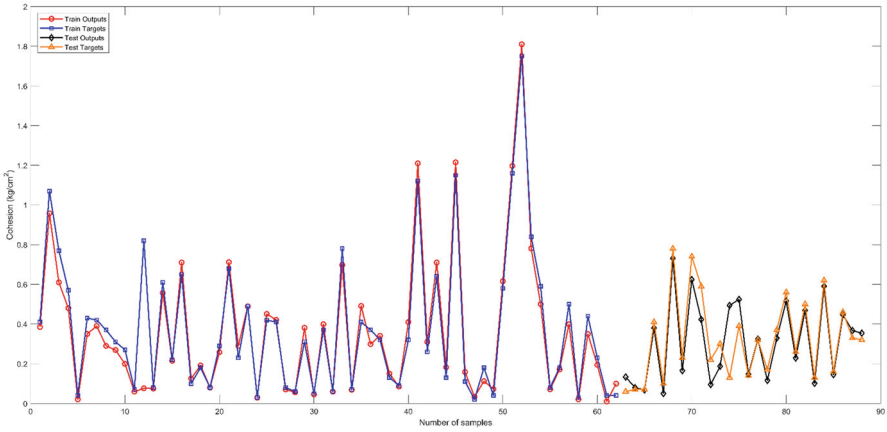

Fig. 6 Comparison of the testing and training data of actual and predicted cohesion

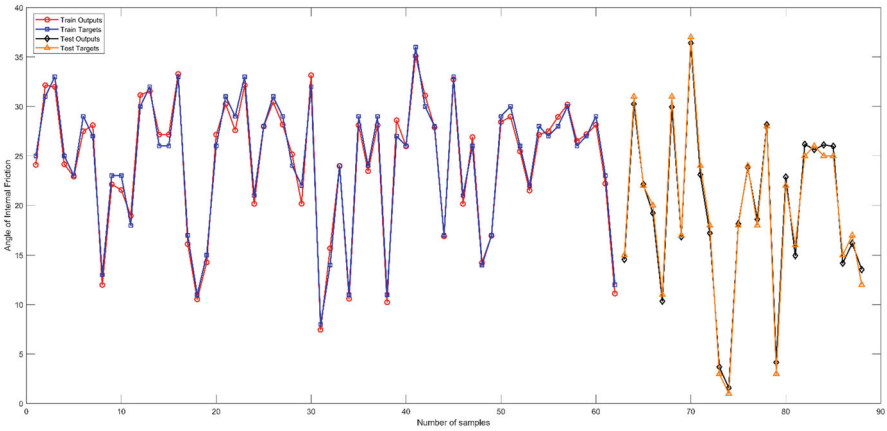

Fig. 7 Comparison of the testing and training data of actual and predicted internal friction

Using Eq. (6) energy consumption for the testing of three samples of each type of test can be calculated. Table 3 shows these values, along with GHG emission by the production of 1 kWh of energy at a thermal power plant obtained from Mittal [23]. Also, the total power consumption range and corresponding emissions range are mentioned.

The development of the model required a PC with a power consumption of 200 W, which was used for 15 days, with an average usage of 8 h, resulting in a total consumption of 24 kWh. The average time taken to use the model for a new prediction is 15 min, which accounts for 0.05 kWh of energy consumption, less than 9.9 times UU, 1782 times CU, and 14,256 times CD test energy consumption and thereby the reduction of GHG emissions by the same number of times.

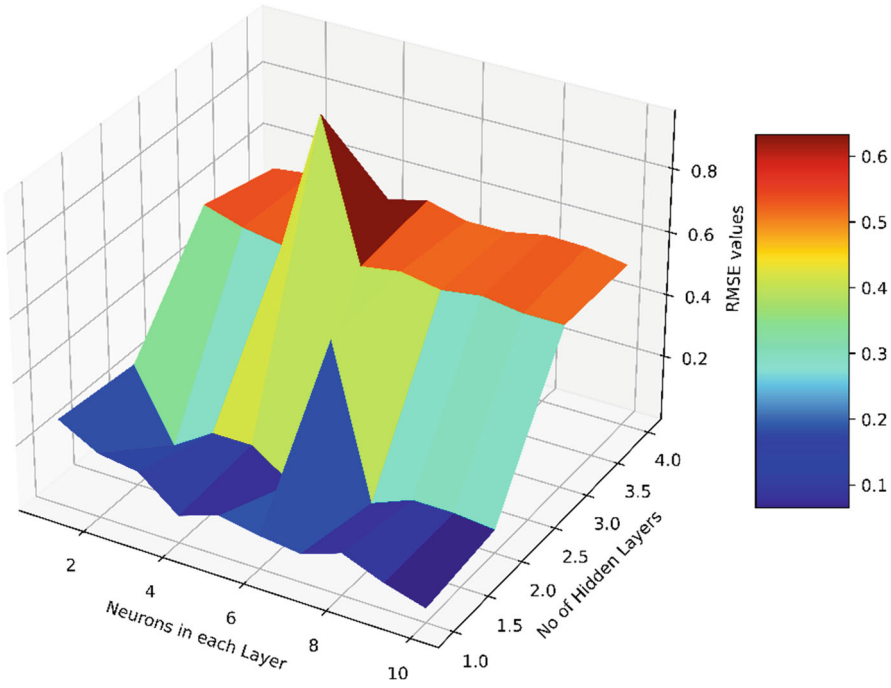

Fig. 8 Change in root mean squared error of cohesion owing to neurons in the hidden layers

7.1 Limitations

- The data utilized for the model are rather limited, and data from a single site have been incorporated.
- The testing and training data exhibit a lack of diversity in soil type and its properties.
- The accuracy of the model may diminish when applied to soils with extreme and typical properties.
- Consequently, the applicability of the model for diverse soils on a global scale may reduce its predictive capabilities.

8 Conclusion

In this paper an alternative to traditional testing for obtaining cohesion and the angle of internal friction is proposed using an ANN optimized with the Bayesian regularization algorithm. During development of the model, it was noticed that performance of the model declined significantly from the third hidden layer onward. This was primarily due to overfitting of the model; as the number of neurons and layers

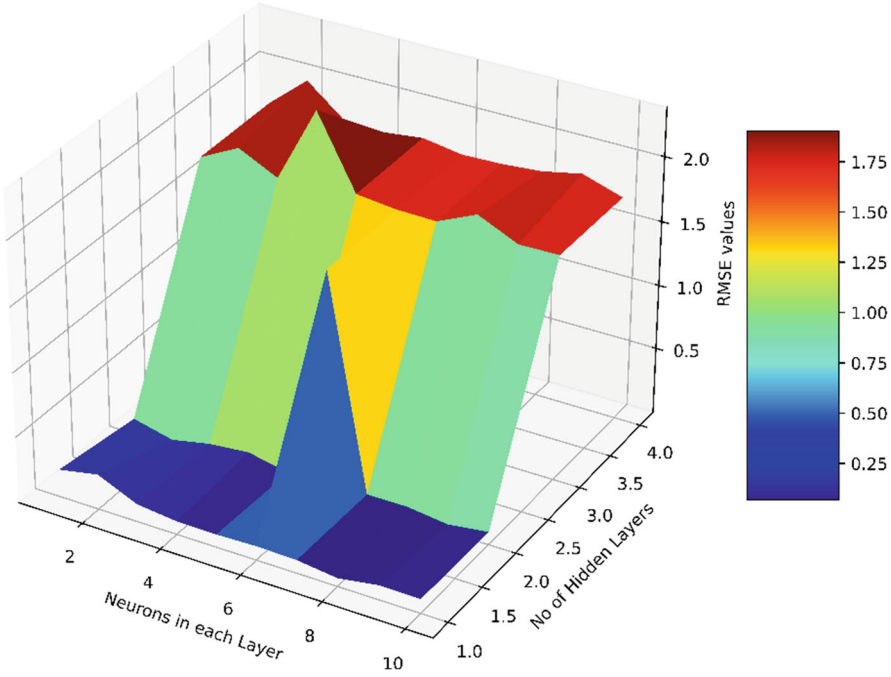

Fig. 9 Change in root mean squared error of phi owing to neurons in the hidden layers

Table 3 Energy consumption and corresponding emissions

	Ideal	UU	CU	CD
Energy (kWh)	1	0.246–0.495	77.22–89.1	499.89–712.8
CO_2 (kg/kWh)	0.95	0.234–0.470	73.36–84.64	474.89–677.16
SO_2 (g/kWh)	7.2	1.774–3.564	555.98–614.52	3599.21–5132.16
NO (g/kWh)	4.38	1.079–2.168	338.22–390.26	2189.52–3122.06

increased, it began to capture noise in the data rather than the underlying patterns. The final proposed model checked using statistical metrics such as RMSE, R^2, and MAE for cohesion values of 0.293, 0.89, and 0.548, and for angle of internal friction values of 0.386, 0.819, and 0.7739.

From comparison of the reduction in carbon footprint by the ANN model developed it is evident that it demonstrated a substantial reduction in GHG emissions. During the development phase the emissions caused were 0.021, 3.71, and 29.7 times lower than those caused by the UU, CU, and CD tests respectively. When the model was used for actual predictions, the emissions caused by the power consumption of the PC were 10.1%, 0.056%, and 0.007% of the emissions caused by the UU, CU, and CD tests respectively. These findings confirm that the utilization of the ANN model contributes to resource conservation and minimizes the environmental impact associated with laboratory testing procedures. However, the model

developed here is site specific, and further research is needed to improve the model and enhance its predictive capabilities by including a wide range of soil data, thereby making it applicable across diverse geotechnical contexts worldwide.

1 Introduction

A durable pavement is characterized by a well-constructed road surface composed of an asphalt mixture with an optimal air void content, effective binder, and well graded, high-quality aggregates [1]. Air void content is a crucial parameter that affects asphalt pavement quality and long-term performance [2] . Factors such as durability, fatigue cracking resistance, strength, and stiffness have shown to be highly influenced by air void content [1, 3].

Proper execution of the compaction process is essential to achieve good pavement performance. Regardless of perfect pavement design or high-quality asphalt mixture, improper compaction will negatively impact the pavement's overall performance [4, 5]. Over-compaction can lead to reduction in air void content, making the pavement less flexible, thus more susceptible to premature rutting under repeated traffic loads [2, 6]. Additionally, a lower air void content might also lead to

permeability loss resulting in clogging problems [2]. Neither too many nor too little air voids in the asphalt are desirable. The presence of too many air voids can increase water permeability [2], which weakens the adhesion between the binder and aggregates while also disrupting the cohesive strength within the binder itself, reducing the service life of the pavement [7].

In Norway, the Norwegian Public Roads Administration (NPRA) is responsible for road development, with a primary emphasis on guaranteeing excellent services and ensuring the safety of road users, as well as prioritizing environmental preservation. In their current practices, the NPRA relies on performing laboratory tests to compute air void content in order to assess the quality of asphalt pavements. However, research has shown that current practices can lead to inaccurate air void measurements [8–10].

With the advancement in technology in recent years, the possibility of developing digital twins has increased significantly. These technological evolvements have opened up new opportunities for digitization in the Architecture, Engineering, and Construction (AEC) sector [11]. This study aims to introduce a new method for air void calculation and observation, namely the "digital twin," created by microcomputer tomography and MATLAB analysis. This chapter aims to investigate the potential of developing a digital twin of asphalt pavements as a substitute for conventional laboratory tests in assessing asphalt pavement quality.

2 Method

To validate the accuracy of the digital twin, numerical data from laboratory investigations were gathered and compared to the data from the digital twin. Relevant road sections were selected based on asphalt composition and durability. Laboratory tests were performed for air void calculations and resistance to permanent deformations. The digital twin was generated by microcomputed tomography of asphalt samples from the road sections and processed using a MATLAB script.

2.1 Description of Chosen Road Sections

This study investigated the wearing course of two road sections, national road 4 at Gjøvik and E-road 6 at Tretten in Norway. These sections were selected based on their durability, expected lifespan, and asphalt composition. The roads are both paved with SMA 16 PMB, allowing for a better comparison between them.

National road 4 at Gjøvik (G-series) This road section is located in Gjøvik municipality in Norway. The wearing course of this section exhibits higher air void content than specified in the contractual agreement, where a shorter lifespan is expected.

E-road 6 at Tretten (H-series) The second road section that was investigated is situated in Øyer municipality in Norway. This pavement distinguishes itself from the previously mentioned pavement by demonstrating a high-performance asphalt pavement, characterized by an optimal quantity of air voids. Consequently, a longer lifespan is anticipated for this road section.

2.2 Samples

A total of 12 core samples (six from each section) were extracted from all the layers of the pavement structure. The samples were taken with a diameter of 200 mm and a height of around 300 mm. The samples were drilled in the laboratory to a height of approximately 40 mm, in order to closely examine the wearing course. Among the samples, six of them were kept with their original diameter of 200 mm, while the remaining ones were further drilled to three samples of 50 mm and three 100 mm diameter samples.

The bulk density of all 12 samples was measured using three different laboratory tests. Digital twins were generated for the 100 mm samples only, and then the maximum density was calculated as a mean value of these same samples. Given that these samples were extracted from the same core samples, it was decided to consider the maximum density of the 100 mm samples as representative for all samples. Wheel track testing was performed solely on the 200 mm samples.

2.3 Determining Air Void Content

Laboratory tests The air void content of the asphalt samples was calculated according to the laboratory procedures described in standard NS-EN 12697-8 [12]. The air void content is calculated from the maximum density and bulk density shown in the formula below:

$$V_m = \frac{\rho_m - \rho_d}{\rho_m} \cdot 100\% \tag{1}$$

where V_m is the amount of air voids (%), ρ_m is the maximum density (kg/m^3), and ρ_d is the bulk density (kg/m^3).

Maximum density The maximum density was determined using a pycnometer and water. Disparities are prone to arise between the density values obtained from the asphalt recipes and the core samples obtained from the road, due to variations in binder content and aggregate density during production. Moreover, the mathematical approach necessitates assumptions regarding binder absorption resulting in uncertainties [13]. Hence, relying on maximum density from the pycnometer ensures that

an accurate value of the actual density is acquired, preventing potential inaccuracies from the mathematical approach.

The bulk density was determined by three different methods: measurement of dimensions, hydrostatic surface-dry method, and sealing using CoreLok. It is worth noting that the first two methods are standardized methods by the NPRA, whereas CoreLok is a method that had been under testing by the NPRA.

Measurement of dimensions This method as its name implies involves the calculation of the volume of the asphalt sample based on measuring its dimensions using a caliper. This method is suitable for very porous samples with air voids over 10% or for samples abundant with connected pores. The bulk density calculated by measurement of dimensions is given by the equation below:

$$\rho_d = \frac{m_1}{\left(\frac{d}{2}\right)^2 \cdot \pi \cdot h} \cdot 10^3 \tag{2}$$

where m_1 is the mass of dry sample (g), d is the average diameter of the cylindrical sample (mm), and h is the average height of the cylindrical sample (mm).

Saturated surface-dry method The saturated surface-dry method relies on determining the volume of sample based on its buoyancy in water. The bulk density determined by the hydrostatic surface-dry method is calculated using the following equation:

$$\rho_d = \frac{m_1 \cdot \rho_w}{m_3 - m_2} \tag{3}$$

where ρ_w is the density of water at 25 °C (Mg/m^3), m_1 is the mass of dry sample (g), m_2 is the mass of sample immersed in water (g), and m_3 is the mass of wet sample (g).

CoreLok vacuum-sealing method CoreLok is a device designed to seal asphalt samples in specialized polymer bags [14]. To inquire more about this method, the reader is directed to this article [9].

To calculate the bulk density using CoreLok, the following formula is employed:

$$\rho_d = \frac{m_1}{\frac{(m_2 - m_3)}{\rho_w} - \frac{(m_2 - m_1)}{\rho_{sm}}} \tag{4}$$

where ρ_{sm} is the density of the plastic polymer bag at 25 °C (Mg/m^3), m_1 is the mass of unsealed sample in air (g)], m_2 is the mass of sealed sample in air (g)], and m_3 is the mass of sealed sample in water at $t = 1$ min (g).

Microcomputed tomography Microcomputed tomography (micro-CT) is a nondestructive imaging method that utilizes X-ray radiation to generate three-dimensional images of objects [15]. It makes it possible to visualize the internal microstructure of objects, making it particularly suitable for examining the internal structure of asphalt samples. The approach is based on distinguishing different components of the asphalt structure based on differences in X-ray absorption rates leading to density changes [16].

Equipment The scanning equipment employed in this study is a Nikon Metrology XT H 225 LC industrial scanner located at the Norwegian Geotechnical Institute (NGI) in Oslo. The scanner is capable of delivering a maximum voltage of 225 kV and electrical current of 1 mA [17].

Scanner setup and parameter selections The scanning settings were consistent for all samples, where each scan lasted for roughly 43 minutes per sample. The scans were conducted at a voltage of 225 kV and 240 μA. To filter out the X-ray radiation, a 2.5 mm copper filter was employed. A total radiation of 360° was selected with 2500 projections and an angular step about 0.14°. The exposure time was 1000 ms.

Limitations in sample dimensions The used equipment imposes restrictions on allowable dimensions for samples due to available space inside the scanner, weight restrictions of the object turntable, and image quality.

The maximum allowed object dimensions for the Nikon Metrology XT H 225 LC industrial scanner from [17] are presented in Table 1.

The choice of sample size and distance from the X-ray source must be carefully considered to achieve adequate 3D image resolution. Image resolution relies on voxel size, where a smaller voxel size corresponds to a higher image resolution [18]. Scanning the entire sample width in a single scan is desirable; thus, using small samples is preferable. Optimal placement of the test sample involves positioning it as close as possible to the X-ray source [17]. This results in a larger magnification of the sample on the detector, thereby achieving a better image resolution.

Scanned samples A total of six asphalt samples (1G, 2G, 3G, 1H, 2H, and 3H) were scanned in which three were from each road segment. The obtained samples possessed dimensions of 100 mm in diameter and an approximate height of

Table 1 Allowed sample dimensions for the Nikon Metrology XT H 225 LC scanner

Sample dimension	Requirement
Maximum diameter in a single scan[a]	Ca. 30 cm
Weight limit of object turntable	Up to 70 kg
Maximum height[b]	1 m

[a]Maximum diameter during a single scan to achieve an adequate image resolution is ca. 30 cm which corresponds to a resolution of 150 μm

[b]Objects with a maximum height of 1 m can be entirely scanned by merging multiple scans with a height of up to 135 cm or with 165 cm height if additional restrictions on width and resolution are applied

40 mm. An attempt to scan 200 mm and 50 mm samples was also done. Samples of 200 mm were found to be inappropriate for micro-CT due to volumetric constraints and high density. These constraints hindered the effectiveness of penetration of X-rays, which consequently resulted in poor image quality.

Image processing using MATLAB The image processing of the micro-CT data was done in a MATLAB code created by [19]. This code generates 3D digital representations of air void distribution in asphalt samples with the help of binarization from manual histogram-based thresholding. Additionally, the code is able to calculate mean values for air void percentage present in a sample while also presenting graphical representations of distribution of porosity throughout the height of the sample. The initial cross-sectional images obtained from the scanning process usually appear unclear, often due to the inclusion of the object turntable that needs to be excluded. The inclusion of all cross-sectional images in the image processing may hinder the code's ability to correctly differentiate between voids, aggregate, and binder during binarization, thereby leading to inaccurate results. Thus, the image selection begins with the first high-quality image and progresses to the final image.

Wheel track test Wheel tracking is a method used to evaluate the resistance against permanent deformations of an asphalt mixture and is performed under specific load, speed, and temperature to simulate field conditions [20, 21].

Wheel track testing was performed on six samples with a diameter of 200 mm (4G, 5G, 6G, 4H, 5H, and 6H) at a temperature of 50 °C according to procedure B in NS-EN12697-22 [22]. The equipment used in this study was WTEN2 produced by Cooper Research Technology, located in the NPRA's laboratory in Trondheim. The test computes the rut depth (RD), proportional rut depth (PRD), and wheel tracking slope (WTS). The maximum allowed PRD for the wearing course of a stone mastic asphalt with AADT between 5001 and 10,000 is 7% and 5% for AADT larger than 10,000 [23].

3 Results and Discussion

3.1 Wheel Track Results

The results of PRD for the 200 mm samples are shown in Table 2.

The H-series resulted in an average PRD value of 1.8%, while the G-series had a slightly higher PRD value of 3.7%. However, both road sections have a PRD within the 5% PRD limit value for stone mastic asphalt. Surprisingly, the G-series demonstrated favorable wheel track results, despite the high air void content observed in the experimental results. This is most likely due to the robust aggregates present in the SMA that contribute to the section's resistance to permanent deformations. Consequently, it can be interpreted that wheel track results alone, provide an incomplete

Table 2 PRD values for H-series

Sample	PRD (%)
H-series	
H4 200 mm	1.8
H5 200 mm	1.9
H6 200 mm	1.7
Average	**1.8**
G-series	
G4 200 mm	3.4
G5 200 mm	4.1
G6 200 mm	3.7
Average	**3.7**

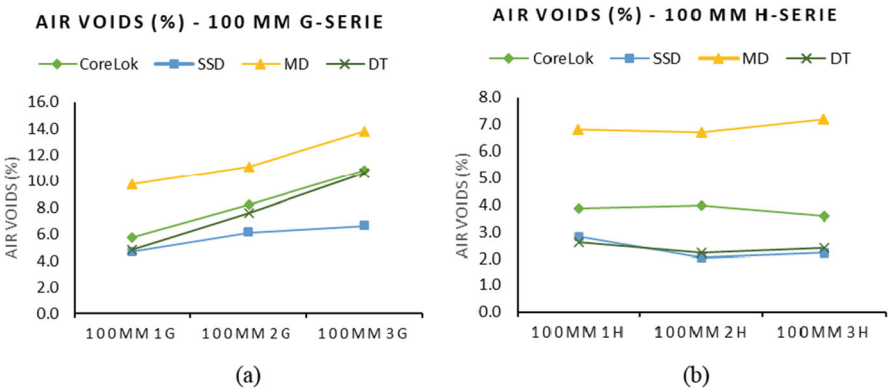

Fig. 1 Air void measurements of 100 mm diameter samples from (**a**) G-series and (**b**) H-series

evaluation of the quality of asphalt, particularly regarding durability. Therefore, wheel track results should be complemented by additional computations of air void percentages for a complete assessment.

3.2 Comparison of Air Void Content from Laboratory Tests and the Digital Twin

The following graphs represent a comparison between the air void content from the different measurements (Figs. 1 and 2).

A noticeable trend in the results from testing both different sample sizes and two road sections is evident, that is, measurements of dimensions are always giving the highest air void percentage, CoreLok is giving a middle value, and surface-dry method is giving the lowest percentages.

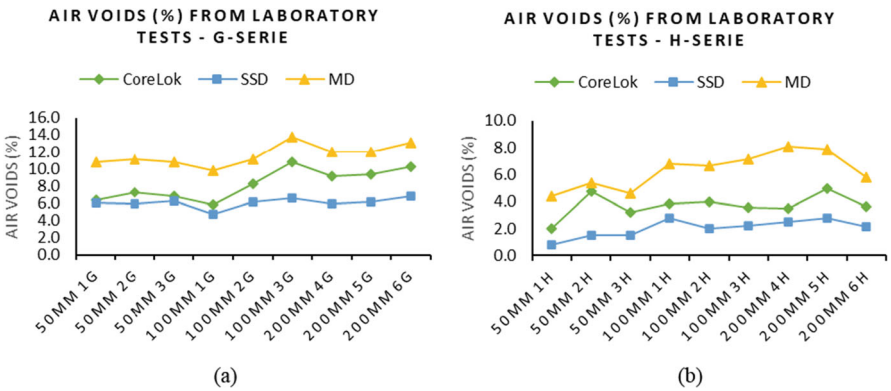

Fig. 2 Air void measurements from laboratory tests for all samples in (**a**) the G-series and (**b**) the H-series

Measurement of dimensions Both sections demonstrate high void content in the dimensional method. For the G-series, the air void content is above 10%; thus, according to the regulations stated in [24], this method is the one that should be applied for this section. Current practices by the NPRA are that asphalt pavements with over 10% air void content will lead to a 100% contractual deduction. Despite this, the G-series presents good resistance against permanent deformations from the wheel track testing. This can be assumed to be related to the high durability and structural stability properties of stone mastic asphalt [25]. It should be kept in mind that the coarse surface structure is included in this calculation method, thus leading to too high air void percentages. Therefore, it could be said that this method is too strict in this case. Hence, a decision regarding how much of the coarse surface structure that should be included in the computations should be made.

Saturated surface-dry method As stated in the methodology section, the saturated surface-dry method is applicable for samples with air voids up to 7%. For the G-series, the average void percentage from the samples is 6.1%; therefore, the saturated surface-dry method is applicable. However, water leakage from the sample on the scale was observed during experimentation. This means that the results from this method are inapplicable for the G-series. On the other hand, the H-series had an average void percentage of 2%, making this method applicable for it. This method accounts only for the isolated voids within the sample, since water flows through connected pores, whereas isolated voids contribute to buoyancy when immersed in water. Given that the H-series exhibits fewer isolated voids, a lower void percentage is shown in this method.

CoreLok Issues were encountered during the execution of CoreLok, specifically in the G-series. Problems such as water penetration into the polymer bag sealed samples or mistakes when calibrating the weight are assumed to be the reasons,

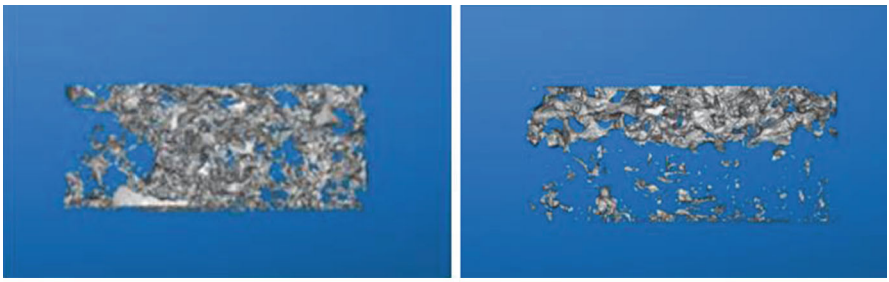

Fig. 3 3D views of 100 mm samples: (**a**) 1G and (**b**) 1H from MATLAB

and these are difficult to discover during execution. Nevertheless, these errors can be identified in the results. The experimentation for test sample 100 mm 3G was repeated several times, until the result was acceptable.

Digital twin Figures from the three-dimensional views of the void distribution from the digital twin for two samples from each road section are presented below. The first observation is the great difference between the void distribution of the two road sections. It is evident that the G-series has connected voids divided evenly throughout the height of the sample, indicating possible mistakes during compaction of the road. On the other hand, the voids in the H-series are mostly concentrated at the top constituting the rough surface layer, which is normal for SMA (Fig. 3).

Validation of digital twin results with laboratory tests Examining the results of the digital twin in the H-series, its results are aligned with the results from the saturated surface-dry method, which is the applicable method for this section. This indicates that the H-series is well compacted with few isolated air voids which is also proven by the digital twin.

In the case of the G-series, the results from the digital twin show a high degree of similarity with those from CoreLok. This could be explained by the exclusion of some of the rough surface layer of the SMA during vacuuming of the sample during the CoreLok procedure. This was also done during the creation of the digital twin, where some of the cross-sectional images were excluded to find the actual air void percentage of the samples. As discussed earlier, although measurement of dimensions is the applicable method for the G-series according to current regulations, it can be considered too strict which is proven by the digital twin.

4 Conclusion

In this chapter, an in-depth comparison of two road sections was examined for air void content and resistance against permanent deformations. The study also presents the digital twin technology obtained by microcomputer tomography as a new method for evaluating air void content in asphalt samples. The main conclusions from this study can be drawn as follows:

1. Based on the qualitative assessment, the digital twin demonstrated highly accurate air void measurements compared with those from conventional laboratory tests. However, more simulations might need to be performed with more samples to establish a statistical quantitative assessment.
2. The digital twin provided unique insights into the internal microstructure of asphalt samples, that is, new information that is unachievable/unavailable from conventional methods. This can be used to control the quality of the asphalt compaction process.
3. The digital twin proved to be a more flexible method in terms of accommodating a wider range of air void percentage in samples, eliminating constraints of traditional laboratory procedures.
4. Reduced physical demands, less repeatability, and less labor-intensive computations by utilizing the digital twin, rather than conventional methods.

5 Future Work

Digital twins from microcomputer tomography can still not fully replace laboratory tests due to sample size constraints of the employed equipment; however, its multiple benefits present promising potential for future applications. A suggestion for future work is to examine alternative scanning methods for creating digital twins to overcome the sample size constraints.

Acknowledgments The authors wish to thank the Norwegian Public Roads Administration for providing asphalt samples and access to their laboratory for conducting tests. Furthermore, we want to thank the Norwegian Geotechnical Institute for allowing us to use their micro-CT scanner.

1 Introduction

Ground-borne vibrations derived from several sources, such as machine foundations [1], road and rail traffic [2], and construction operations [3, 4], can cause harmful effects on the built environment. Therefore, it is necessary to adopt some isolation techniques to tackle the issue. Generally, the vibrations are screened out either at the origin or along the propagation path. Several researchers have recommended ground improvement techniques wherein sandbags, geocell-reinforced soil beds, and rubber

sheets were placed under the excitation source to provide a dampening effect [5–7]. These approaches are generally labour-intensive due to the significant material modification required to improve the dynamic properties of soil. Furthermore, these processes generate a substantial amount of carbon footprint [8]. Therefore, a simple, cost-effective, and environmentally friendly solution represented by wave barriers which can be constructed open or infilled has attained significant attention in recent decades.

Several field studies have assessed the isolation potential of single open and infilled trenches [9–12]. The former ones were observed as the best mitigation solution as they create a discontinuity in the medium that stops the wave propagation. Several studies have shown that a small discontinuity in the soil medium is effective since the surface motions require a solid body to advance [13, 14]. However, this solution may lead to some environmental challenges, e.g., the trenches may get filled up with water and may facilitate the growth of vermin and insects [10]. In addition, side empty walls may collapse if not properly designed. The opportunity to fill the empty trenches using different sustainable materials is currently being explored by several researchers [9, 10, 15].

Çelebi et al. [9] conducted field tests to explore the suitability of softer (bentonite) and stiffer (cement concrete) materials as infilling agents in a single empty trench. The results showed that the isolation performance of the bentonite was superior to that of the cement concrete in isolating the vibrations. Ulgen and Toygar [12] conducted field tests to evaluate the performance of open, water-filled and geofoam-filled trenches. The isolation potential pertaining to water was observed to be inferior to open and geofoam-filled solutions. Mahdavisefat et al. [10] conducted a series of field experiments to examine the performance of sand-rubber mixture (*SRM*) under a wide range of frequencies (10–600 Hz). The margin of isolation efficiencies (*IE*) between the single open and SRM-filled trenches was only 10%, with the former being superior. The researchers recommended a depth of $1.50L_R$ (L_R = Rayleigh wavelength) for the efficient mitigation of vibrations. Furthermore, the optimum rubber content was suggested to be 30%. Alzawi and El Naggar [13] conducted outdoor field tests to assess the performance of open and geofoam-infilled barriers and observed that the mitigation improved significantly for depths greater than $0.6L_R$. Naghizadehrokni et al. [14] conducted field experiments using thin foam and suggested a required depth of $1.0L_R$.

Current solutions to vibration mitigation using single trenches have recommended a depth ranging from $0.6L_R$ to $1.5L_R$. However, the suggested depth is found unfeasible in many practical scenarios due to poor subsoil conditions and stability issues. Jauhari et al. [15] conducted full-scale field tests to assess the isolation efficacy of dual open and geofoam-infilled trenches. The depth requested for the former ones was 55% less than the single open trench for an *IE* of 50%. Furthermore, the *IE* for dual open and geofoam-infilled trenches for a depth of $0.3L_R$ was noted as 76% and 71%, respectively.

It is apparent that the performance of dual trenches is significantly higher compared to that of single ones. However, there is a significant lack of thorough research dwelling on dual trenches and finding the most suitable sustainable infill material. Therefore, an attempt has been made in this study to appraise the

performance of a combination of softer and stiffer materials placed inside the trenches compared to the natural soil. Geofoam and aggregate were used as the soft and stiff materials, respectively. A harmonically-varying dynamic load was applied using a Lazan-type mechanical oscillator within a frequency range of 20–45 Hz. Furthermore, the infill materials were interchanged in the dual trenches to assess the most suitable location for each.

2 Material Properties

Full-scale field vibration tests were conducted on a dedicated site in the campus of the Indian Institute of Technology Patna (Bihta, India). The soil stratigraphy of Patna city is closely related to the meandering and migrating nature of two rivers, Sone and Ganges. Therefore, the study area lies in the Indo-Gangetic alluvial plain consisting mostly sand and silt particles. A soil sample was collected from a depth of 0.5 meters from the experimental site and was subjected to different laboratory tests to assess the physical properties. The bulk density (ρ_S) of the soil was calculated as 1.79 g/cc. The soil was classified as *SM* as per the Unified Soil Classification System. Multichannel Analyses of Surface Wave (*MASW*) tests were performed to investigate the dynamic properties [16]. The waves with an average shear wave velocity (V_s) of 157.84 m/s propagated near the surface and down to a depth of 3 m. The acoustic impedance ($Z_S = \rho_S \times V_S$) of soil was calculated as 2.83×10^5 kgm^{-2}s^{-1}.

The expanded polystyrene geofoam, supplied by Gupta polymers private limited, Patna, Bihar, India, was used as an infilling material. Its physical properties were calculated using ASTM standards. The density (ρ_g) was 0.015 g/cc as per ASTM C303 [17]. The primary (V_{pg}) and secondary (V_{sg}) wave velocities were 710 m/s and 476.6 m/s, respectively as per ASTM C597 [18]. The acoustic impedance ($Z_g = \rho_g \times V_{sg}$) was 7.15×10^3 kgm^{-2}s^{-1}.

Natural aggregates, procured from a quarry near Gaya, Bihar, India, were also used as an infill material. The particle size ranges between 31 and 50 mm as per IS 2386-1 [19]. The mean particle size (D_{50}) was 42 mm. The bulk specific gravity was 2.79 as per IS 2386-3 [20].

3 Test Procedure

The Lazan-type mechanical oscillator, rated to operate up to a speed of 3000 revolutions per minute, was used to generate the dynamic forces. The device was placed on a concrete block of dimensions $0.6 \times 0.6 \times 0.5$ m^3 and exerted frequencies ranging from 20 to 45 Hz. A unit (1 kN) vertical dynamic force was maintained throughout the study.

Initially, the amplitudes of vertical vibrations were noted for the condition "without trench" (*WT*). The recorded data was used to compare the results in the presence of the two mitigation systems. The two trenches, at distances of 1.5 m and

3 m from the source, were excavated to a depth of 1 m. The width of the trenches was 0.5 m. In the first trench, a material softer than in-situ soil, i.e., geofoam (G), was placed, whereas a stiffer material, i.e., aggregate (A), was allocated in the second trench. Therefore, the incoming waves were first subjected to interact with the soft material and then the stiffer one. This mitigation system has been abbreviated as $G + A$ in the following discussion. Subsequently, the materials in the trenches were interchanged, with the former being filled with the aggregate and the latter with the geofoam. In this case, the waves firstly encountered the stiff material and afterward the softer one ($A + G$). Figure 1 schematically shows the dimensions and location of the dual trenches and the point of interest.

In order to record the amplitude of vibrations, a piezoelectric constant current line drive accelerometer operating in the frequency range of 0.1–6000 Hz and a sensitivity of 1 mV/ms^{-2} was placed at a distance of 1 m from the edge of the second trench. The position was maintained at the same place for all the experiments. The vibration data were recorded for a duration of 15 seconds with a sampling rate of 65,536 Hz. The $A + G$ and $G + A$ setups are shown in Fig. 2.

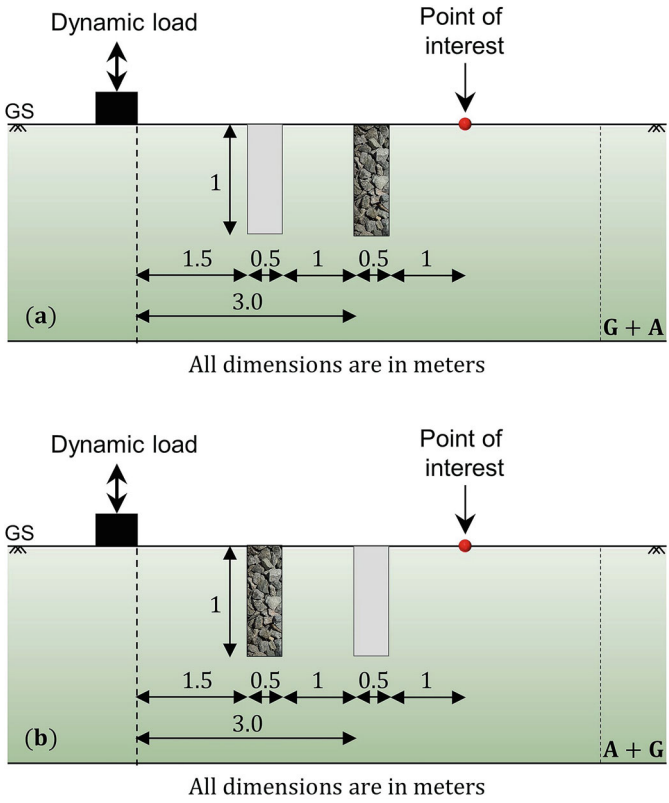

Fig. 1 Schematics of barrier systems: (**a**) geofoam and aggregate ($G + A$); (**b**) aggregate and geofoam ($A + G$). All dimensions are in meters

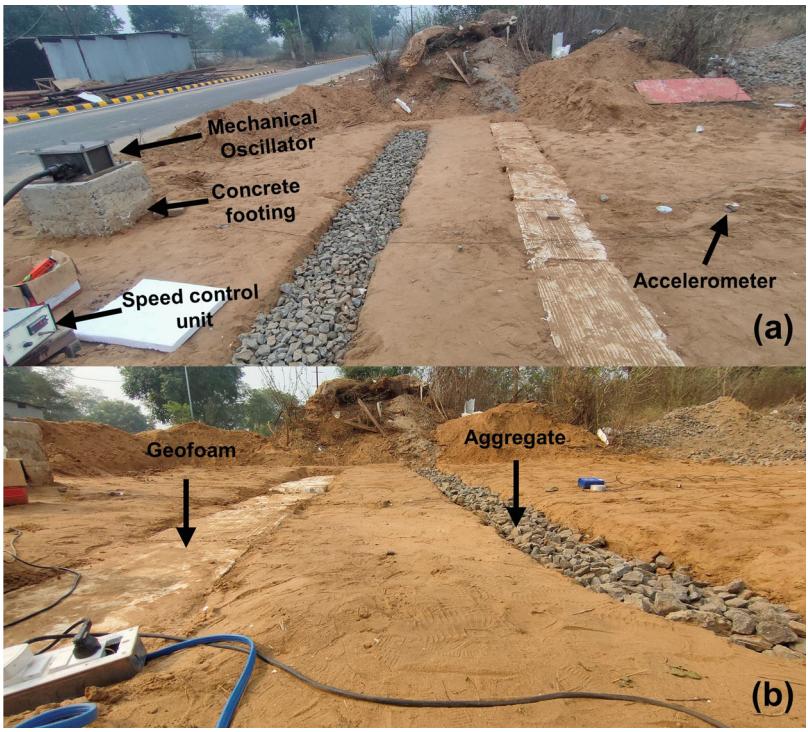

Fig. 2 Field photographs of the vibration mitigation systems: (**a**) $A + G$; (**b**) $G + A$

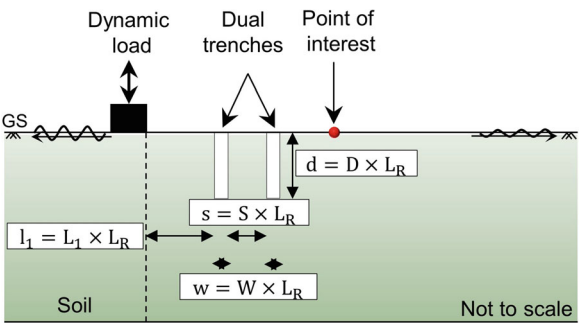

Fig. 3 Interrelations between actual and normalized parameters of the dual trench system

The geometric parameters, namely, location (l), width (w), depth (d), and spacing (s) associated with the mitigation systems, were normalized by means of the Rayleigh wavelength (L_R) to get the respective dimensionless parameters, namely normalized location (L), normalized width (W), normalized depth (D), and normalized spacing (S). Such a normalization process was implemented to remove the dependency of the results on the excitation frequencies. Figure 3 presents the correlations between the actual and dimensionless parameters of the dual trench systems.

4 Results and Discussion

4.1 Insertion Loss

Insertion loss (IL) can be defined as the reduction in the vibration levels due to the introduction of the mitigation systems. The IL in decibels can be calculated using the equation suggested by Hoorickx et al. [21] as

$$\text{IL (dB)} = 20 \log_{10}\left(\frac{A_{\text{without}}}{A_{\text{with}}}\right) \tag{1}$$

where A_{with} and A_{without} symbolize the peak acceleration amplitudes of the vibrations in the presence and absence of a barrier system, respectively.

Figure 4 shows the insertion loss variation with the excitation frequency at the point of interest for two mitigation systems. A higher insertion loss was observed for the vibrations generated due to higher excitation frequencies. An insertion loss of 12 dB and 16 dB was observed for the $G + A$ and $A + G$ setups for an excitation frequency of 45 Hz.

4.2 Time History and Fast Fourier Transform

Figure 5 depicts the variation of time history and frequency domain data at the point of interest. The plots were developed for an excitation frequency of 45 Hz. The time history plots, as depicted in Fig. 5a, show that the presence of mitigation systems weakens the vibration amplitudes significantly at the measuring point. The amplitudes of the vertical vibrations were noted as 1.00 m/s^2, 0.25 m/s^2, and 0.16 m/s^2 for *WT*, $G + A$, and $A + G$ mitigation systems, respectively.

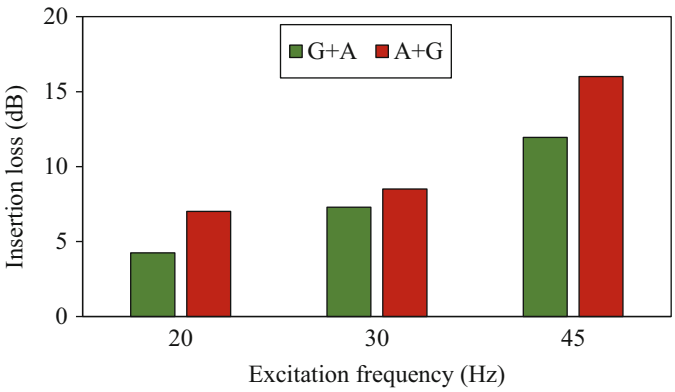

Fig. 4 Variation of insertion loss with the excitation frequency

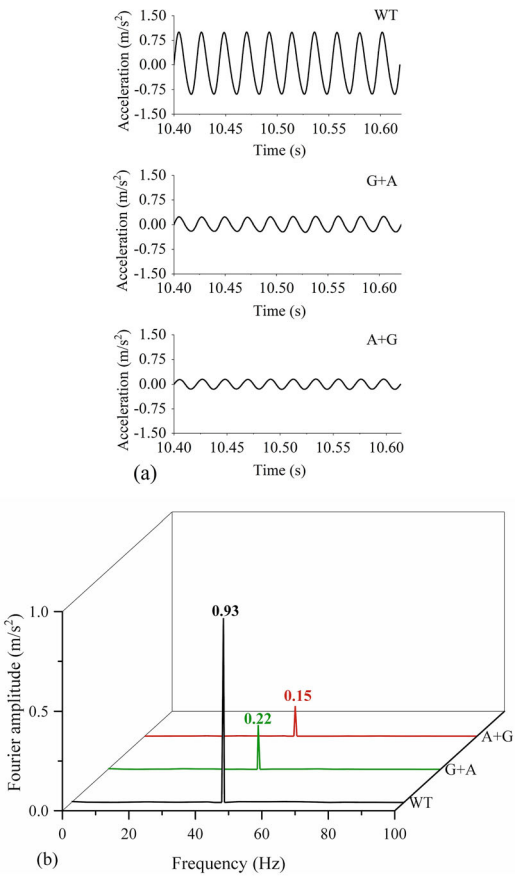

Fig. 5 Variation of acceleration: (**a**) time history; (**b**) fast Fourier transform

Furthermore, Fig. 5b shows the frequency domain plots representing the distribution of vibration energy over a range of frequencies. The result shows that the ground response matches the same frequency as that of the applied dynamic load. The peak Fourier amplitude was 0.93 m/s^2, 0.22 m/s^2, and 0.15 m/s^2 for WT, $G + A$, and $A + G$ mitigation systems, respectively.

4.3 Effect of the Normalized Depth of Trenches

The normalized depth of the trenches was varied between 0.14 and 0.31 during the tests. The influence of the increase in D on the isolation performance of the mitigation systems was observed in terms of the Amplitude Reduction Ratio (ARR), which was calculated at the point of interest. This parameter is the ratio

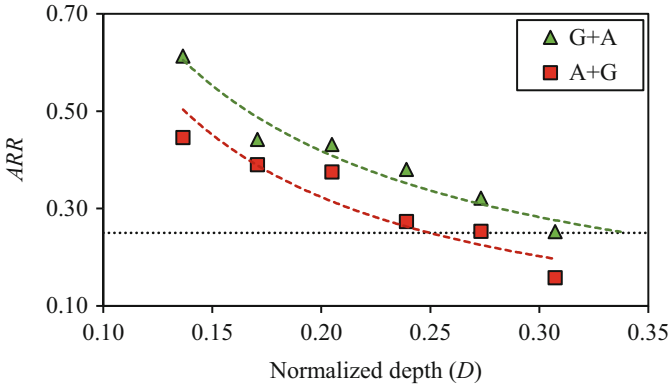

Fig. 6 Variation of *ARR* with normalized depth

between the amplitude of the ground vibrations in the presence of a mitigation system and the corresponding one in its absence as follows:

$$\text{ARR} = \frac{\text{Amplitude of ground motion with a mitigation system}}{\text{Amplitude of ground motion without a mitigation system}} \quad (2)$$

Its variation with the normalized depth for the two mitigation systems is shown in Fig. 6. It is possible to note a negative correlation between *ARR* and the normalized depth.

The performance of the dual trenches filled successively with aggregate and geofoam ($A + G$) was superior to that of system filled with geofoam and aggregate ($G + A$). Several researchers have suggested that a barrier system would be efficient if it attains an *ARR* value equal to or less than 0.25 [22, 23]. The required depth for the $A + G$ and $G + A$ setups to reach this limiting criterion was noted as $0.25L_R$ and $0.34L_R$, respectively.

In the case of the $A + G$ mitigation system, the incoming waves from the source initially confront the trench filled with aggregate, which exhibits a random arrangement of air pockets, thus weakening the advancement of the wave energy. Furthermore, a significant amount of vibration becomes absorbed, diffracted and scattered at the interfaces of particles. Thereafter, the transferred waves encounter the geofoam-filled trench, undermining the propagation toward the point of interest due to its low acoustic impedance value.

5 Conclusions

The current study discussed the use of wave barriers as mitigation systems in isolating ground vibrations generated due to machine foundations. Full-scale field experiments have been conducted to examine the isolation efficiency of dual barriers

infilled with geofoam and aggregate. These two filling materials were also interchanged to assess the most suitable location for each.

- The amplitudes of the vertical vibrations were 1.00 m/s^2, 0.25 m/s^2, and 0.16 m/s^2 for *WT*, $G + A$, and $A + G$ mitigation systems, respectively. The Fourier amplitude was reduced by 76% and 84% for the $G + A$ and $A + G$ setups compared to the free field condition.
- Maximum insertion losses of 12 dB and 16 dB were recorded at the point of interest under an operating frequency of 45 Hz for $G + A$ and $A + G$ setups, respectively.
- The optimal depth required to reach an *ARR* less than or equal to 0.25 was $0.25L_R$ and $0.34L_R$ for $A + G$ and $G + A$ mitigation systems, respectively.
- The results suggest that infilling the first trench with aggregate and the second one with geofoam achieves the best performance.

Eventually, it may be worth stressing that the findings are only valid for the soil condition and stratigraphy considered in this research, which aimed at mitigating continuous harmonic vibrations. Further experimental studies can be performed to assess the efficacy of dual trenches in the isolation of ground vibrations due to other types of loading, e.g., impact.

1 Objective and Literature Review

Artificial intelligence (AI) has garnered considerable interest in various scientific domains in recent years, spanning from managing large datasets to aiding in medical diagnostics. Its integration into everyday life is evident through personalized advertisements, virtual assistants, autonomous vehicles, and more. Unsurprisingly, AI techniques have permeated engineering disciplines, including civil and structural engineering [1, 2], showcasing remarkable achievements [3, 4].

Málaga-Chuquitaype [5] authored a thought-provoking review article on the application of machine learning (ML) in structural design. The article raises a compelling query regarding the future necessity of human engineers in the field of

structural design. Notably, the paper refrains from providing a direct answer to this question but rather operates on the assumption that the role of human engineers in traditional design practices is steadily diminishing. In another work, Nguyen and Vu [6] undertook a comparative analysis of ML algorithms aimed at predicting the behavior of truss structures. They conducted this comparison through the examination of two numerical examples, evaluating the performance of multiple ML algorithms using three error metrics. The outcomes of their investigation demonstrated that AdaBoost outperformed the other six algorithms that were considered in the study.

Mai et al. [7] introduced a deep unsupervised learning framework for optimizing truss structures under various constraints. They explored several illustrative examples to showcase the effectiveness of their proposed framework, highlighting its ability to deliver high-quality optimal solutions while significantly reducing computational costs compared to traditional methods. Kang and Yoon [8] focused on the configuration and training of a two-layer ANN tailored for truss design applications, highlighting its potential roles in structural design problem-solving. Mai et al. [9] introduced a straightforward and resilient unsupervised ANN framework designed for conducting geometrically nonlinear analyses of inelastic truss structures. The fundamental concept involved utilizing the ANN to directly predict nonlinear structural responses without resorting to time-consuming incremental-iterative algorithms typical in standard finite element (FE) methods.

Khodadadi et al. [10] developed an innovative enhanced ANN model tailored for optimizing the design of truss structures which featured two distinct characteristics. Firstly, an improved initialization mechanism was introduced, leveraging opposite-based learning. Secondly, the algorithm incorporated a small set of tunable parameters to enhance its ability for exploration and exploitation. The efficacy of the method was evaluated in engineering design scenarios.

The primary objective of this study is to assess and compare the performance of various regression models in the context of predicting critical structural parameters within a plane truss model. Specifically, we aim to examine the effectiveness of linear, polynomial (both second and third degrees), and artificial neural network (ANN) regression models in estimating the maximum displacement, maximum (tensile) stress, and minimum (compressive) stress exhibited by the truss structure. By subjecting these diverse regression techniques to a rigorous evaluation, we seek to identify which model excels in capturing the intricate and nonlinear relationships that govern the behavior of the truss under varying conditions. This research objective is crucial for providing valuable insights into the selection of the most suitable regression model for structural analysis and design, with potential applications spanning fields such as civil engineering, architecture, and materials science.

Furthermore, this study also endeavors to investigate the role of model complexity in enhancing predictive performance. By systematically transitioning from simpler linear models to more intricate polynomial and ANN models, we aim to discern how adding complexity to the regression models affects their accuracy and generalization capabilities. Understanding the interplay between model complexity and predictive accuracy is essential, as it can guide practitioners and researchers in selecting the most appropriate modeling approach for diverse structural scenarios.

The remainder of this paper is structured as follows: Section 2 provides an in-depth overview of the truss analysis problem being examined, Sect. 2.2 delves into the framework for data generation, accompanied by a discussion of its primary attributes. Section 3 outlines the various regression models that have been used and assessed, whereas Sect. 4 presents and deliberates upon the findings obtained. Lastly, Sect. 5 encapsulates the conclusions drawn from this study.

2 Truss Structure and Dataset

The truss considered is a standard 10-bar plane truss, depicted in Fig. 1. The model has six nodes and ten elements in total, numbered from 1 to 10, as shown in the figure. The members have a modulus of elasticity (E) equal to 10,000 ksi ($\approx$ 68.95 GPa), while the length L is equal to 360 in (9.144 m). Each of the applied nodal loads is equal to 100 kip ($\approx$ 444.82 kN). This truss structure has been extensively used as a benchmark problem in structural optimization, with the objective being to minimize the weight of the structure under constraints on stresses and displacements [11–13].

The dataset comprises 2000 data points, each featuring five input variables and three output variables, resulting in a tabular format with dimensions of 2000 rows and 8 columns. The outputs of the dataset are computed using an FE analysis code written in MATLAB. The whole dataset is stored as a text file with 253 kB file size. A portion of the data, specifically 15% (or 300 data points), is reserved for testing purposes and remains excluded from the training of any of the models. For comprehensive information about the input and output variables, please refer to the subsequent subsections.

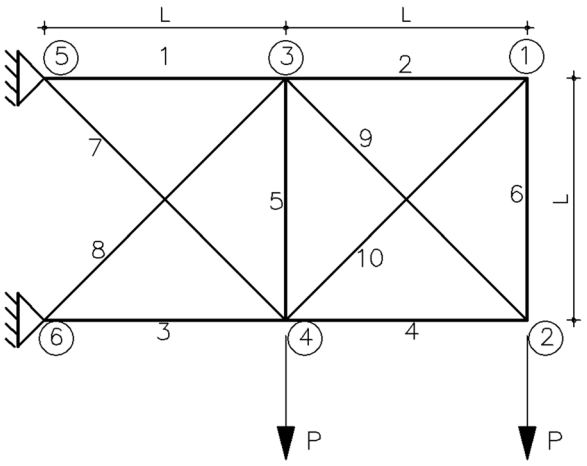

Fig. 1 The 10-bar truss structure considered

2.1 Input and Output Variables

There are five input variables related to the cross-sectional area of individual members. Given that there are a total of ten members, it becomes necessary to organize them into specific groups. Table 1 provides an overview of both the input variables and the grouping arrangement for these elements. For example, input variable I-4 is the section area of members 7 and 9 of the truss (diagonals in the NW-SE direction).

There are three output variables: (1) Maximum absolute vertical displacement (in the y direction), in inches (in), (2) Maximum stress (ksi) of all members (maximum tensile stress), (3) Minimum stress (ksi) of all members, in absolute terms (i.e., maximum compressive stress).

2.2 Generation of the Dataset

The five input variables correspond to section areas, each falling within the specified range of [0.1, 35]. These inputs are created as random values within this range using a uniform distribution and are then randomly combined with each other. Consequently, the first five columns of the dataset consist of random numbers selected from this specified range ($2000 \times 5 = 10{,}000$ random numbers in total for the first five columns). The output variables, on the other hand, are determined through FE analysis of the truss structure. This analysis is carried out 2000 times, resulting in the generation of 2000 distinct output values.

In Fig. 2, box plots depict the input and output variables, highlighting distinct characteristics. It is evident that the input variables exhibit a uniform distribution

Table 1 Input variables and grouping of the truss elements

Input variable	Elements	Range	Units
I-1 (A_1, A_2)	1, 2 (top, horizontal)	[0.1, 35]	in^2
I-2 (A_3, A_4)	3, 4 (bottom, horizontal)	[0.1, 35]	in^2
I-3 (A_5, A_6)	5, 6 (vertical)	[0.1, 35]	in^2
I-4 (A_7, A_9)	7, 9 (diagonal NW-SE)	[0.1, 35]	in^2
I-5 (A_8, A_{10})	8, 10 (diagonal SW-NE)	[0.1, 35]	in^2

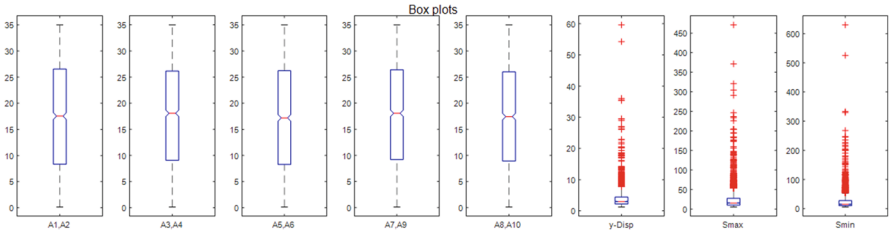

Fig. 2 Box plots of input and output variables

within the [0.1, 35] range. In contrast, the distribution of the output variables shows considerable non-uniformity, marked by the presence of numerous outliers.

3 Regression Models

3.1 Linear (First Order) and Polynomial Regression (Second and Third Order)

Linear regression [14] (LR) is a fundamental statistical method used to model the relationship between a dependent variable and one or more independent variables. This method assumes that the relationship between the variables is linear, i.e., can be represented by a straight line. In its simplest form, known as simple linear regression, the model predicts the dependent variable based on a single independent variable (one input). It calculates the best-fitting line through the data points, where "best-fitting" is defined as minimizing the sum of the squares of the differences between the observed and predicted values. This line is represented by the equation "$y = mx + c$," where y is the dependent variable, x is the independent variable, m is the slope of the line, and c is the y-intercept. Linear regression is widely used in various fields for predictive analysis and inferential statistics, owing to its simplicity and interpretability. In our specific analysis, we deal with a more intricate scenario involving five input variables and three output variables. Consequently, the number of independent variables amounts to five.

Polynomial regression [14] is a versatile statistical method employed to capture nonlinear relationships between a dependent variable and one or more independent variables. Unlike linear regression, which assumes a linear relationship, polynomial regression allows for the modeling of more intricate patterns by introducing polynomial terms of the independent variables into the equation.

In our analysis, we employ two distinct polynomial regression models to better capture complex relationships within our dataset. The first model is a second-degree polynomial regression model, which introduces second-degree terms and interactions between the independent variables. For instance, in a second-degree model featuring two independent variables, x and y, the terms incorporated would include the constant, x, x^2, y, xy, and y^2. This model extends beyond the simplicity of the linear (first degree) model, allowing us to account for nonlinearities and more intricate patterns.

Moreover, we also utilize a third-degree polynomial regression model, which incorporates third-degree terms and further enriches the model by including additional interactions between the independent variables. This third-degree model surpasses the complexity of the second-degree model, enabling us to comprehensively explore and represent the nonlinear relationships and higher-order interactions among our five independent variables, thereby enhancing our understanding of the underlying data dynamics.

To accommodate the three outputs, we run the linear and polynomial regression models three times each, generating three distinct sub-models for each model, each tailored to predict one of the three output variables. This is not the case with the Artificial Neural Network model, which can handle all output variables simultaneously.

3.2 Artificial Neural Network

Artificial Neural Network (ANN) regression is a robust ML technique used to model complex relationships between input variables and predict output values, which has several applications in structural engineering problems [15–19]. In our study, we implement a back-propagation ANN regression model with specific architectural characteristics to suit our research needs. Our ANN model consists of two hidden layers, each containing 25 neurons, making it a deep neural network capable of capturing intricate patterns and nonlinear dependencies within the data. The input layer comprises five neurons, corresponding to our five independent variables, while the output layer consists of three neurons, aligning with the three output variables we aim to predict.

For the training process, we employ the Levenberg–Marquardt training algorithm [20], a widely used optimization method for fine-tuning neural network weights and biases. To ensure the model's robustness and generalization capability, we divide our dataset into three distinct subsets: 15% of the data is used for testing, the same as with the previous models, 70% of the data is allocated for training itself, while another 15% is used (during training) for validation purposes. The validation procedure monitors the performance of the network on the validation data during training to prevent overfitting. This comprehensive approach ensures that our ANN regression model not only learns from the available data but also generalizes well to make accurate predictions on new and unseen data points, ultimately enhancing the reliability of the research findings. It has to be noted that the testing set is exactly the same for all regression models. In all cases, the testing is done after the model has been fully developed and the testing data remains unseen to the model until then.

3.3 Performance Metrics

To assess the performance of each model, we utilize three separate metrics: (i) the Root Mean Squared Error (RMSE), (ii) the Pearson correlation coefficient (R), and (iii) the Mean Normalized Gross Error (MNGE). The formulas for these three metrics are outlined in Eqs. (2)–(4):

$$\overline{p} = \frac{1}{N}\sum_{i=1}^{N} p_i, \quad \overline{r} = \frac{1}{N}\sum_{i=1}^{N} r_i \tag{1}$$

$$\mathrm{RMSE} = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(p_i - r_i)^2} \tag{2}$$

$$R = \frac{\sum_{i=1}^{N}(p_i - \overline{p})(r_i - \overline{r})}{\sqrt{\sum_{i=1}^{N}(p_i - \overline{p})^2} \cdot \sqrt{\sum_{i=1}^{N}(r_i - \overline{r})^2}} \tag{3}$$

$$\mathrm{MNGE} = \frac{1}{N}\sum_{i=1}^{N}\frac{|p_i - r_i|}{r_i} \tag{4}$$

In these equations, N represents the total count of data points in the entire dataset, or within a specific subset such as the training or testing subset, depending on the subset chosen for evaluating the regression model. In addition, r_i represents the real (target) value, p_i denotes the predicted value, and $\overline{r}$, $\overline{p}$ denote the mean values of the real and predicted values, respectively. RMSE is expressed in the units of the corresponding output, while R and MNGE are unitless quantities. More detailed information about these metrics is available in reference [21].

Additionally, we employ the Taylor diagram, which integrates three statistical parameters—namely, (i) the Centered Root Mean Square Difference (CRMSD), (ii) R, and (iii) the Standard Deviation σ—into a single, easily interpretable diagram. The Taylor diagram proves valuable for summarizing and comparing the relative strengths of various models, as discussed in Ref. [21]. The formula for the calculation of CRMSD is given in Eq. (5).

$$\mathrm{CRMSD} = \sqrt{\frac{1}{N}\sum_{i=1}^{N}[(p_i - \overline{p}) - (r_i - \overline{r})]^2} \tag{5}$$

4 Numerical Results

Figure 3 displays plots depicting the predicted values contrasted with the actual (target) values for each model and output variable. Additionally, the graph features a reference line, $y = x$, representing an ideal match, accompanied by two error boundary lines signifying a 10% prediction error tolerance.

Table 2 presents the error metrics values for each model and each output. The target values, denoting a perfect match, are also shown in the table. Figure 4

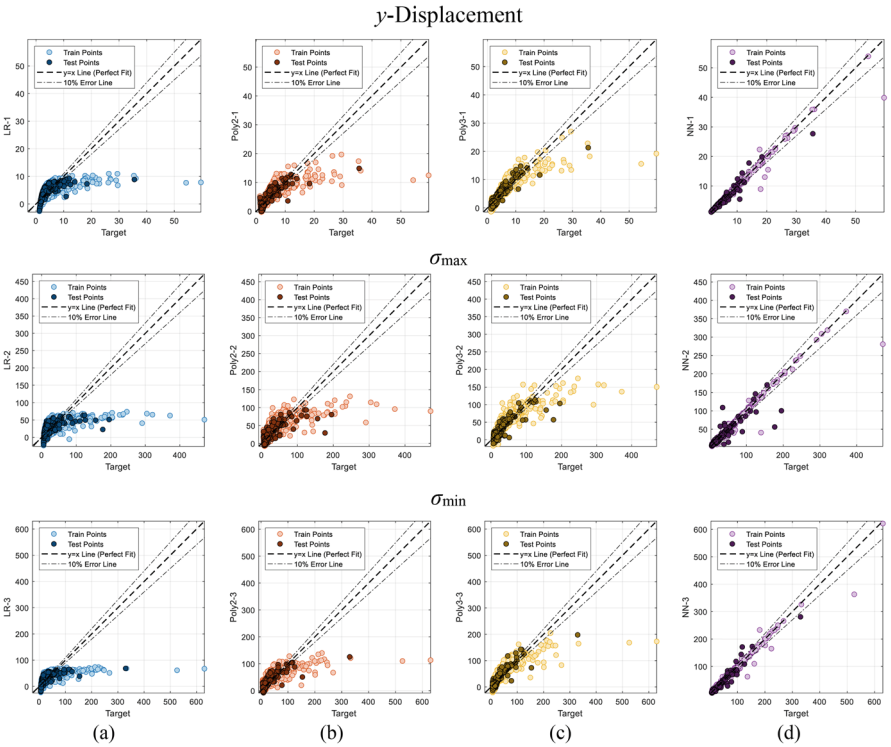

Fig. 3 Predicted vs. actual (target) values for all four models, for all three outputs: (**a**) LR Model, (**b**) Poly2 Model, (**c**) Poly3 Model, (**d**) NN Model

Table 2 Error metrics values

		All data (train and test)			Test data		
	Model	RMSE	R	MNGE	RMSE	R	MNGE
Output variable	Target	0	1	0	0	1	0
1 (y-displacement)	LR	2.96	0.603	0.403	2.32	0.638	0.408
	Poly2	2.41	0.760	0.307	1.81	0.798	0.311
	Poly3	1.96	0.849	0.263	1.39	0.888	0.264
	NN	0.62	0.987	0.030	0.71	0.971	0.043
2 (σ_{max})	LR	25.54	0.571	0.701	20.19	0.570	0.677
	Poly2	21.08	0.735	0.551	16.46	0.740	0.538
	Poly3	17.03	0.837	0.459	13.86	0.826	0.470
	NN	6.80	0.976	0.072	11.39	0.884	0.106
3 (σ_{min})	LR	28.27	0.559	0.737	22.25	0.625	0.693
	Poly2	23.58	0.722	0.572	17.97	0.782	0.580

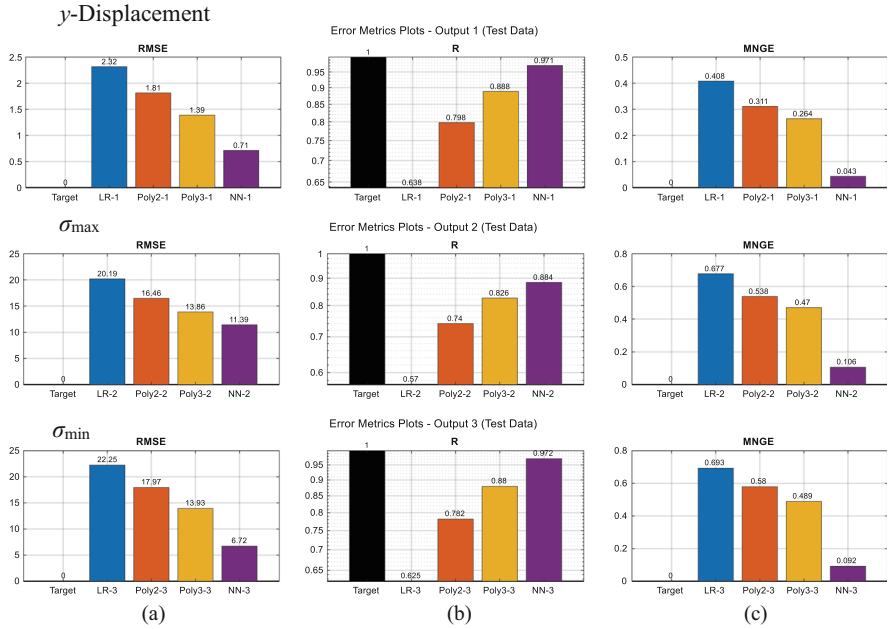

Fig. 4 Error metrics for all models and all outputs (Test data only): (**a**) RMSE, (**b**) *R*, (**c**) MNGE

illustrates the error metrics for all four models across each output variable, exclusively for the test dataset. To facilitate comparison, we have included an initial column that serves as a reference point denoting the "target" value for each metric. In other words, it represents the value associated with a perfect fit, which is zero for RMSE and MNGE and 1 for *R*. Importantly, these diagrams exclusively pertain to test predictions, omitting the training data employed by the models. This deliberate exclusion ensures a fair assessment of the models' generalization capabilities, highlighting their performance on unseen data points. While it is evident that all models perform optimally on the training set, our focus here centers on the test set, where models typically exhibit comparatively lower performance.

Notably, the ANN model outperforms the other models across all considered metrics. Additionally, the introduction of complexity to simpler models proves beneficial, with the second-degree polynomial model demonstrating superior performance compared to the linear model, and the third-degree polynomial model surpassing the second-degree model in terms of predictive accuracy.

The MNGE metric provides valuable insights into the model's real-world performance. Specifically, when analyzing the ANN model's MNGE value of 0.043 for the first output, it signifies an average prediction error of 4.3% across all test data set predictions for the maximum *y*-displacement of the nodes.

Digging deeper into the output data, we find that the median error is even lower than the MNGE, at 2.9%. It is important to note that in this context, MNGE for a single observation represents the bias error (the difference between the predicted

value and the real value) over the real value, in absolute terms. In stark contrast, the MNGE values for the other models consistently exceed 25%, rendering them impractical for real-world applications.

4.1 Taylor Diagrams

In Fig. 5, we display three Taylor diagrams, each corresponding to an individual output variable, and exclusively based on the data of the test set. Within these diagrams, every model is symbolized as a distinct point, with the reference target point positioned at the diagram's bottom. In a Taylor's diagram, the proximity of a model point to this target point serves as an indicator of the model's predictive accuracy—closer points signify better predictions. As before, it remains evident that the ANN model consistently outperforms the other models. Furthermore, the trends

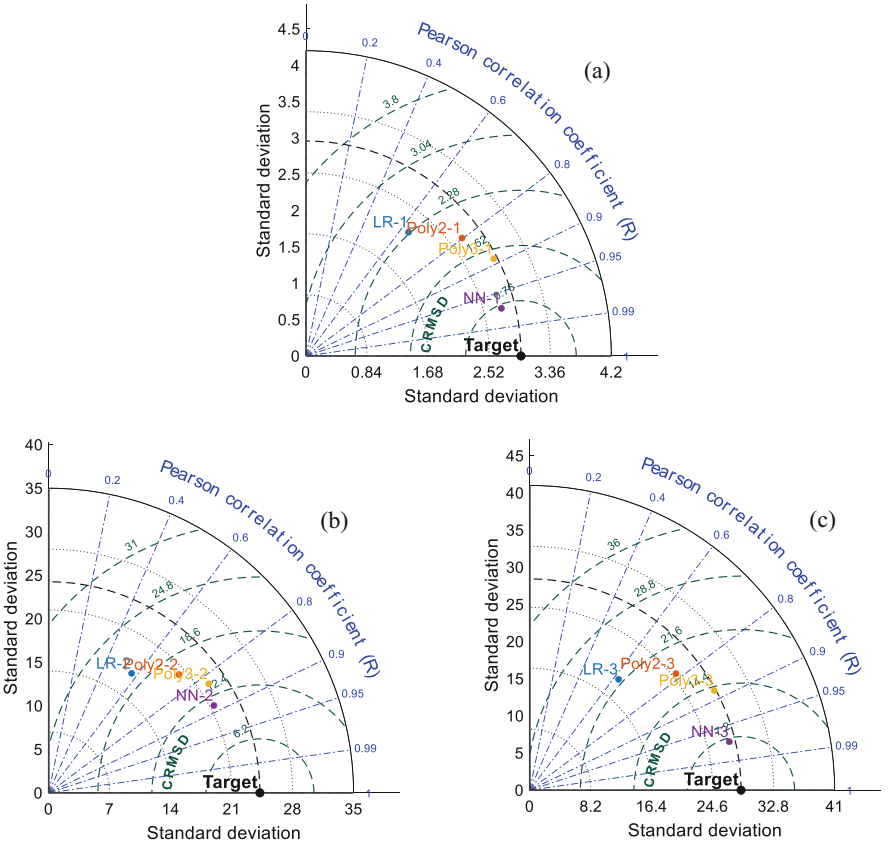

Fig. 5 Taylor diagrams for all models, for all three outputs (test data only): (**a**) output 1 (y-displacement), (**b**) output 2 ($\sigma_{\max}$), (**c**) output 3 ($\sigma_{\min}$)

observed in the previous paragraph, regarding error metrics, are reaffirmed here, underscoring the ANN model's superior performance across these visual representations as well.

5 Conclusions

Our study has undertaken a comprehensive evaluation of various regression models, encompassing linear, second- and third-degree polynomial, and ANN models, to predict crucial parameters within a plane truss model. Our findings unequivocally establish the supremacy of the ANN model, demonstrating its exceptional aptitude for capturing intricate nonlinear relationships within the dataset. Notably, our exploration has shed light on the pivotal role of model complexity. The augmentation of complexity, observed in the transition from linear to polynomial models, has yielded tangible improvements in predictive performance. The superior performance exhibited by the ANN model holds promise for a wide array of practical engineering applications.

While our study represents a significant stride in comprehending the performance of regression models, promising avenues for further investigation persist. Future research might delve deeper into hyperparameter tuning, refined feature selection techniques, and the exploration of model architectures, with the aim of further optimizing the ANN model's capacity. Moreover, the realm of regression modeling extends far beyond the models assessed in this study. The incorporation of additional models, such as Support Vector Machine (SVM), K-nearest neighbors (KNN), and Decision Tree, among others, could offer additional insights into predictive accuracy.

The ANN's predictions of structural behavior serve a dual purpose. They serve as valuable surrogate modeling tools, reducing the computational demands for the analysis of intricate structural models with minimal compromise in accuracy, but also open doors to various practical applications. For instance, they can be integrated into the context of structural optimization, furnishing predictions of structural responses and obviating the need for FE analysis in every optimization iteration. This capability can prove highly beneficial, particularly in the initial phases of optimization.

However, it is imperative to approach such predictions with discernment. While the overall performance of advanced regression models remains commendable, certain cases may yield predictions significantly divergent from actual output values. This is substantiated by the presence of outliers observed in the "Predictions vs. Targets" plots, even in the case of the best-performing model. Hence, while regression models offer remarkable predictive capabilities, their outputs should be interpreted cautiously, with consideration for potential outliers and/or anomalies.

1 Introduction

Many current and future challenges are related to the efficient management of limited financial and natural resources or the appropriate mitigation of consequences due to climate change. Engineering structures play a fundamental role in this regard since they consume large amounts of raw materials and contribute significantly to greenhouse gas emissions worldwide, e.g., [1–4]. As the challenges will become bigger, the demand for innovative and sustainable solutions well beyond traditional structural engineering practice will increase.

Structural design codes, which regulate the safety of our built environment and the corresponding use of structural materials, are crucial in this context. They feature safety concepts that are highly generalized to make them simple and applicable to a large variety of structures at the same time. This leads to structures that are

sufficiently safe and functional, but where structural material is not utilized in an optimal manner. For a sustainable built environment, this is not good enough. We need to unlock the potential offered by risk-based decision approaches in order to utilize our resources in structural design procedures as efficient as possible. Intensively discussed in the scientific literature over the past decades, e.g., [5–8], and by now supported by standardized guidance [9], these approaches facilitate optimized solutions such that a balance is achieved between a specific structural safety level and the corresponding resources invested.

In the past, the objective of such optimization procedures was mainly of economic nature, i.e., with focus on minimizing costs. While this approach may contribute likewise to mitigation of material consumption and greenhouse gas emissions, it was recently suggested to explore the potential benefits of addressing such environmental objectives explicitly, since the corresponding optimum might significantly deviate from the solution based on an economic decision framework [10, 11].

On the grounds of an emission-based objective function (Sect. 2), the paper assesses the material and greenhouse gas emission-saving potential of a risk-informed design of floor structures with reinforced concrete members. The environmental benefits compared to the application of the standardized design rules (Partial Factor Method) as defined in the Eurocodes [12] are demonstrated and discussed (Sect. 3).

2 Optimization Framework

2.1 Objective Function

Taking the widely accepted economic optimization framework proposed by Rackwitz [5] as a basis, an objective function for a risk-informed design based on carbon emissions (CE) is being defined, see Eq. (1). In this formulation, the benefits have been considered independent of the decision parameter p (e.g., a cross-section dimension), wherefore the optimization problem simplifies to the determination of $p = p_{\text{opt}}$ which minimizes the expected total emissions CE_{tot} associated with a specific decision, as illustrated in Fig. 1. The total emissions CE_{tot} are constituted by the sum of the emissions related to investments into safety (CE_{s}) and those expected in consequence of a failure event (CE_{f}). The former are defined as the sum of the emissions associated with the production stage, CE_{c} (cradle-to-gate emissions), in the following referred to as *construction-related emissions*, and the expected emissions due to structural obsolescence, CE_{o}.

$$p_{\text{opt}} = \arg \min_{p} \left(\text{CE}_{\text{c}} + \text{CE}_{\text{o}} + \text{CE}_{\text{f}}\right) \tag{1}$$

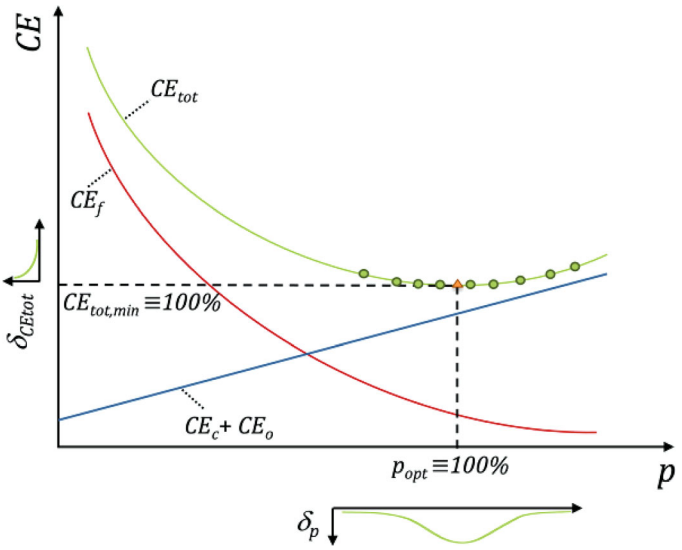

Fig. 1 Illustration of the CE-based optimization principle and deviations $\delta_{CE,tot}$ and δ_p from the minimum total emissions ($CE_{tot,min}$) and optimal decision parameter (p_{opt}), respectively

In Eq. (2), the construction-related emissions CE_c are defined as the sum of term $CE_1 p$, which is proportional to the decision parameter p, and a p-independent constant CE_0. The expected emissions due to failure (CE_f) and obsolescence (CE_o) defined by, respectively, Eqs. (3) and (4), are estimated based on the assumption that structures are continuously renewed either after failure or after becoming obsolete respectively. A discussion and justification of this assumption can be found in [5]. Emissions in consequence of reconstruction are multiplied by the yearly obsolescence-rate ω resulting in the expected yearly obsolescence emissions (CE_o). The expected yearly failure emissions (CE_f) are defined as the sum of reconstruction-related emissions CE_c and indirect failure emissions H, independent of p, multiplied by the yearly failure rate $\lambda P_f(p)$. Like costs, future emissions are to be discounted, see, e.g., [13]. The net present value of the sum of annual expectations with the annual interest rate i is computed by utilizing the asymptotic solution expressed by Eq. (5).

$$\mathrm{CE_c} = \mathrm{CE_0} + \mathrm{CE_1} p \tag{2}$$

$$\mathrm{CE_o} = \mathrm{CE_c} \frac{\omega}{i} \tag{3}$$

$$\mathrm{CE_f} = (\mathrm{CE_c} + H) \frac{\lambda P_f(p)}{i} \tag{4}$$

$$\sum_{\tau=1}^{\infty} \frac{1}{(1+i)^{\tau}} = \frac{1}{i} \tag{5}$$

2.2 Life Safety Constraints

While the objective function given by Eq. (1) pursues an optimum design from an environmental perspective (in this case related to embodied greenhouse gas emissions), it does not guarantee that this optimum (p_{opt}) is consistent with the societal preferences in regard to life safety investments. As illustrated in Fig. 2, this can be considered by imposing a corresponding acceptance criterion to the failure probability, $P_{\text{f,opt}} < P_{\text{f,acc}}$, e.g., based on the marginal life-saving costs principle, see [7, 9] for further guidance.

2.3 Saving Potential

The resource- and emission-saving potential of the described optimization framework in relation to the sub-optimal decisions based on the standardized design rules defined in structural codes and standards, such as the Eurocodes, is illustrated in Fig. 1. Generally, these sub-optimal decisions, represented by the dots, entail a certain deviation, in terms of the expected total emissions CE_{tot} from their respective optimum, $\delta_{\text{CE,tot}}$. Further, it is of interest, how the sub-optimal solutions deviate from the optimum in terms of the decision parameter p, which is representative of the material consumption and of the associated embodied greenhouse gas emissions at the structural design stage, i.e., when the decision is made. In contrast to $\delta_{\text{CE,tot}}$, the deviation δ_{p} can theoretically occur on both sides of the optimum p_{opt}, see Fig. 1.

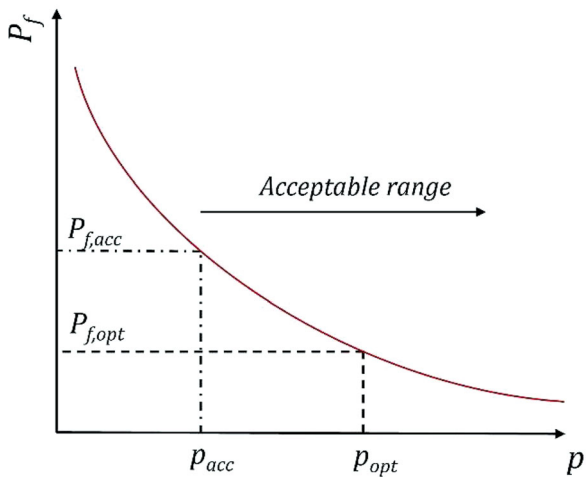

Fig. 2 Illustration of life-safety acceptance (acc) criteria as constraint to the optimization (opt)

3 Case Study

3.1 Structural System and Loads

The case study assumes two different types of floor systems in office buildings (Fig. 3): (A) RC floor beams which provide support to one-way RC slabs spanning in the direction perpendicular to the beam orientation and (B) a floor system supported by T-beams. In both systems, the beams of span L are simply supported and spaced at a distance D.

Permanent loads g acting on the beams include the structural self-weight (g_{sw}) of both the beams, $g_{sw,b}$ (limited to the web in case of the T-beam system) and the slabs, $g_{sw,sl}$, as well as the weight of non-structural permanent loads, g_{nspl}, including the flooring and roofing system attached to the slabs. In addition, the beams sustain a uniformly distributed imposed load q (Fig. 4).

3.2 Limit State Function

Bending failure at mid-span of the beams is considered. The limit state function (LSF) represents the state of equilibrium between acting and resisting bending moments at mid-span of the beams, respectively M_E and M_R. These are specified in Eqs. (6) and (7), where Θ_E and Θ_R denote the corresponding model uncertainties. Variable Θ_q in Eq. (6) represents the uncertainties associated with the imposed load

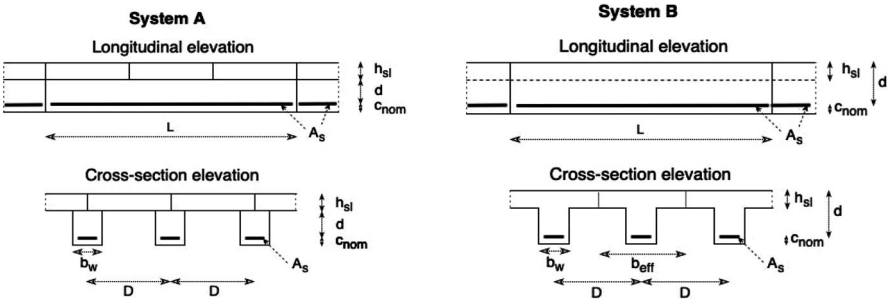

Fig. 3 Sketch of the floor systems: (**a**) RC beams supporting one-way RC slabs; (**b**) RC T-beam slab

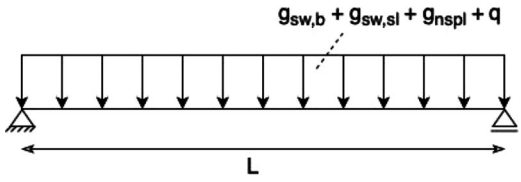

Fig. 4 Structural system and loads

model. The bending resistance M_R is specified in a generic way such that it represents both systems analyzed, A and B (Fig. 3). In the latter, the beam flange contributes to resistance of the concrete compression stresses over an effective width $b = b_{eff}$ according to EN1992-1-1 [14], in the former $b = b_w$, see Eq. (8). The reinforcement ratio ρ_s is defined accordingly in Eq. (9). Variables f_y and f_c represent the yield strength of the reinforcing steel and the compressive strength of concrete, respectively.

$$M_E = \Theta_E \frac{\left(g_{sw} + g_{nspl} + \Theta_q q\right) DL^2}{8} \tag{6}$$

$$M_R = \Theta_R b \rho_s d^2 f_y \left(1 - 0.5 \rho_s \frac{f_y}{f_c}\right) \tag{7}$$

$$b = \begin{cases} b_w & \text{(A)} \\ b_{eff} & \text{(B)} \end{cases} \tag{8}$$

$$\rho_s = \begin{cases} \rho_{s,w} = \dfrac{A_s}{b_w d} & \text{(A)} \\ \rho_{s,eff} = \dfrac{A_s}{b_{eff} d} & \text{(B)} \end{cases} \tag{9}$$

3.3 Characteristic Values

With the aim to define a representative set of design situations, the parameters most relevant to the design of the concrete floor beams are varied within reasonable ranges.

Three spans L are distinguished (6, 12, and 18 m) in addition to four different spacings D between members ($L/1$, $L/2$, $L/3$, $L/4$) (Fig. 3). The beams effective cross-section depth d is kept constant equal to $L/15$. A nominal concrete cover to the tensile reinforcement of 30 mm is adopted. Reinforcing steel grade B500 ($f_{yk} = 500$ N/mm^2) is assumed in combination with concrete of type C20/25 ($f_{ck} = 20$ N/mm^2).

In line with EN1991-1-1 [15], a characteristic value of the imposed load of $q_k = 3$ kN/m^2 is adopted. A wide range of ratios a_q of variable (q_k) to total (g_k + q_k) characteristic loads between 0.05 and 0.95 is considered, with an interval size $\Delta a_q = 0.05$. In addition, three ratios a_g of structural self-weight $g_{sw,k}$ to total permanent loads ($g_{sw,k}$ + $g_{nspl,k}$) ranging between 0.6 and 1.0 are adopted ($\Delta a_g = 0.2$). Based on these assumptions, $g_{sw,k}$ and $g_{nspl,k}$ are computed.

An array for beam tensile reinforcement ratios $\rho_{s,w}$ varying from $\rho_{s,w} = 0.002$ to 0.03 ($\Delta a_q = 0.004$) is defined, within the limits of the prescribed $\rho_{s,w,min}$ and $\rho_{s,w,max}$ thresholds according to EN 1992-1-1 [14]. Note that for system B, this results in a corresponding $\rho_{s,eff}$ array ($\rho_{s,eff} = \rho_{s,w}\, b_w/b_{eff}$).

3.4 Eurocode Design

Given the characteristic values described under Sect. 3.3, a strict Eurocode design ($M_{Ed} = M_{Rd}$) of the beam's mid-span cross-section is performed based on the Partial Factor Method (PFM) according to EN1990 [12], with partial factors for f_c and f_y taken from EN1992-1-1 [14]. This results in the strictly required cross-section width b, see Eq. (8)—note that in case of system B, the design procedure is iterative. The geometry of the beam is thereby established, allowing for a distinction of the structural self-weight of beam and slab, respectively. The depth of the latter, h_{sl}, can then be inferred under the assumption of typical densities for RC members ($\rho_{sl} = 2500$ kg/m^3).

To confine the scope of the study to practically relevant design situations, maximum and minimum slab depth to span ratios (h_{sl}/D) are imposed, as specified in Table 1. In addition, a minimum slab depth h_{sl} of 100 mm is required. Furthermore, boundaries for the ratio of effective beam cross-section depth (d) to width (b_w) are specified (Table 1). Finally, it is ensured that only ductile cross-sections complying with a $x/d < 0.45$ are considered, where x is the neutral axis depth of the mid-span cross-section.

For system A, the latter of the described boundary conditions is the most stringent and only 24 relevant design situations are identified. For system B, where the contribution of the flange to the compression forces in the concrete leads generally to relatively small neutral axis depths x (generally $x < h_{fl}$), a total of 145 design situations comply with the imposed boundary conditions.

3.5 Risk-Informed Design

3.5.1 Decision Parameter

In the risk-based optimization of the RC beams, the dimensions of the, respectively, 24 (system A) and 145 (system B), concrete cross-sections obtained in the Eurocode design (Sect. 3.4) are adopted. The decision parameter (p) corresponds to the optimal amount of tensile reinforcement (A_s) according to the framework established by Eqs. (1)–(5). The corresponding assumptions are described below.

Table 1 Boundary conditions for selection of design situations included in the study

Variable	Min	Max
h_{sl}/D	20	30
h_{sl} [mm]	100	–
d/b_w	1	5

3.5.2 Construction-Related Emissions

Construction-related carbon emissions CE_c according to Eq. (2) are specified by Eq. (10) as the sum of the contribution of concrete (c) and reinforcing steel (s), respectively. These respective contributions are computed as the product of the material mass M ($= V\rho$, where $\rho_c = 2400$ kg/m^3 and $\rho_s = 7850$ kg/m^3) and the corresponding carbon emission intensities (CEI_c and CEI_s). Since the optimization procedure is limited to the beam, V_c excludes the volume of the RC slabs in system A, i.e., $V_c = V_{c,b}$ (concrete volume of the beam), while the emissions embodied in the RC slabs are accounted for in the indirect failure costs term, see Sect. 3.5.3. In system B, however, the slab (i.e., the flange of the T-beam) contributes to the resistance mechanism of the beam and is hence included in CE_c, i.e., $V_c = V_{c,b+sl}$. Note that the term $V_{c,b+sl}\rho_c CEI_c$ in Eq. (10) corresponds to the p-independent component C_0 in Eq. (2).

The emission intensities for concrete, CEI_c and reinforcing steel, CEI_s, reflect cradle-to-gate emissions and have been adopted or inferred from Environmental Product Declarations (EPD) according to EN 15804, issued by the German Institute for Construction and Environment (IBU) [16]. The values are given in Table 2.

$$CE_c = \begin{cases} V_{c,b}\rho_c CEI_c + V_s\rho_s CEI_s & (A) \\ V_{c,b+sl}\rho_c CEI_c + V_s\rho_s CEI_s & (B) \end{cases} \tag{10}$$

3.5.3 Failure Emissions

The study considers carbon emissions in consequence of beam failure, CE_f, see Eq. (4). In addition to those embodied in the re-constructed system (after failure), considered in Eq. (10), indirect failure emissions H need to be accounted for. These are estimated according to Eqs. (11) and (12) as the sum of the emissions embodied in: the collapsed RC slabs (only for system A following the explanation given in Sect. 3.5.2), the non-structural permanent loads g_{nspl}, i.e., the flooring and roofing systems attached to the slabs, and the non-permanent building equipment, such as furniture or movable partitions. The latter is approximated as a function of the 5 year mean value of the sustained load contribution in office buildings, $q_s = 0.5$ kN/m^2 [17].

$$H = c_e A_{col} \tag{11}$$

$$c_e = \begin{cases} g_{sw,sl}CEI_{sl} + g_{nspl}CEI_{nspl} + q_s CEI_{q,s} & (A) \\ g_{nspl}CEI_{nspl} + q_s CEI_{q,s} & (B) \end{cases} \tag{12}$$

Table 2 Carbon emission intensities [kg$CO_{2,eq}$/kg]

CEI_c	CEI_s	CEI_{sl}	CEI_{nspl}	$CEI_{q,s}$
0.074	1.23	0.12	1.13	1.65

In Eq. (11), A_{col} denotes the area affected by the collapse of a beam, which, for both systems (A and B) is approximated as $A_{col} = 4LD$ (floor area supported by and below the collapsing beam). The CEI involved in Eq. (12) are given in Table 2. The value for the RC slabs (system A), CEI_{sl}, represents a weighted average of CEI_c and CEI_s, whereas the value for non-structural permanent loads, CEI_{nspl}, corresponds to an average out of 32 different configurations of such loads, comprising four different flooring (ceramic tiles [18], laminate [19], PEC floor [20], in all cases including screed [21], and raised floor [22]) and roofing systems (suspended ceiling [23], plaster boards [24], mineral boards [25], and metal ceiling [26], in all cases including metal ducts for ventilation or installations [27]), respectively. Each of the system components is represented by two different EPDs. This procedure leads to a weighted average value of $CEI_{nspl} = 1.13\ kgCO_{2,eq}/kg$ (weighted with regard to the contribution of each component to the total weight of flooring and roofing system).

The carbon emission intensity corresponding to non-permanent building equipment, $CEI_{q,s} = 1.65\ kgCO_{2,eq}/kg$, has been estimated as an average value of the CEI reflected in a variety of EPDs for different furniture types (e.g., office chair, desks, shelves, meeting tables), compiled in [28].

3.5.4 Obsolescence, Interest Rate, and Probabilistic Models

The calculation of expected emissions due to structural obsolescence CE_o based on Eq. (3) assumes an annual obsolescence rate $\omega = 1/50$. The considered annual discount rate i is 3%. The probabilistic models for the loads (g_{sw}, g_{nspl}, q), material strengths (f_y, f_c) and model uncertainties (Θ_E, Θ_R, Θ_q) are adopted from [17].

3.6 Results

The difference δ_{CEtot} (see Fig. 1) between the expected value of the total emissions corresponding to, respectively, the optimized (OPT) and the Eurocode (EC) solution is depicted in Fig. 5 depending on the ratio of variable to total loads a_q, which is found to range between 0.2 and 0.45 (System A, Fig. 5a) and 0.15 and 0.5 (System B, Fig. 5b), respectively—design situations with smaller or larger a_q led to non-compliance with the imposed boundary conditions described in Sect. 3.4). In both systems, A and B, the obtained δ_{CEtot} are of the same order. For system A, a mean value δ_{CEtot} of around 2% is found, the maximum reaches nearly 4%. The corresponding mean and max values for system B are $<1\%$ and approximately 2%.

With respect to the EC solution, the optimization entails *significant material (reinforcement) and emission reductions at the design stage* of the floor systems. This can be observed in Fig. 5c, d, which show the difference δ_p (Fig. 1) between the realizations of the decision parameter p according to EC and optimized design, respectively. In case of system A, δ_p attains on average about 10%, with a maximum

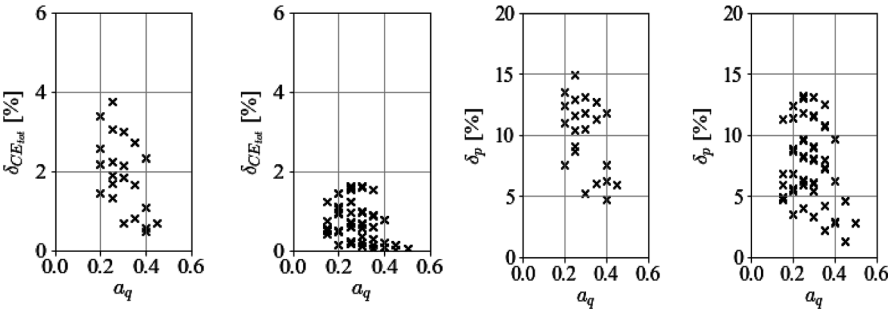

Fig. 5 Savings δ_{CEtot} in terms of expected total emissions $\mathrm{CE_{tot}}$ for (**a**) System A; (**b**) System B; Savings δ_{p} in terms of reinforcement consumption and associated emissions at the design stage for (**c**) System A; (**d**) System B

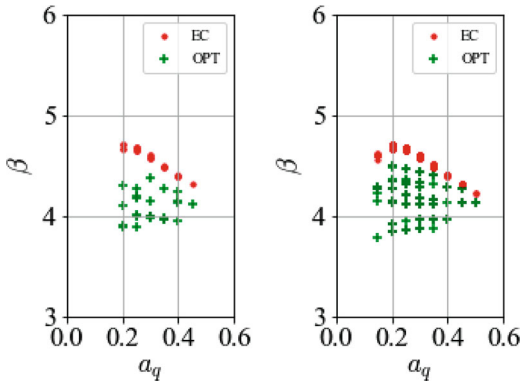

Fig. 6 Annual ($T_{\mathrm{ref}} = 1y$) reliability index β corresponding to Eurocode (EC) and optimal (OPT) design. (**a**) System A; (**b**) System B

of up to 15%. Similarly, for the T-beam system (B), mean and max δ_{p} are around 7% and 13%, respectively. In all cases, $\delta_{\mathrm{p}} > 0$, i.e., $p_{\mathrm{EC}} > p_{\mathrm{OPT}}$ (Fig. 1). Accordingly, the optimal (annual) reliability indices β_{OPT} are in all cases below the corresponding β_{EC} values. As Fig. 6 shows, β_{OPT} vary between around 3.9 and 4.4 for system A, and between 3.8 and 4.5 for system B. For larger a_{q} ratios the difference between β_{OPT} and β_{EC} diminishes and so does the saving potential δ_{p}.

3.7 Discussion

3.7.1 Emission-Saving Potential

The results presented in Fig. 5a, b point to a relatively low saving potential of the risk-based optimization (with respect to the EC solution) in terms of the total expected carbon emissions, $\mathrm{CE_{tot}}$. The reason for this is that emission savings at

the design stage, due to lower material consumption, are partially offset by increased failure-emissions, due to lower structural safety levels, i.e., those emissions which arise in case of a structural failure event and the corresponding need for reconstruction of the floor system and the replacement of both permanent and non-permanent building equipment affected by the collapse.

While this appears to be at first sight a sobering observation, the promising result is that the potential emission savings at the design stage, δ_p, are found to be significant. Given the need for urgent measures to reduce embodied greenhouse gas emissions in constructions, the opportunity for potential "immediate" emission reductions of the order of $\delta_p = 7–10\%$ (average of results in Fig. 5c, d), achieved through application of advanced and rational structural safety concepts in structural design procedures, should not be ignored. In any case, it should be ensured that the safety level exceeds the human safety requirements (Sect. 2.2). According to the results shown in Fig. 6, it might be possible that this is not fulfilled in all analyzed situations. In this case, the corresponding δ_p are expected to decrease *slightly* when imposing human safety constraints to the failure probability (Fig. 2). However, given the large number of structures erected every day all over the globe, the resource- and emission-saving potential with respect to a standardized Eurocode design is, even then, to be judged as large, at least when assessed in absolute terms.

3.7.2 Limitations and Outlook

The presented case study is limited to a specific set of design situations comprising reinforce concrete members. A similar study on the flexural design of steel beams supporting prestressed hollow-core slabs in buildings [11] revealed similar results as found herein. Future studies should assess to which extend these findings can be extrapolated to design situations characterized by other failure modes and loading scenarios, including situations governed by environmental loads, such as snow and wind.

In addition, it is imperative for future endeavors to address the inherent complexity that impedes the seamless integration of risk-based approaches into daily structural design procedures. Beyond advancing understanding through education, there are two primary ways to mitigate this challenge. One approach involves leveraging higher-level safety concepts to calibrate simplified decision rules such as the Partial Factor method [10]. However, it is contended that a significantly greater degree of optimization could be attained by directly applying risk-based decision analysis to individual structural design projects. The emergence of digital tools presents a transformative opportunity to efficiently implement this approach on a wide scale. Departing from the current analogue approach to structural decision-making, reliant on codified rules and coarse information, the adoption of user-friendly and operationally intuitive IT tools would make the identification of optimal solutions by means of flexible risk-based design accessible for routine applications in daily engineering practice. For a more detailed exploration of strategies to surmount the complexities inherent in risk-based design approaches, refer to [10].

4 Conclusions

Within the context of limited resources and a strong need for mitigation of greenhouse gas emissions, the development of a sustainable built environment in general, and of its loadbearing systems in particular, is of paramount importance. Modifications to the safety concepts and rules for design of such systems bear the potential for significant material savings. A case study addressing risk-based design of RC floor systems has illustrated this. Future studies should increase the scope of the study to other materials, failure modes, and loading scenarios, providing the basis for a consistent risk-based calibration of the standardized design rules and hence for a broad implementation of sustainability principles in structural engineering decision-making.

Acknowledgments This study has received funding from the European Union's Horizon 2020 research and innovation program under the Marie Sklodowska-Curie grant agreement No. 893527.

1 Introduction

Reinforced concrete corbels and brackets play a crucial role in the structural integrity of beam-column connections, commonly appearing as projecting cantilevers from walls or columns. These structural members are engineered to resist horizontal and vertical forces arising from diverse expected conditions. Traditional design approaches for corbels encompass techniques like the strut-and-tie model (STM) and the utilization of shear friction [1, 2]. Following the seismic events of the 1985 Mexico City earthquake, a necessity emerged to fortify the resilience of beam-column connections [3]. The durability of these connections holds significant importance in reinforced concrete frame structural systems, given their critical function in

the distribution and transmission of seismic forces [4, 5]. However, the dense arrangement of reinforcement hoops, bars, and ties in these junctions presents obstacles in the placement and consolidation processes [6]. Additionally, the design complexity of abbreviated corbels is compounded by the presence of floor slabs, transverse beams, and restricted entry to connection sites [3, 7].

Fiber-reinforced polymer (FRP) sheets are considered optimal for enhancing the strength of corbels due to their improved resistance to inter-story drift, stiffness, and strength. FRP sheets exhibit considerable potential to improve the structural efficacy of RC corbels, notably by augmenting their shear capacity [8, 9]. As per existing literature [10, 11] and shear friction theory [2], strengthening RC corbels with diagonal FRP boosts ultimate capacity by over 30% against sheets/plates alone. Empirical tests confirm the efficiency of pairing inclined and horizontal FRP [10–12].

To prevent brittle failure in construction, adhering to specific ranges for reinforcing bar percentages of primary and secondary reinforcements, including steel ties and stirrups, is crucial [9]. As per ACI 318-19 [2], the minimum area for horizontal or vertical stirrups should exceed half of that of steel ties ($A_{sh} > 0.5A_s$). Secondary bars are predominantly utilized to control the width of cracks [13], which can increase the first cracking load and ultimate load in normal and high-strength self-compacting concrete corbels (NSCC and HSCC) [14] or high-strength fiber-reinforced concrete corbels [15].

Due to the considerable expenses entailed in experimental inquiry, Finite Element (FE) analysis stands out as one of the foremost efficient approaches in projecting the behavior of reinforced concrete (RC) corbels. The findings from the numerical investigations by El-Maddawy and Sherif [11] demonstrated that increasing the steel reinforcement reduced the involvement of CFRP and that the use of horizontal stirrups influenced the development of cracks, causing the shear cracks to be more curved toward the outer surface of the corbel [11].

In a study on secondary steel reinforcement options for enhancing RC corbels with CFRPs, it was observed that the presence of such reinforcement not only prevented the development of cracks but also enhanced the ultimate load capacity by as much as 24%, primarily through the action of stirrups bridging the primary cracks [12]. However, a dearth of research exists on comparing the impacts of secondary steel reinforcements with different CFRP configurations, as well as the effects of increasing the geometrical transverse steel ratios (ρ_{sh}) of horizontal closed stirrups.

While prior work has studied the effects of secondary steel bars or discrete CFRP configurations independently, the direct assessment and contrast of the structural performance and load capacity improvements provided by each technique individually or in combination is lacking. Identifying the optimal strengthening scheme through a comparative evaluation of horizontal closed stirrups and CFRP configurations using nonlinear FEA modeling with validation from experimental data can help inform reinforcement design practices and material selection decisions to enhance structural integrity and service life. Additionally, apart from the detailed experimental case, two different ρ_{sh} values for the same CFRP sheet configuration

were investigated, and the optimal ρ_{sh} was confirmed. The research compares the influence of the optimal CFRP sheet configuration with equal volume and ρ_{sh} on the ultimate load capacity of strengthened RC corbels.

2 Optimized Reinforcement Strategies of Strengthened Corbels

To ascertain the optimized horizontal closed stirrups for corbels and compare them with the optimal CFRP configuration, two additional ρ_{sh} values were proposed, modeled, and analyzed using ABAQUS software. In alignment with the research by Kheyroddin et al. [16], experimental data presented in the work of Assih et al. [17] was employed to validate the numerical model, and four distinct CFRP sheet configurations were proposed and analyzed. The CFRP sheet configuration suggested as optimal in the study by Kheyroddin et al. [16] was selected to compare the effects of increasing ρ_{sh} on the ultimate load capacity.

3 Numerical Modeling

The work of Assih et al. [17] was utilized to validate the numerical model, which is made of concrete columns supporting reinforced concrete cantilevers. The dimensions and reinforcement details of the test specimens are shown in Figs. 1 and 2. The chosen specimen was strengthened with three layers of CFRP sheets using the EBR technique (CB3u) with the mechanical properties of Table 1. In the experiments, The specimens underwent three-point flexural loading at a rate of 0.2 kN/s, during which strain gauges were affixed to the primary reinforcing bar of the corbel (designated as point G1) to quantify displacements. The steel rebar diameters of 6, 10, and 14 mm were used with a yield strength of 500 MPa.

The concrete components were modeled using 8-node brick finite elements featuring linear geometry approximation and reduced integration. Reinforcing steel elements, including primary corbel bars, secondary bars, longitudinal reinforcement, and column ties, were represented by 2-node truss elements to account for their load-carrying behavior in the axial direction only. FRP sheets were simulated using 4-node thin shell elements. The bond between the concrete and steel reinforcement was enforced through embedded constraints. An ideal adherence was defined at the concrete-FRP interface using tying in ABAQUS. Refinement of the discretization scheme was found to impact load-deformation response as cracking initiation and propagation depends sensitively on stress distributions which are governed by element size and shape. Ultimate capacity predictions also varied with mesh characteristics due to altered failure mechanics within the composite structure, which, according to the study of Kheyroddin et al. [16], the optimal mesh size was

20 × 20 mm, see Fig. 3. In addition, the displacement and rotational constraints at the base of the corbel were individually imposed on distinct reference points, RP1 and RP2, facilitating controlled analysis of the structure's behavior, see Fig. 4.

3.1 Material Properties

The investigation involved numerical simulations performed on the experimental sample, utilizing the documented uniaxial compressive strength of the concrete ($f'_C = 33$ MPa) as documented in the experimental research publication [17]. In alignment with guidelines outlined in ACI 318-19 [2], the concrete's modulus of

elasticity (E_C) was determined to be 26.9 GPa. The concrete damaged plasticity (CDP) model (Fig. 5 and Table 2) was utilized to generate more accurate representations of concrete cracking behavior, accounting for rate effects. The CDP model simulates degradation in stiffness upon damage initiation, enabling the prediction of strength and fracturing as loads increase. The steel rebar diameters were 6, 8, and 10 mm, and their mechanical properties are presented in Table 3.

Given the orthotropic nature of FRP composites, thin shell elements with an orthotropic "LAMINA" material formulation were employed in the simulation [18, 19]. While FRPs generally exhibit anisotropic behavior, the unidirectional fiber architecture of the carbon FRP used permitted simplification to an orthotropic model. The mechanical properties in Table 4 [19, 20] characterized the linear elastic and pre-failure response, assuming the specified moduli for the carbon FRP reinforcement. This modeling approach captured the directionally-dependent stiffness of the FRP material.

4 Proposed Strengthening Method

Two steel reinforcement ratios (ρ_{sh}) were introduced to discern the most effective method for strengthening RC corbels and to assess how the variations in CFRP configurations and geometric secondary steel reinforcement ratios (ρ_{sh}) impact the ultimate load capacity and behavior of strengthened RC corbels. In a study by Kheyroddin et al. [16], the optimal CFRP configuration for RC corbels, among four proposed configurations with the same volume, was the 3R-45-50+4Triangle specimen. This specimen featured six inclined strips of CFRPs at a 45-degree angle and with a width of 50 millimeters, and it was reinforced at the corner of the RC corbel by four triangle-shaped CFRP sheets, as illustrated in Fig. 6.

In this study, two models were presented, both sharing the same CFRP configuration as the modeled experimental case (comprising three unidirectional CFRP layers wrapped horizontally), but with the diameters of the closed stirrups modified to 8 and 10 mm, named 1R-0-200+ST8 and 1R-0-200+ST10, respectively. The steel reinforcement ratios (ρ_{sh}) for the proposed specimens were 0.33% and 0.52%, respectively. Initially, this study explored the impact of augmenting the steel reinforcement ratio (ρ_{sh}) on the load capacity of RC corbels, and subsequently, the outcomes were compared with those of the study by Kheyroddin et al. [16] to delineate the optimal reinforcement means for strengthening RC corbels.

5 Analysis and Interpretation of Finite Element Results

5.1 Enhanced Corbel Load Capacity Analysis

By increasing the diameter of the closed stirrups from 6 to 8 mm and 10 mm in the 1R-0-200+ST8 and 1R-0-200+ST10 specimens, a respective 5.52% and 11.55% enhancement in the ultimate load capacity was achieved through a higher steel reinforcement ratio (ρ_{sh}). On average, for specimens featuring the same CFRP configuration, the results demonstrated a 5.6% increase in capacity for every 0.17% rise in the steel reinforcement ratio. Nonetheless, in a study by Kheyroddin et al. [16], the median increase in load capacity for four proposed CFRP arrangements was 28%, with the 3R-45-50+4Triangle configuration showing a substantial 33% capacity boost.

To ascertain the relationship between the CFRP configuration and the increase in steel reinforcement ratio (ρ_{sh}), the specimen 3R-45-50+4Triangle+ST10, with a 10 mm diameter of closed stirrups (resulting in a ρ_{sh} increase up to 0.52%), was analyzed, revealing a 4.39% surge in capacity.

5.2 Behavioral Analysis: Load–Displacement

The load–displacement curves of the five investigated samples are presented in Fig. 7. The research findings reveal that, in comparison, the most effective strengthening method for increasing the ultimate load entailed an optimal CFRP configuration in conjunction with an increase in the geometrical secondary steel reinforcement ratio (ρ_{sh}). Overall, specimens with higher (ρ_{sh}) but the same CFRP configurations demonstrated greater stiffness. The extent of stiffness enhancement varied, particularly across different CFRP configurations. For instance, in the case of the 1R-0-200+ST10 specimen (initial configuration), the percentage increase in load capacity was more than double that of the same (ρ_{sh}) in the optimized CFRP configuration (11.55% versus 4.39%).

The process of loading experienced by the simulated and investigated samples can be delineated into five stages, all uniformly undergone by each specimen. These stages can be identified as initial flexural/shear cracking, splitting cracking, concrete failure on the flange-to-column joint, yielding of the primary steel reinforcement, and cracking of the vertical-sided area of the corbel flange, as illustrated in Fig. 8.

The notable distinction between the two prime reinforcement approaches, CFRP configurations and the secondary steel reinforcement ratio, pertains to the Mises stress contour. The findings suggest that alterations in the secondary steel reinforcement ratio do not impact the Mises stress contour, while changes in the CFRP configuration do, as depicted in Fig. 9.

5.3 Evaluation of Primary Reinforcement Load–Strain

Per the guidelines outlined in the CEP-FIP code [21], it is possible to convert the stress–strain characteristics of reinforcement bars confined by concrete into a standard load–strain curve. Similar to the impact of the CFRP configuration, an increase in the ρ_{sh} parameter is observed in post-yield zone D. However, it is noted that specimens with an increased ρ_{sh} exhibit a reduced load–strain slope compared to those with an altered CFRP configuration (3R-45-50+4Triangle). This observation underscores the significant influence of the CFRP configuration despite the utilization of the same amount of material, as depicted in Fig. 10.

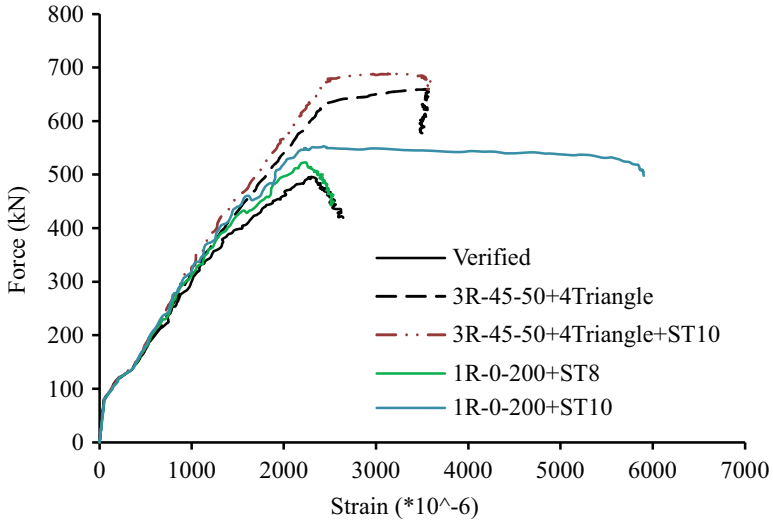

Fig. 10 Load–strain curves of proposed strengthened specimens

6 Conclusion

This study introduced two steel reinforcement ratios (ρ_{sh}) for a particular CFRP configuration. The optimal ρ_{sh} was determined through an analysis of the proposed reinforcement models utilizing nonlinear finite element (FE) techniques. Subsequently, the optimized CFRP configurations were modeled with the selected optimal ρ_{sh}. Their stress–strain behavior, stiffness, maximum load-bearing capability, Mises stress contours, and displacement were compared. The outcomes of the research substantiate the following conclusions:

- The CFRP configurations can impact the amount of influence of horizontal closed stirrups.
- Despite utilizing the same amount of material in different CFRP configurations, the general Mises stress contour of specimens alters. However, the mentioned factor is the same with changing the (ρ_{sh}).

In comparison to employing various CFRP configurations, the effect of modifying the (ρ_{sh}) during the crack-formation phase of the specimens is somewhat more pronounced, albeit not statistically significant. Nonetheless, the substantial impact of CFRP configurations becomes noticeable in the post-yield phase and the bearing capacity. It is advisable for future research to explore the influence of closed stirrups arrangements like vertical or the combination of horizontal and vertical, and in which CFRP configurations (horizontal, vertical, and inclined) the effect of the horizontal closed stirrups are the most.

Notation

A_s = Area of longitudinal steel bars
A_{sh} = Area of horizontal or vertical stirrups
ρ_{sh} = The geometrical transverse steel ratios

1 Introduction

Functionally graded materials (FGMs) signify a significant advancement in engineering and scientific domains, offering solutions to intricate challenges encountered across diverse industries, notably aerospace and biomedical applications [1–3]. It is crucial to recognize that porosities may arise within FGMs during the sintering phase of fabrication, mainly because of the differences in solidification temperatures between the different materials [4, 5]. In the design of FGM structures exposed to dynamic loads, accounting for the influence of porosity is paramount [6, 7]. The

disparity in solidification temperatures between metals and ceramics gives rise to the formation of metal phase grains, while ceramics persist as interspersed particles. Furthermore, the varied sizes and configurations of the reinforcement (ceramics) powders can engender pore formation in proximity to the reinforced particles, leading to divergent levels of porosity within both phases [6].

This investigation examines the repercussions of distinct porosity types within both ceramic and metal constituents. Each discussed porosity type manifests differing percentages of porosity in ceramic and metal phases. The analysis encompasses how the stiffness of functionally graded beams is affected by the power-law index, furnishing elucidations into their dynamic response. Furthermore, scrutiny of the length-to-thickness ratio yields significant insights into the ramifications of geometric proportions. Collectively, this study offers novel insights into the behavior of porous functionally graded beams, considering a spectrum of parameters and underscoring their relevance in real-world applications.

2 Problem Formulation

2.1 Constitutive Relations of FG Beams Made of Metal and Ceramic

We examine an imperfect FGM characterized by the porosity volume fraction, a (where $a \ll 1$), evenly distributed between the two constituents. The rule of mixture (modified), as proposed by [8], is

$$P = P_m\left(V_m - \frac{\alpha}{2}\right) + P_c\left(V_c - \frac{\alpha}{2}\right) \tag{1}$$

$$V_c = \left(\frac{z}{h} + \frac{1}{2}\right)^k \tag{2}$$

$$V_c + V_m = 1 \Rightarrow V_c = 1 - V_m \tag{3}$$

The power law of volume fraction is described in detail in Table 1. The properties of the imperfect FGM can be formulated as

$$P = (P_c - P_m)\left(\frac{z}{h} + \frac{1}{2}\right)^k + P_m - (P_c + P_m)\frac{\alpha}{2} \tag{4}$$

The parameter k, a non-negative real number ($0 \leq k \leq \infty$), represents the volume fraction or power-law index, while z denotes the distance from the mid-plane of the beam. The FG beam transitions to a fully ceramic one as k approaches zero, and to a fully metallic one as k becomes large. The equations for Elastic Modulus (E) and the density of the material (ρ) of the imperfect FGM beam are detailed in [9]. Table 1 shows the equations used for E for the various porosity distributions present in the

Table 1 Porosity distribution in the FGM's (ceramic/metal): different types

Types	Porosity rate distribution		Elastic modulus, $E(z) =$
	Ceramic	Metal	
T-1	Perfect FG beam, without porosity ($a = 0$)		$(E_c - E_m)\left(\frac{z}{h} + \frac{1}{2}\right)^k + E_m$
T-2	50%	50%	$E_m\left(V_m - \frac{\alpha}{2}\right) + E_c\left(V_c - \frac{\alpha}{2}\right)$ $(E_c - E_m)\left(\frac{z}{h} + \frac{1}{2}\right)^k + E_m - (E_c + E_m)\frac{\alpha}{2}$
T-3	60%	40%	$E_m\left(V_m - \frac{2\alpha}{5}\right) + E_c\left(V_c - \frac{3\alpha}{5}\right)$ $(E_c - E_m)\left(\frac{z}{h} + \frac{1}{2}\right)^k + E_m - (3E_c + 2E_m)\frac{\alpha}{5}$
T-4	40%	60%	$E_m\left(V_m - \frac{3\alpha}{5}\right) + E_c\left(V_c - \frac{2\alpha}{5}\right)$ $(E_c - E_m)\left(\frac{z}{h} + \frac{1}{2}\right)^k + E_m - (2E_c + 3E_m)\frac{\alpha}{5}$
T-5	75%	25%	$E_m\left(V_m - \frac{\alpha}{4}\right) + E_c\left(V_c - \frac{3\alpha}{4}\right)$ $(E_c - E_m)\left(\frac{z}{h} + \frac{1}{2}\right)^k + E_m - (3E_c + E_m)\frac{\alpha}{4}$
T-6	25%	75%	$E_m\left(V_m - \frac{3\alpha}{4}\right) + E_c\left(V_c - \frac{\alpha}{4}\right)$ $(E_c - E_m)\left(\frac{z}{h} + \frac{1}{2}\right)^k + E_m - (E_c + 3E_m)\frac{\alpha}{4}$

FGMs. The Poisson's ratio (ν) is assumed to remain constant. In the special case where $a = 0$, we obtain material properties corresponding to a perfect FG beam.

2.2 Theoretical Formulation

2.2.1 Assumptions

The theory operates under the following assumptions:

- Displacements are significantly smaller in magnitude compared to the height of the beam, thus resulting in infinitesimal strains.
- The displacement in the transverse direction, w, comprises two components for bending (w_b) and shear (w_s), which are both solely functions of the coordinates x and t:

$$w(x, z, t) = w_b(x, t) + w_s(x, t) \tag{5}$$

- Normal stress σ_z (in the transverse direction) is considerably smaller in magnitude compared to the in-plane stresses σ_x.
- Axial displacement u (in the x-direction), comprises extension, bending, and shear components.

$$u = u_0 + u_b + u_s \tag{6}$$

- The component of bending, u_b, is assumed to closely resemble the displacements predicted by the beam theory. Hence, u_b can be expressed as

$$u_b = -z\frac{\partial w_b}{\partial x} \tag{7}$$

- The combination of the shear component u_s with w_s results in a hyperbolic variation of shear strain γ_{xz}, causing shear stress τ_{xz} to distribute across the thickness of the beam. This distribution ensures that shear stress τ_{xz} is zero at both the top and bottom surfaces of the beam. Thus, the expression for u_s can be stated as follows:

$$u_s = -f(z)\frac{\partial w_s}{\partial x} \tag{8}$$

$$f(z) = -\frac{z}{4} + \frac{5z^3}{3h^2} \tag{9}$$

2.2.2 Constitutive Equations and Kinematics

Utilizing the formulations outlined in the previous section, the field of displacements can be derived from Eqs. (5), (6), (7), (8), and (9) as

$$u(x,z,t) = u_0(x,t) - z\frac{\partial w_b}{\partial x} - f(z)\frac{\partial w_s}{\partial x} \tag{10}$$

$$w(x,z,t) = w_b(x,t) + w_s(x,t) \tag{11}$$

The strains corresponding to the displacements in Eqs. (10) and (11) are as follows:

$$\varepsilon_x = \varepsilon_x^0 + z\,k_x^b + f(z)\,k_x^s \tag{12}$$

$$\gamma_{xz} = g(z)\,\gamma_{xz}^s \tag{13}$$

where

$$\varepsilon_x^0 = \frac{\partial u_0}{\partial x}, \quad k_x^b = -\frac{\partial^2 w_b}{\partial x^2}, \quad k_x^s = -\frac{\partial^2 w_s}{\partial x^2}, \quad \gamma_{xz}^s = \frac{\partial w_s}{\partial x} \tag{14}$$

$$g(z) = 1 - f'(z), \quad f'(z) = \frac{df(z)}{dz} \tag{15}$$

Assuming adherence to Hooke's law for the material of the FG beam, the stresses within the beam can be determined:

$$\sigma_x = Q_{11}(z)\ \varepsilon_x \tag{16}$$

$$\tau_{xz} = Q_{55}(z)\ \gamma_{xz} \tag{17}$$

$$Q_{11}(z) = E(z) \tag{18}$$

$$Q_{55}(z) = E(z)/[2(1+\nu)] \tag{19}$$

2.2.3 Motion Equations

In this context, Hamilton's principle is utilized to end up to the equations of motion, as follows [10]:

$$\delta \int_{t_1}^{t_2} (U - T)dt = 0 \tag{20}$$

Here, t represents the time, t_1 is the initial, t_2 denotes the final time, δU signifies the virtual variation of the strain energy, and δT represents the virtual variation of the kinetic energy. The variation in strain energy of the beam is

$$\begin{aligned} \delta U &= \int_0^L \int_{-h/2}^{h/2} \left(\sigma_x \delta\varepsilon_x + \tau_{xz}\delta\gamma_{xz}\right) dz dx \\ &= \int_0^L \left(N_x \delta\varepsilon_x^0 - M_x^b \delta k_x^b - M_x^s \delta k_x^s + Q_{xz}\delta\gamma_{xz}^s\right) dx \end{aligned} \tag{21}$$

where the four stress resultants can be defined as

$$\left(N_x, M_x^b, M_x^s\right) = \int_{-h/2}^{h/2} (1, z, f(z))\ \sigma_x dz \tag{22}$$

$$Q_{xz} = \int_{-h/2}^{h/2} \tau_{xz} g(z) dz \tag{23}$$

The kinetic energy variation is given by

$$\begin{aligned}\delta T = & \int_0^L \int_{-h/2}^{h/2} \rho(z)[\dot{u}\delta\,\dot{u} + \dot{w}\delta\,\dot{w}]\, dz_{ns} dx \\ = & \int_0^L \left\{ I_0[\dot{u}_0 \delta\,\dot{u}_0 + (\dot{w}_b + \dot{w}_s)(\delta\,\dot{w}_b + \delta\,\dot{w}_s)] - I_1\left(\dot{u}_0 \frac{d\delta\,\dot{w}_b}{dx} + \frac{d\,\dot{w}_b}{dx}\delta\,\dot{u}_0\right)\right. \\ & + I_2\left(\frac{d\dot{w}_b}{dx}\frac{d\delta\,\dot{w}_b}{dx}\right) - J_1\left(\dot{u}_0 \frac{d\delta\,\dot{w}_s}{dx} + \frac{d\,\dot{w}_s}{dx}\delta\,\dot{u}_0\right) + K_2\left(\frac{d\dot{w}_s}{dx}\frac{d\delta\,\dot{w}_s}{dx}\right) \\ & \left. + J_2\left(\frac{d\dot{w}_b}{dx}\frac{d\delta\,\dot{w}_s}{dx} + \frac{d\dot{w}_s}{dx}\frac{d\delta\,\dot{w}_b}{dx}\right)\right\} dx\end{aligned} \tag{24}$$

In the provided context, the dot-superscript notation means differentiation with respect to the time variable t. $\rho(z)$ represents the mass density, and the mass inertias are defined as

$$(I_0, I_1, J_1, I_2, J_2, K_2) = \int_{-h/2}^{h/2} \left(1, z, f, z^2, zf, f^2\right)\rho(z) dz \tag{25}$$

By using Eqs. (21) and (24) into Eq. (20), we have

$$\delta u_0 : \frac{dN_x}{dx} = I_0\ddot{u}_0 - I_1\frac{d\ddot{w}_b}{dx} - J_1\frac{d\ddot{w}_s}{dx} \tag{26}$$

$$\delta w_b : \frac{d^2M_b}{dx^2} = I_0(\ddot{w}_b + \ddot{w}_s) + I_1\frac{d\ddot{u}_0}{dx} - I_2\frac{d^2\ddot{w}_b}{dx^2} - J_2\frac{d^2\ddot{w}_s}{dx^2} \tag{27}$$

$$\delta w_s : \frac{d^2M_s}{dx^2} + \frac{dQ_{xz}}{dx} = I_0(\ddot{w}_b + \ddot{w}_s) + J_1\frac{d\ddot{u}_0}{dx} - J_2\frac{d^2\ddot{w}_b}{dx^2} - K_2\frac{d^2\ddot{w}_s}{dx^2} \tag{28}$$

Introducing Eqs. (22) and (23) into Eqs. (26), (27), and (28), the motion equations can be expressed as follows, in terms of u_0, w_b, w_s:

$$A_{11}\frac{\partial^2 u_0}{\partial x^2} - B_{11}\frac{\partial^3 w_b}{\partial x^3} - B_{11}^s\frac{\partial^3 w_s}{\partial x^3} = I_0\ddot{u}_0 - I_1\frac{d\ddot{w}_b}{dx} - J_1\frac{d\ddot{w}_s}{dx} \tag{29}$$

$$B_{11}\frac{\partial^3 u_0}{\partial x^3} - D_{11}\frac{\partial^4 w_b}{\partial x^4} - D_{11}^s\frac{\partial^4 w_s}{\partial x^4} = I_0(\ddot{w}_b + \ddot{w}_s) + I_1\frac{d\ddot{u}_0}{dx} - I_2\frac{d^2\ddot{w}_b}{dx^2} - J_2\frac{d^2\ddot{w}_s}{dx^2} \tag{30}$$

$$B_{11}^s\frac{\partial^3 u_0}{\partial x^3} - D_{11}^s\frac{\partial^4 w_b}{\partial x^4} - H_{11}^s\frac{\partial^4 w_s}{\partial x^4} + A_{55}^s\frac{\partial^2 w_s}{\partial x^2} = I_0(\ddot{w}_b + \ddot{w}_s) + J_1\frac{d\ddot{u}_0}{dx} - J_2\frac{d^2\ddot{w}_b}{dx^2} - K_2\frac{d^2\ddot{w}_s}{dx^2} \tag{31}$$

Where the beam stiffnesses are defined by

$$\left(A_{ij}, A_{ij}^s, B_{ij}, D_{ij}, B_{ij}^s, D_{ij}^s, H_{ij}^s\right) = \int_{-h/2}^{h/2} Q_{ij}\left(1, g^2(z), z, z^2, f(z), zf(z), f^2(z)\right)dz \tag{32}$$

2.2.4 Analytical Solution

The analytical solutions in the Navier-type format are derived for the free vibration analysis of FG beams. Following this approach, the variables (unknown displacements) are expanded into a Fourier series as follows:

$$\begin{Bmatrix} u_0 \\ w_b \\ w_s \end{Bmatrix} = \sum_{m=1}^{\infty} \begin{Bmatrix} U_m \cos(\lambda x)\, e^{i\omega t} \\ W_{bm} \sin(\lambda x)\, e^{i\omega t} \\ W_{sm} \sin(\lambda x)\, e^{i\omega t} \end{Bmatrix} \tag{33}$$

In the above, U_m, W_{bm}, and W_{sm} denote arbitrary parameters that are to be calculated, ω is the frequency associated with the m-th eigenmode, and $\lambda = m{\cdot}\pi/L$. By substituting Eq. (33) into Eqs. (29), (30), and (31), the analytical solution can be derived through the eigenvalue equations below, for any given value of the eigenmode m.

$$\left([K] - \omega^2[M]\right)\{\Delta\} = \{0\} \tag{34}$$

$$[K] = \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{12} & a_{22} & a_{23} \\ a_{13} & a_{23} & a_{33} \end{bmatrix}, \tag{35}$$

$$[M] = \begin{bmatrix} m_{11} & m_{12} & m_{13} \\ m_{12} & m_{22} & m_{23} \\ m_{13} & m_{23} & m_{33} \end{bmatrix}, \tag{36}$$

$$\{\Delta\} = \begin{Bmatrix} U_m \\ W_{bm} \\ W_{sm} \end{Bmatrix}, \tag{37}$$

$$a_{11} = A_{11}\lambda^2, \quad a_{12} = -B_{11}\lambda^3, \quad a_{13} = -B^s_{11}\lambda^3, \tag{38}$$

$$a_{22} = D_{11}\lambda^4, \quad a_{23} = D^s_{11}\lambda^4, \quad a_{33} = H^s_{11}\lambda^4 + A^s_{55}\lambda^2 \tag{39}$$

$$m_{11} = I_0, \quad m_{12} = -I_1\alpha, \quad m_{13} = -J_1\alpha, \tag{40}$$

$$m_{22} = I_0 + I_2\alpha^2, \quad m_{23} = I_0 + J_2\alpha^2, \quad m_{33} = I_0 + K_2\alpha^2 \tag{41}$$

3 Results

We present the results for the numerical frequencies of imperfect FGM beams with various rates of porosity distribution, with the aim of validating the accuracy of the present formulation. The properties of the beam's material are outlined below:

- Ceramic part: Al_2O_3 (Alumina) with $\nu = 0.3$, $E_c = 380$ GPa, $\rho = 3960$ kg/m^3.
- Metal part: Al (Aluminum) with $\nu = 0.3$, $E_m = 70$ GPa, $\rho = 2702$ kg/m^3.

The following non-dimensional parameter has been used for simplicity:

$$\overline{\omega} = \frac{\omega \cdot L^2}{h}\sqrt{\frac{\rho_m}{E_m}} \tag{42}$$

The natural frequencies of both imperfect and perfect beams were examined for $L/h = 5$ and $L/h = 20$ across various power-law indices (k), with results summarized in Table 2. The present theory's outcomes are corroborated and demonstrate excellent alignment with previously published findings. Additionally, the analysis extends to different porosity types categorized as T-1 to T-6, as detailed in Table 1. The results reveal that the natural frequency attains its maximum for T-6, followed by the cases T-4, T-2, T-3, T-5, and T-1.

When the beam is composed entirely of ceramic ($k = 0$), an escalation in grading indices results in a greater proportion of metal within the beam, consequently diminishing its stiffness and subsequently reducing its natural frequency. This trend mirrors the behavior observed in the non-dimensional flexural natural frequencies of porous functionally graded beams, as depicted in Table 3 (for $L/h = 5$) and Table 4 (for $L/h = 20$). Across all instances, the natural frequency is higher for porous beams in comparison to non-porous beams.

Figure 1 shows the evolution of the frequency of imperfect FG beams across a range of power-law indices (k). The analysis reveals a decline in frequency with the augmentation of the porosity fraction k. Specifically, when k is less than 5, a sharp

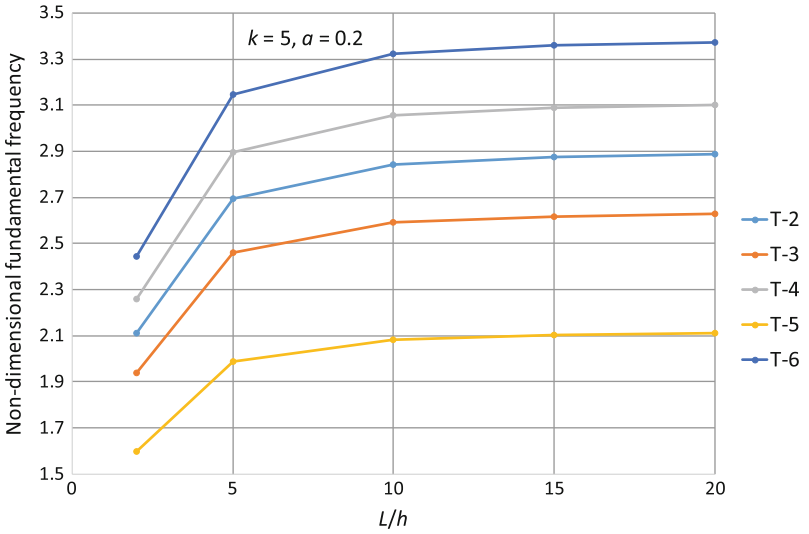

Fig. 2 Fundamental frequency $\overline{\omega}$ of imperfect beams versus L/h ratio ($k = 5$, $a = 0.2$)

decrease in frequency occurs, whereas beyond k greater than 5, a consistent decrease in natural frequency is observed. Furthermore, the investigation into natural frequency encompassed various L/h ratios and different porosity types, demonstrating an increase in frequency with higher L/h ratios (Fig. 2).

4 Conclusions

This study conducted a comprehensive analysis of the free vibration behavior of FG beams with porosities, considering various types of porosity. The investigation focused on evaluating the impact of differing levels of porosity within ceramic and metal components. Specifically, the analysis examined how the power-law index, length-to-thickness ratio, and porosity distribution types influenced the natural frequency.

Validation of the obtained results was performed by comparing them with existing literature for cases where the beam exhibited no porosity. The findings revealed that an increase in the power-law indices resulted in a decrease in the stiffness of functionally graded beams, leading to a corresponding reduction in natural frequency. Additionally, it was observed that a higher length-to-thickness ratio (L/h ratio) was associated with an increase in natural frequency.

Furthermore, the study demonstrated a significant decrease in the natural frequency as the percentage of porosity increased, regardless of the specific porosity types examined. These findings provide valuable insights for industries engaged in the manufacturing of porous beams, aiding in the decision-making process for

selecting the most suitable porosity type to achieve optimal performance objectives. Overall, this analysis contributes to advancing our understanding of the complex interplay between porosity, material properties, and geometric parameters in functionally graded structures, with implications for various engineering applications.

1 Introduction

As the global construction industry steers toward sustainable practices, optimizing structural designs becomes paramount in achieving net-zero buildings while aligning with sustainable development goals. With the increasing complexity of modern structures and the necessity to meet stringent performance criteria, optimization tools play a pivotal role in assisting engineers to make informed design decisions efficiently. This chapter presents a comprehensive approach to optimize steel usage, leading to a lightweight structural system that minimizes carbon footprints in the built environment. This optimization design works with the integration of a nonlinear programming solver with ETABS, a structural analysis and design software [1]. This integration streamlines the optimization process, enabling engineers to systematically identify optimal design solutions while considering structural capacities and serviceability constraints.

This study focuses on identifying optimum cross-sectional dimensions of structural sections to withstand lateral wind loads. The optimization objective function defined as the volume/weight of structural steel to ensure sustainability, drives the search for configurations that minimize material usage, while two constraints of the demand to capacity index (DCI) of structural members as a strength condition and inter-story drift ratio as a serviceability constraint are taken into account to meet performance criteria, safety, and cost-effectiveness designing process. The results show that this optimized design can effectively reduce the volume/weight of the structural steel usage to achieve sustainable buildings. Section 2 of this chapter outlines the optimization problem and its components, while Sect. 3 provides a case study on design iterations for a 15-story building. Section 4 explains the results obtained from the case study, and Sect. 5 summarizes the main conclusions.

2 Optimization Formulation

In this study, a nonlinear programming solver in MATLAB was utilized to optimize the thickness of structural members. This solver offers a powerful tool designed to find the minimum of a constrained nonlinear multivariable function. Specifically, a nonlinear sequential quadratic programming (SQP) method was used. This method has proven to be more efficient, accurate, and successful than other existing methods. This was confirmed through numerous test problems [2, 3]. Previous studies showed that this method closely resembles Newton's method of constrained optimization, which is similar to unconstrained optimization. This is an iterative process that involves approximating the Hessian of the Lagrangian function using the quasi-Newton updating method. Consequently, a quadratic programming subproblem was generated [4]. The optimization problem can be defined as follows:

$$\begin{aligned} &\text{Minimize steel volume/weight} \\ &\text{Subjected to}: \quad \text{DCI} \le 1.0 \ \text{(strength condition)} \\ &\qquad\qquad\quad \text{Inter-story drift ratio} \le 1/400 \ \text{(serviceability condition)} \end{aligned}$$

Critical factors such as structural strength, represented by the DCI, and serviceability constraints like inter-story drift ratio were defined in the first step. The DCIs were calculated using Eqs. (1) and (2) from AISC 360-22 [5]:

$$\text{DCI} = \frac{P_\text{r}}{\varnothing_\text{p} P_\text{n}} + \frac{8}{9}\left(\frac{M_{rx}}{\varnothing_\text{m} M_{nx}} + \frac{M_{ry}}{\varnothing_\text{m} M_{ny}}\right) \quad \frac{P_\text{r}}{\varnothing_\text{p} P_\text{n}} \ge 0.2 \tag{1}$$

$$\text{DCI} = \frac{P_\text{r}}{2 \times \varnothing_\text{p} P_\text{n}} + \left(\frac{M_{rx}}{\varnothing_\text{m} M_{nx}} + \frac{M_{ry}}{\varnothing_\text{m} M_{ny}}\right) \quad \frac{P_\text{r}}{\varnothing_\text{p} P_\text{n}} < 0.2 \tag{2}$$

where P_r and P_n are the demand and nominal axial strength; M_{rx} and M_{nx} are the demand and nominal flexural strength about the major axis; M_{ry} and M_{ry} are the

Table 1 Acceptance criteria for various performance levels [7]

Performance levels	Story drift response	Residual story drift
Occupant comfort	–	–
Operational	*H*/400	–
Continuous occupancy	*H*/200	*H*/1000

demand and nominal flexural strength about the minor axis; and $\varnothing_p$ and $\varnothing_m$ are the resistance factors.

The inter-story drift ratio is a crucial metric in structural engineering that measures the relative translational displacement observed between two consecutive floors in a building, divided by the height of each story. This parameter significantly evaluates structural performance, especially when exposed to seismic or wind forces [6]. Saini et al. [7] conducted a study on the performance of a steel building based on three criteria: occupant comfort, operational efficiency, and continuous occupancy. The referenced study [8–12] calculated different performance measures, such as inter-story drift ratio, as one of the most critical criteria. The calculated inter-story drift ratio was compared to the acceptance criteria of the desired performance objectives, as listed in Table 1. The performance assessment revealed that the building met the requirements for strength design, as well as performance limitations for continuous occupancy and limited interruption in Risk Category II. However, the building failed to meet the serviceability requirement for the performance level of operation, which has a limited story drift of *H*/400, where *H* is the story height. As a result, the building needed to be redesigned to meet this performance level. In the current study, to optimize the building design for serviceability requirements, a limit for the story drift equal to *H*/400 was considered.

Initially, within the ETABS software environment, frame elements and floor decks were created, along with their respective constraints and boundary conditions. Subsequently, preliminary design parameters were defined. The numbers of property types for beams, columns, and braces were chosen, and initial section dimensions were assigned to members. Then, all the crucial data such as node and frame coordinates, frame labels, and section properties were extracted from ETABS and stored within MATLAB for further analysis.

Load patterns and combinations were then defined, and lateral loads were applied to model joints. The maximum values of DCIs and inter-story drift ratios were determined by considering the wind loads acting laterally and the gravity loads, such as dead and live loads. The load combination specified in ASCE 7-22 [13] was used (Eq. 3), involving the consideration of dead load (DL), live load (LL), and wind load (WL).

$$\text{Load combination} = 1.2\,\text{DL} + 1.0\,\text{LL} + 1.0\,\text{WL} \tag{3}$$

At the next step, the optimization phase commenced to determine the optimal thickness for each section property. Using the solver in MATLAB, member thickness was optimized to minimize steel volume/weight while limiting the predefined

criteria, such as the DCI or DCI and drift ratio within specified thresholds. Finally, after finding the thicknesses, the volume/weight of steel and DCI for the optimized frame members were recalculated and presented, signifying the conclusion of the optimization process, and providing insights into an enhanced structural design.

3 Steel Building Structure

In this section, the optimization process is studied for a 15-story moment resisting frame building. This building had a floor height of 4.0 m and bay width of 7.62 m. All the beams of the building were assumed to have one HSS section with outer dimensions of 300 mm × 300 mm, while the column sections were assumed to be HSS section with outer dimensions of 400 mm × 400 mm for the first five stories (stories 1–5), 300 mm × 3000 mm for the next five stories (stories 6–10), and 200 mm × 200 mm for the last five stories (stories 11–15), respectively. Floor diaphragms were modeled. In addition to the dead loads, a live load of 2.4 kN/m^2 is applied on floor slabs of each floor, which are typical live load expected for the office building. On one face of the building, a constant point load of 50 kN was applied on all nodes in the horizontal direction.

Before optimization, the first step was to create a model of the beam and column elements using ETABS software. This model includes specific section properties and the geometry of the model, which can be seen in Fig. 1. Once the model was complete, the optimization code was initiated. It began by extracting all section

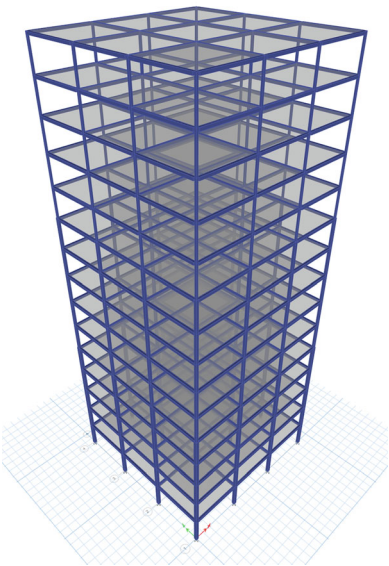

Fig. 1 A 15-story building model developed in ETABS with necessary beam, column, and connection details

properties from the ETABS model and then iterated through each beam and column type, retrieving important parameters such as area, torsional properties, moments of inertia, and other relevant data.

The optimization code then sets out to determine the optimal thickness for both beam and column sections including T_{C1}, T_{C2}, and T_{C3}, which refer to the thickness of columns at first five stories (story 1 to story 5), second five stories (story 6 to story 10), and third five stories (story 11 to story 15), respectively, and the beam thickness which refers to as T_b. Determining the optimal thickness was achieved by formulating an objective function based on the volume/weight of the steel sections, while also applying constraints on the DCI indices and story drift ratios. This constraint framework is necessary to ensure the performance of the building design. Specifically, the constraints of this study ensured that the DCI indices for structural members did not exceed one and that the story drift remained within acceptable limits (H/400).

4 Results and Findings

In this section the results of design optimization are discussed. Section 4.1 evaluates the optimization results for strength constraint, and Sect. 4.2 examines the results for both strength and serviceability constraints.

4.1 Optimization Results with Strength Constraint

The design of the building was investigated for achieving optimal section properties while adhering to strength constraints, ensuring that the DCI indices for all the structural members do not surpass one. The lower and upper bounds for the flange/web thickness of beam and column sections were set at 12.7 mm and 100 mm, respectively. These bounds allowed the optimization algorithm to explore a range of thickness options while maintaining structural integrity within specified limits. Initially, the beam and column sections are configured with flange and web thicknesses set to 12.7 mm. After the optimization code was executed, the results indicated a shift in the thickness values of both column and beam sections from their initial starting points to the end points. The results of the optimization are summarized in Table 2. In the referenced table, the *Feasibility* column indicates the maximum constraint violation, with lower values reflecting closer adherence to

Table 2 Optimization results for member thicknesses with strength constraint

Iter.	Feasibility	T_b (mm)	T_{C1} (mm)	T_{C2} (mm)	T_{C3} (mm)	Weight (ton)
0	6.60E-01	12.70	12.70	12.70	12.70	424.21
7	1.92E-13	15.60	23.21	19.63	21.14	563.40

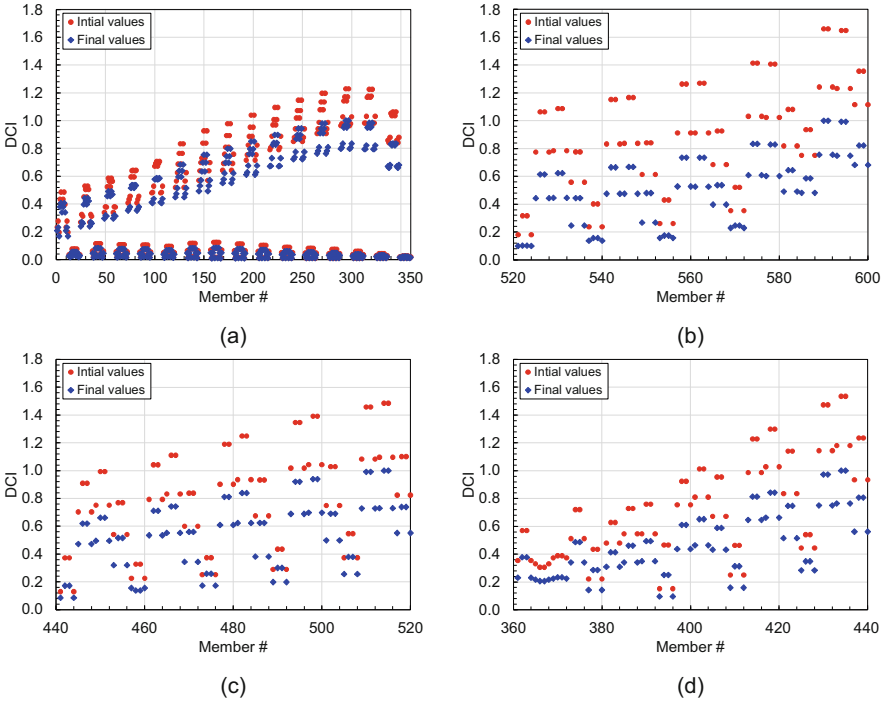

Fig. 2 Optimization results of DCI indices for building with strength constraint: (**a**) beams, (**b**) columns at stories 1–5, (**c**) columns at stories 6–10, and (**d**) columns at stories 11–15

constraints. A decrease in *Feasibility* indicates a closer match and convergence in the results. The optimization process was initiated with an initial thickness of 12.7 mm for each component. Through iterative adjustments, the thickness values evolved until convergence or meeting the specified stopping criteria; and shifted to a stable solution, which was between the defined lower and upper bound, meeting all the constraints. Column thicknesses were shifted to 23.21, 19.63, and 21.14 mm, while beam thickness became 15.60 mm after seven iterations. The objective function of this case, which was the total steel volume/weight, had an initial value of 424.21 ton and a final value of 563.40 ton.

Figure 2 illustrates the comparison between the initial and final DCI indices. Initially, the DCI indices for beam and column members surpassed 1.0, implying member failure. After optimization, the maximum DCI for these members was reduced to 1.0. For instance, the maximum DCI for stories 1–5 columns decreased from 1.65 to 1.00, as depicted in Fig. 2b. This shows that the structural elements now offer adequate capacity to withstand applied loads without risking failure, while having the optimum member size with the minimum steel usage.

4.2 Optimization Results with Both Strength and Serviceability Constraints

The optimization results for the same 15-story building were further evaluated by considering both serviceability and strength constraints. To verify the serviceability constraint, larger member sizes were found to be needed to meet the requirements compared to Sect. 4.1. Therefore, for the beams, HSS sections were employed with outer dimensions of 400 mm × 400 mm. As for the column sections, HSS sections were assumed with outer dimensions of 500 mm × 500 mm for the stories at floors 1–5, 450 mm × 450 mm for the next five stories at floors 5–10, and 400 mm × 400 mm for the last five stories at floors 11–15. The lower and upper bounds for the flange/web thickness of beam and column sections were set at 12 mm and 100 mm, respectively. These bounds allowed the optimization algorithm to explore a range of thickness options while maintaining structural integrity within specified limits. Initially, the beam and column sections were configured with flange and web thicknesses set to 16 mm. After the optimization code was executed, the results indicated a shift in the thickness values of both column and beam sections from their initial starting points to the end points. The results of the optimization for iteration 0 (start point) and final iteration are summarized in Table 3.

The optimization process commenced with an initial uniform thickness setting of 16 mm for all columns and beams. The optimization algorithm continuously improved the solution by adjusting the thickness of the members to minimize the steel volume/weight, while meeting strength and serviceability criteria. In Table 3, *Feasibility* shows how much a solution violates the constraints. It quantifies the degree of constraint violation, with lower values indicating closer adherence to constraints. A decrease in *Feasibility* indicates a better convergence in results.

After 29 iterations, column thicknesses evolved to 64.59, 29.81, and 12.00 mm for T_{C1}, T_{C2}, and T_{C3}, respectively, while beam flange and web thicknesses became 39.17 mm. The initial objective function was 738.53 ton, which ultimately reached a final value of 1672.68 ton steel. Table 3 also shows the initial and final inter story drift ratios, confirming that serviceability constraints have been satisfied. The final story drift ratio matched the specified limit of 0.0025H, meeting the requirements set forth by the serviceability constraint. This outcome ensured that the structure maintains adequate performance under operational conditions, safeguarding against excessive drifts that could compromise its usability and safety.

Figure 3 shows the DCI values for structural members. All elements exhibited final DCI values within acceptable limits, confirming compliance with strength constraints and ensuring an economically efficient structural design. The final DCI

Table 3 Optimization results for member thicknesses with both strength and serviceability constraints

Iter.	Feasibility	T_b (mm)	T_{C1} (mm)	T_{C2} (mm)	T_{C3} (mm)	Weight (ton)	Max IDR
0	3.20E-03	16.00	16.00	16.00	16.00	738.53	0.0057H
29	1.65E-12	39.17	64.59	29.81	12.00	1672.68	0.0025H

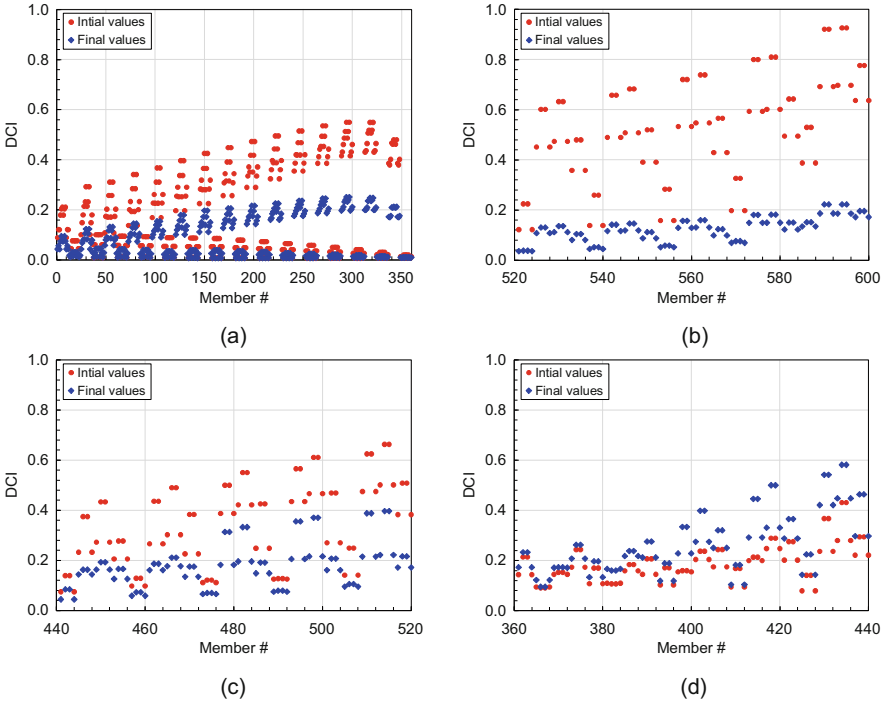

Fig. 3 Optimization results of DCI indices for building with strength and serviceability constraints: (**a**) beams, (**b**) columns at stories 1–5, (**c**) columns at stories 6–10, and (**d**) columns at stories 11–15

indices were in the range of 0–0.6, which is less than 1.0. It shows that inter story drift ratio governed the member size in a way that maximum inter story drift ratio was less than *H*/400.

In summary, the optimization method effectively generates cost-effective designs for structural members of a 15-story building under different scenarios, including both strength and serviceability constraints. These results highlight the versatility of the approach in achieving sustainable outcomes. Sustainable design practices, including minimizing material usage and optimizing energy efficiency, are essential for achieving net-zero buildings. By reducing steel usage while maintaining structural integrity, engineers contribute to environmental sustainability and align with broader goals of sustainable development.

5 Conclusions

This study evaluated the design optimization of steel buildings to optimize steel usage for achieving net-zero buildings, aligning with sustainable development goals. The outcome presented a robust framework for engineers to efficiently identify the

optimal cross-sectional dimensions of structural sections through automating the iterative design refinement process, while ensuring compliance with performance criteria, and minimizing carbon footprints in the built environment. The results obtained from applying the optimization tool to a 15-story building demonstrate its effectiveness in meeting both structural yield requirements and operational performance criteria, including a maximum story drift limited to $H/400$. This indicates that the presented approach offers a viable solution for designing buildings that not only fulfill structural demands but also uphold stringent operational standards, contributing to sustainable construction practices.

1 Introduction

To design a bridge structure, the following permanent and transient loads shall be often considered: horizontal earth pressure load, earth surcharge load, vertical pressure from dead load of earth fill, blast load, vehicular force (collision), ice load, water load and stream pressure, wave load, scour, and wind load [1] In the event of the occurrence of an extreme event, the specified load(s) will be allocated or augmented to exacerbate the pre-existing loads. This phenomenon underscores the importance of understanding and mitigating the impact of hazards on structural systems. Fragility functions are dependent on hazard intensity measures (IMs), which are used to create a fragility surface representing the probability of bridge failure. Khatami and Shafei [2] proposed a risk-based life-cycle analysis framework to enhance current bridge management systems by incorporating the consequences of sudden extreme events, such as environmental stressors and seismic hazards, into condition state predictions, thus improving performance and cost predictions, particularly in scenarios where the impact of extreme events cannot be overlooked.

Khatami and Shafei [3] investigated how climate conditions influence the deterioration of reinforced concrete bridges specifically in the US Midwest region. The referenced study aimed to understand the relationship between climate factors and the degradation of bridges in service to provide insights into improving maintenance practices and structural design considerations. A comprehensive study that involved collecting data on climate conditions, such as temperature, precipitation, humidity, and freeze-thaw cycles, in the US Midwest region was completed. Also, data on the condition of reinforced concrete bridges, including factors such as cracking, spalling, and corrosion, was gathered through field inspections and existing databases to correlate climate data with the observed deterioration of bridges. The study found significant correlations between certain climate conditions and the deterioration of reinforced concrete bridges. The results also highlighted specific vulnerabilities of these bridges to certain climate stressors, providing valuable insights for infrastructure management and maintenance planning. The current study aimed to explore the implications of load allocation and intensification in the context of hazards, specifically flood, and whether frequency has been considered to investigate the results of that.

Flood hazards can be defined in terms of the chance that a certain magnitude (area and depth) of flooding is exceeded in any given year (probabilistic event) or as a specific, deterministic event, such as a historic peak flow or recent event captured with high water marks. Depth, duration, and velocity of water in the floodplain are the primary factors contributing to flood losses. Other hazards associated with flooding that contribute to flood losses include channel erosion and migration, sediment deposition, bridge scour, and the impact of flood-borne debris. Flood magnitude is usually measured as a discharge value, flood elevation, or depth. Using the flood frequency convention, flood hazard is defined by a relation between the depth of flooding and the annual likelihood of inundation greater than that depth [4]. Flood hazards emphasize the challenges posed by scour, hydrodynamic loading, inundation, and debris accumulation.

2 Intensity Measures of Flood Hazard

2.1 Without Considering Climate Change

Lee et al. [5] investigated the vulnerability of bridges to floods, emphasizing factors such as water pressure, scour, corrosion, and debris as common causes of bridge destruction. The water pressure was identified as a critical water load, with AASHTO [6] defining it as the pressure of flowing water acting in the longitudinal direction of bridge substructures. The debris accumulation leads to increased water pressure on the bridge, affecting piers and girders. Water velocity was introduced as an intensity measure, and AASHTO [7] provides an equation to calculate water pressure based on flow velocity and drag coefficients for different pier types. The water pressure P (MPa) as Eq. (1), and the force exerted on the bridge was

determined by multiplying the calculated hydrodynamic pressure by the projected area subjected to the pressure. Also, Liao et al. [8] considered loads, including the vertical load, wind load, and hydrodynamic pressure.

The hydrodynamic pressure was calculated according to Eq. (1).

$$P = 5.14 \times 10^{-4} \, C_{\mathrm{D}} V^2 \tag{1}$$

where C_{D} denotes the drag coefficient for piers, depending on the geometric shape of the bridge and the accumulated debris or absence thereof, and V denotes the flow velocity (m/s) during a flood. Kim et al. [9] calculated scour depths around each pier by using an empirical equation, and the stiffness values of springs below the calculated scour depth remained unchanged. The study experimentally observed scour depth ratios for multiple piles to account for variations in scour depths based on pile arrangement and geometric shapes. Kim et al. [9] considered the increase in water velocity due to debris accumulation around bridge piers. The water pressure was estimated using equations recommended by AASHTO [7] and the Korean Highway Bridge Design Specification [10], incorporating the drag coefficient that depends on the pier type. The calculated water pressure as Eq. (1) was applied to bridge piers as an external load. An accurate consideration of scour is crucial, as it directly impacts bridge stability calculations. The scour depth for a single pier can be calculated using an empirical formula, e.g., Eq. (2) [9]:

$$S = 1.564 \, X^{0.405} \left(\frac{V}{\sqrt{gd}} \right)^{0.413} \tag{2}$$

where S is the scour depth, X is the relative approach flow depth, V is the water velocity, g is the gravitational acceleration, and d is the depth of the approach flow. Oppong et al. [11] investigated the vulnerability of bridges over navigable waterways to the combined effects of scour and barge collision. Scour scenarios were developed for 100- and 500-year flood events (determined from the annual peak discharge data reported by the United States Geological Survey (USGS)), following the procedure in the Hydraulic Engineering Circular No. 18 [12]. Alipour et al. [13] developed a multi-hazard reliability-based framework to assess the structural response of reinforced concrete (RC) bridges under combined pier scour and earthquake events, aiming to calibrate scour load-modification factors for bridges in high seismic areas. A deterministic approach utilizes established equations to calculate scour depth, while a probabilistic approach introduces uncertainties inherent in model parameters. Field data suggested discrepancies between observed and calculated scour depths, addressed by introducing a model factor with a normal distribution. Uncertainties in influential model parameters such as streambed condition coefficient and Manning roughness coefficient were considered with assumed probability distributions. Moreover, variability in flow discharge rate, a key factor in scour depth determination, was accounted for using peak annual discharge rate data from USGS, represented by rivers with low-flow and high-flow discharge rates, respectively.

Tubaldi et al. [14] developed a three-dimensional mesoscale representation of masonry arch bridges. Water flow imposed various actions on arch bridges during floods, including hydrodynamic pressure on submerged surfaces, reduced foundation capacities, buoyant forces affecting load-carrying capacity, impact from debris, and scour at bridge foundations, the latter being a common cause of collapse for arch bridges due to their vulnerability to foundation settlements. Arch bridges' low clearance makes them susceptible to debris accumulation, exacerbating scour and hydrodynamic forces. Khandel and Soliman [15] calculated hydrodynamic flood-induced load (F_{dyn}) based on FEMA [4] recommendations as Eq. (3).

$$F_{\text{dyn}} = \frac{1}{2}\, C_{\text{D}}\, \rho V^2 A \tag{3}$$

where C_{D} drag coefficient; ρ mass density of fluid (9.81 kN/m^3 for freshwater); V water velocity; and A surface area of obstruction normal to flow. Ahamed et al. [16] utilized HEC-RAS (River Analysis System) for one-dimensional surface profile analysis, which incorporated Manning's equation for discharge estimation and the energy equation for water surface profile computation. Hydraulic models, such as HEC-RAS [17] developed by the US Army Corps of Engineers, simulate river hydraulics by considering factors like discharge, velocity, and flow depth. HEC-RAS generates flow hydraulic properties, including velocity, flow depth, and discharge at the bridge location, and calculates local, and contraction scours around bridge piers using established bridge scour relations from [12]. The discharge was estimated using Manning's equation as Eq. (4).

$$Q = \left(\frac{1}{n}\right) A R^{2/3} \sqrt{S} \tag{4}$$

where n is Manning's roughness coefficient, A is the area of the flow, R is the hydraulic radius, S is the slope of energy line.

Anisha et al. [18] reported that the stochastic responses of a bridge are influenced by random geometric and material parameters and flood loading parameters. Parameters like pile diameter, pier depth, pier width, deck width, span, pile height, steel yield strength, modulus of elasticity, concrete mass density, and compressive strength are considered random. Various flood-related parameters such as hydrodynamic loads, scouring, water table depth, buoyancy, debris accumulation, turbulence, and frequency of flood events, were treated as highly uncertain. The water pressure was determined by a formula incorporating flow velocity and a random parameter, Q.

$$F(h) = Q.F_0(h) \tag{5}$$

$$F_0(h) = 52KV(h)^2 \tag{6}$$

where $V(h)^2$ in m/s represents the flow velocity at a height h, and K is a constant that depends on the shape of the pier. The randomness in water pressure $F_0(h)$ is

incorporated by the parameter Q, which was assumed to have a normal distribution with a unit mean and a 10% standard deviation.

2.2 With Considering Climate Change

Kulkarni and Shafei [19] investigated Iowa's transportation infrastructure, particularly focusing on its susceptibility to extreme weather events such as flooding, utilized Bayesian belief networks to assess the impact and predict the probability of damage to roads and bridges, considering climate projections. Future climate conditions in Iowa were projected to include increased precipitation, more extreme temperatures, and more frequent heat waves, leading to higher risks of flooding, landslides, and infrastructure deterioration due to thermal effects, emphasizing the need for long-term design considerations and the assessment of existing infrastructure's resilience to projected environmental stressors. Loli et al. [20] used the Digital Elevation Model (DEM), specifically the FABDEM (Forest and Buildings removed Copernicus Digital Elevation Model) with improved accuracy, which serves as a base layer for mapping elevation, ground slope, and hydrography. Satellite imagery from Copernicus Sentinel-2 aids in land use/cover mapping. The USGS (United States Geological Survey) provides the shear wave velocity map, while soil permeability data are sourced from the global hydrogeology map GLHYMPS 2.0. Using the ERA5-Land dataset, a map of climatological maximum daily accumulated precipitation during Ianos was generated, illustrating the exceptionally intense rainfall in the study area.

Comparison with precipitation records since 1950 underscores the unprecedented intensity, with the Ianos event producing over twice the annual maximum daily precipitation observed from 1950 to 2022 (Fig. 1). The estimated precipitation peak closely aligns with the measured rain gauge value reported in the study. Loli et al.

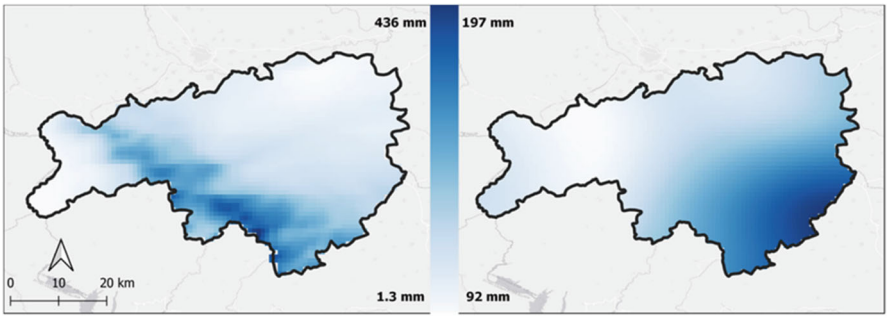

Fig. 1 Rainfall: (**a**) accumulated daily precipitation on the day that Medicane Ianos stroke (September 18, 2020) compared to (**b**) the annual maximum daily precipitation between 1950 and 2022 (Note: the two contour plots have different scales) [20]

[20] considered the hydraulic actions on bridges due to floods with two primary components: Component 1, consisting of hydrodynamic loads (drag and lift forces), and Component 2, involving scour. Hydrodynamic loads act in the direction of and perpendicular to the flow determined by Eq. (3). Scour (d_s) weakens the foundation's bearing capacity due to general scour, contraction scour, and local scour. The scour depth depended on various parameters, and these elements collectively contribute to the formulation of a new index of flood hazard intensity (IFHI). IFHI integrates indicators related to flow intensity, general scour, contraction scour, and local scour, offering a comprehensive assessment of flood hazard on bridges. This index considered parameters, such as flow velocity (U), flow depth (h_w), width of flow obstruction (B), median grain size (D_{50}), and critical flow velocity (U_c). The Index of Flow Intensity (IFI) is a significant component of IFHI, accounting for hydrodynamic loads based on multi-criteria decision-making analysis. Scour indicators (A_1, A_2, A_3) factored into IFHI are estimated following the approach proposed by the AROSA guidelines [21] but modified appropriately to incorporate U in the scoring of scour susceptibility, in agreement with the relevant theoretical framework described by Eq. (7).

$$d_s = f(U, h_w, D_{50}, B, U_c) \tag{7}$$

$$\text{IFHI} = \text{IFI}(A_1 + A_2 + A_3) \tag{8}$$

Kosic et al. [22] utilized numerical simulations to gather hydraulic data for vulnerability assessment, focusing on extreme flooding events in 2014 and 2015. They depicted complex hydraulic conditions at bridge locations through relationships between water height, water discharge, and flow velocities, considering unsteady flow conditions due to data dispersion and limited observations. The assessment incorporated 95% prediction intervals from steady-flow Manning's equation regression to explore severe flooding scenarios. Loads on the bridge structure included gravity, hydrodynamic forces (drag and lift), buoyancy forces, and wood debris accumulation, computed according to the Australian standard [23]. Buoyancy force varied with deck submergence, while debris dimensions were determined by the debris Froude number. The depth of local scour near the bridge pier was calculated using the HEC-18 [12] equation, considering correction factors for pier nose shape, flow angle of attack, and riverbed conditions. The Froude number was defined based on mean flow velocity, gravity, and water height upstream of the pier. Kosic et al. [24] sourced the hydrological data for the bridge from the Karlovac measuring station 20 m upstream, the stream stage-discharge curve exhibits hysteretic behavior, reflecting non-stationary flow influenced by nearby effluents. The relationship between water height and mean flow velocity was not uniquely defined, and an estimation derived from numerical simulations conducted for historical flood events (2005, 2014, 2015) was considered. The depth of local pier scour for each flood scenario was determined using HEC-18 [12] guidelines, incorporating correction factors for pier nose shape, flow angle, and riverbed conditions.

Also, Khatami et al. [25] developed a data-assisted framework that incorporates physics-based models for predicting the deterioration of reinforced concrete bridges, and to improve the condition state predictions made by bridge management systems, which relied heavily on inspection data and expert opinions to develop deterioration models based on Markov processes. The system had limitations due to the unavailability of long-term inspection data, low quality of available data, and potential errors in expert opinions. The physics-based method models the two stages of chloride-induced corrosion in reinforced concrete bridges: (1) The corrosion initiation stage uses Fick's second law to estimate chloride ingress and corrosion initiation time based on diffusion coefficient, surface chloride, and threshold, determining hazard rates for Condition States; (2) The corrosion propagation stage employs Butler-Volmer kinetics and oxygen diffusion to estimate steel mass loss, crack widths from a thick-walled cylinder model mapped to higher condition states, with hazard rates based on Tafel slopes and oxygen concentrations. As mentioned, most existing studies on transportation network resilience did not account for the effects of aging and deterioration of bridges, leading to inaccurate predictions. Alipour and Shafei [26] Developed an integrated simulation-based framework for assessing resilience of deteriorating transportation networks subjected to combined effects of environmental stressors like corrosion, temperature variations, etc. and seismic events.

Despite efforts to enhance bridge resiliency, challenges such as a lack of knowledge, gaps between research and practical approaches, budget constraints, and insufficient risk assessments, urge joint efforts among academia, decision-makers, and technical specialists.

3 Conclusions

The comprehensive exploration of load allocation and intensification within the context of hazards, particularly flood events, underscores the critical importance of understanding and mitigating the impacts of natural disasters on bridge infrastructure. The studies reviewed factors such as hydrodynamic forces, scouring and debris accumulation. Despite the advancements in hydraulic modeling and structural analysis techniques, challenges persist, including uncertainties in hazard prediction, gaps between research and practical applications, and limitations in current risk assessment methodologies. Notably, the absence of consideration for climate change in past studies points to a critical area for future research and intervention. Given the projected increase in the intensity and frequency of extreme weather events due to climate change, incorporating climate variability and long-term trends into hazard assessments and infrastructure design is imperative for ensuring the resilience and longevity of bridge structures. Moving forward, collaborative efforts are essential to address the complex challenges posed by flood hazards and climate change on bridge infrastructure. By integrating advancements in modeling techniques, data analytics, and risk assessment methodologies, alongside proactive adaptation

strategies, the resilience of bridges can be enhanced. This will help mitigate the potential impacts of future flood events, ultimately safeguarding critical transportation networks and promoting sustainable infrastructure development.

1 Introduction

Emissions from the production of traditional building materials, and especially structural materials like reinforced concrete, play an important role in the climate crisis that is facing us today. Cement production alone contributes to almost 7% of global greenhouse gas emissions, and its demand is expected to increase by 12–23% by 2050, whereas the steel and iron industry is responsible to 7–9% of emissions [1]. Because of this, the construction sector is looking for alternative materials for structural applications, and wood is a natural candidate.

1.1 Wood as a Sustainable Building Material

Wood has been used for centuries in construction as an essential, versatile, and truly renewable building material. This is particularly true for the Nordics, whose abundant forest resources produce around 20% of lumber in Europe [2]. In addition to their material availability and long-standing woodworking tradition, the Nordics have climate commitments to carbon-neutral building solutions, which have been propelling the use of timber in buildings.

Furthermore, advancements in engineered wood products and innovative construction techniques have expanded the potential applications of wood in construction projects, making it a viable option for structural elements in large infrastructure with more severe strength and durability requirements, such as bridges.

A few important considerations must be made regarding the sustainability of wood, which will fall outside the scope of the current analysis. Following the projected growth in demand in the coming years, and since its production capabilities are limited, there will be a need to prioritize the use of wood in the coming years, especially in the case of projects that will require a very intensive use of this material. It is also crucial to note that wood has significant impacts across several environmental impact categories during its life cycle. As an example, only recently is the building sector starting to develop tools to assess the biodiversity impacts of wood, as intensive management of forests, land use change, and the subsequent habitat destruction are all causes of biodiversity loss.

The current analysis sets out to focus only on impacts on the climate, so the Global Warming Potential (GWP) is the only indicator considered—from now on referred to as carbon, as it is expressed in kg CO_2-equivalent.

1.2 Climate Impacts of Timber in Bridges

There are currently no standards or guidelines on how to best assess the sustainability performance of timber bridges. It is left to sustainability professionals to decide on what methodology and approach to take, to get around the intricacies of this task.

Only a very limited number of LCA studies have been conducted to assess the sustainability of bridges with timber as a primary construction material, and many intricacies regarding their carbon profile emerged from a review study from 2018 [3]. The authors state in their findings that “the consideration of carbon storage of wood material needs to be carefully treated” and that depending on the main purpose of the investigation, one must consider both options of assuming:

- No carbon storage, thus excluding biogenic carbon from the analysis and treating wood as carbon-neutral
- Carbon storage, thus including biogenic carbon flows in the analysis

All reviewed studies in the chapter except for one fall in the first group, using an approach that arguably oversimplifies the carbon flows from the life cycle of wood products. Our study sets out to include these carbon flows and explore different ways of doing so.

2 Materials and Methods

This section will include a brief description of the subject bridge, one subsection outlining some important concepts in LCA, and the other following the setup of the three comparative LCA studies performed.

2.1 Bridge Design

The original project considered in this analysis is the Remmevej highway overpass, a glued laminated timber bridge opened in 2001 in Jutland, Denmark. As shown in Fig. 1, the bridge has an overall length of 54 m, divided into a main span of 26 m and two side spans of each 14 m.

In the period preceding its construction, the Danish Road Directorate had taken interest in investigating advantages of other types of construction materials used in infrastructures. COWI was thus involved in all stages of the Remmevej bridge project, carrying out conceptual design, preliminary studies, detailed design, and supervising construction operations of this timber bridge. Parameters such as construction and operation costs, service life, aesthetics, climate and ecosystem impacts, and scarcity of local resources (e.g., aggregates) were discussed during the design and construction of the bridge to demonstrate the performance of the structure over its 100 years' service life.

For the purpose of this study, the Remmevej design was compared to a typical pre-stressed concrete bridge with the same use and dimensions, assumed to be built in Denmark in the same year, and for which the bill of quantities was known by

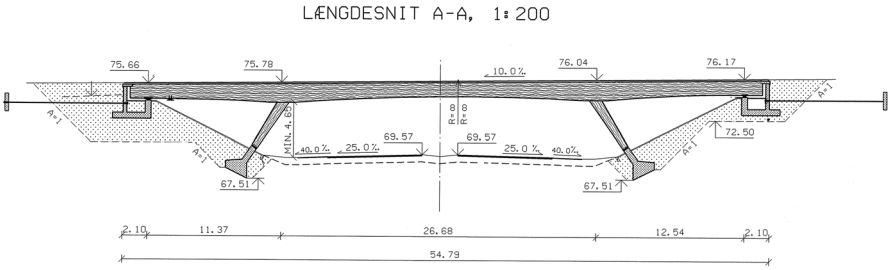

Fig. 1 Drawing of the Remmevej bridge (measures in meters)

COWI. Both bridges were designed to carry normal vehicular loads per codified standards comparable to EN 1991-2 and with a typical geometry to serve such purpose.

2.2 Service Life

The classical definition for service life of concrete bridges in Denmark is 100 years for the primary load carrying structure (concrete, reinforcement, post-tensioning) when operated and maintained at normal and foreseeable efforts and measures. This is confirmed by the Danish Road Directorate's experience with designing, building, and maintaining similar concrete structures.

There is no such proven track record for road carrying bridges using glue laminated timber as the primary construction material. In the case of the Remmevej bridge, Danbro (Danish Road Directorate Bridge Management System, BMS) shows no reported maintenance issues, and the next forecasted primary maintenance effort will be replacement of waterproofing and pavement which is due to happen in some years. This is not different from comparable concrete bridges.

Reviewing the experience from other countries, the service life of timber bridges has a wide range, which can be summarized by the Norwegian requirements: a default service life 100 years, which may be reduced to 50 years if replacement is planned. For this reason, it was decided to assign a service life of 100 years to the concrete bridge, and two alternative service lives of, respectively, 100 and 50 years to the wooden bridge, to cover different potential scenarios. For the shorter service life, it is assumed that the bridge will see a 1 to 1 replacement of structural elements after 50 years, doubling its service life to reach the study's time horizon.

2.3 LCA Concepts Used in the Study

Attributional and Consequential Approaches to LCA

There are two accepted approaches to performing an LCALife cycle assessment (LCA), which aim at answering two different questions. An attributional spiepr IndexRangeStart ID="ITerm48"spiepr IndexRangeStart ID="ITerm13"LCALife cycle assessment (LCA) aims to describe the environmentally relevant physical flows to and from a life cycle and its subsystems, answering the question: what share of the global environmental burdens belongs to a product, process, or system? A consequential LCALife cycle assessment (LCA) aims to describe how environmentally relevant flows will change in response to possible decisions, answering the question: how are the global environmental burdens affected by the production and use of the product? [4, 5].

Following the attributional principle, by compiling the LCA of every activity in the world, the sum of all these results would amount to the actual total anthropogenic

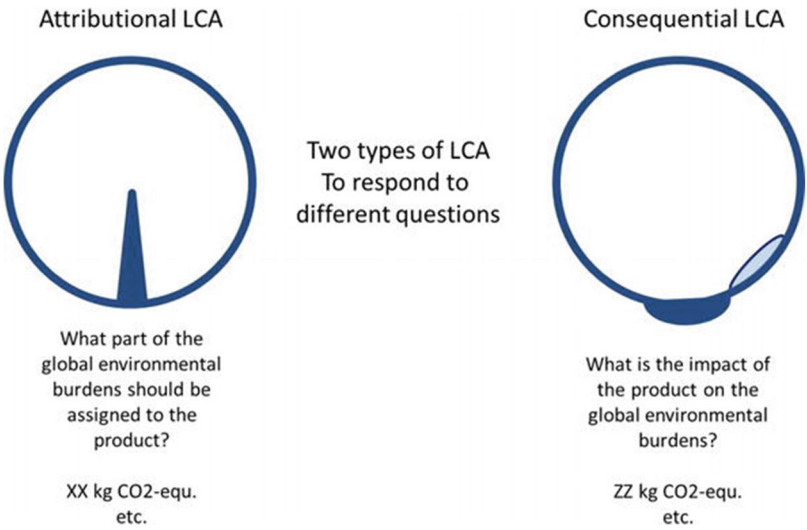

Fig. 2 Illustration of attributional and consequential approaches to LCA. The large circles symbolize the total environmental burdens of the world [5]

environmental impacts at that given time. The consequential principle is instead interested in changes to global production, and it aims at including in its analysis the ripple effects in other product systems reflecting market dynamics and technological change. This is illustrated in Fig. 2.

It must be noticed that there are still some unresolved issues in giving a clear definition to either system. One of the reference documents used in Europe for LCA, the ILCD Handbook [6], contains a distinction between the applicability of each model that has received strong criticism from consequential academia [7]. It is thus important to be extremely clear in formulating the goal, scope, and assumption of each LCA study.

Discounting Emissions

When building with wood, the biogenic carbon absorbed by the tree during its life is stored in the wood for the whole lifetime of the asset, and possibly beyond. To account for this carbon storage, the European Commission's ILCD Handbook [6] and the British Publicly Available Specification (PAS) 2050 [8] allow to discount emissions over time. This approach is based on the IPCC models of the residence time of a CO_2 pulse in the atmosphere following the 100-year criterion. With this approach, delayed emissions are accounted for with a linear discounting rate of 1% per year during a maximum of 100 years. At this point of time there is a cutoff, and all emissions occurring after this will have zero effects on the time interval [9].

It must be noted that the discounting of emissions is a practice that raises some methodological, scientific, and ethical controversies in the world of LCA, and for a more detailed discussion on this, please refer to [9, 10]. This optional method is however tested in this study to explore its implications on the result.

Logging Effect
This is a more conservative approach for accounting for the embodied carbon in wood, which was developed for this analysis based on a study that COWI conducted for the Norwegian Water Resources and Energy Directorate (NVE) in 2015 [11]. This approach includes the following assumptions:

- The decision to cut down a tree does not affect any carbon emissions up to that point; hence, no credits (negative emissions) are assigned for uptake during growth.
- The counterfactual scenario — had the tree not been cut down, how much CO_2 would it have taken up from this point on? This missed carbon sink will be deducted.
- The future uptake from a new tree growing where the old tree was cut will be included.
- Only ¼ of trunks end up as solid wood material, while the rest is planed off or discarded for quality reasons, and instead used for other purposes.
- The emissions from rotting branches left on the forest floor.
- The albedo effect — a clear-cut, snow-covered plot of land reflects more sunlight than an evergreen canopy.

All the above has been modeled in the COWI-NVE study and included in the emission factors in the third LCA presented below, together with the discounting approach.

2.4 Methodology of the LCA Study

Goal
The study sets out to provide a use case for integrating carbon considerations in the choice between wood and reinforced concrete in the construction of road bridges, and a methodological starting point for future LCA investigations on large timber infrastructure. It compares two real bridge designs, one constructed with traditional reinforced concrete and the other utilizing wood as the principal material, with a double goal:

1. Assessing their respective climate performance
2. Assessing the changes in such results when repeating the study through different approaches and assumptions:
   (a) Attributional approach
   (b) Consequential approach
   (c) Consequential approach, logging effect, and discounting of the emissions

   In all three approaches, two options were considered for the timber bridge: one assuming a structure with a life span of 100 years, another assuming a life span of 50 years, with complete replacement of timber elements at 50 years to complete

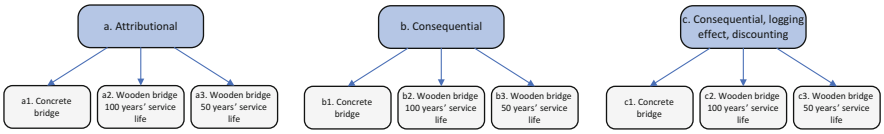

Fig. 3 Structure of the study

the 100 years' service life of the bridge. The structure of the study is illustrated in Fig. 3.

The functional unit is one bridge for road use.

Scope

The LCA is at screening-level and follows the general LCA structure of ISO 14040 and ISO 14044. The life cycle stages used in the study are:

- Production (A1–A3) includes raw materials extraction (including uptake of greenhouse gasses by the trees in the forests), processing of raw materials, transportation, and production of materials and products.
- Replacement (B4) includes replacement of construction elements where needed. The phase includes the production of the element and the end-of-life processes of the removed element.
- End of life (C3–C4) includes waste processing of the materials, such as recycling of steel, downcycling of concrete to produce gravel for roads, or incineration for wood.
- Next product system (D) includes environmental burdens and benefits beyond the defined system boundary, in this case after the bridge's service life, and captures the potential for recycling or utilization of waste materials, e.g., the energy recovered from wood incineration.

In the case of "c," the logging effect was included in the system definition and considered in the analysis, and the emissions for the time series were modeled following the principle of linear discounting over the study's time horizon. In all cases, emissions from traffic on the bridge are excluded from the use stage.

The time horizon of the study is also 100 years, and the geographical scope is Denmark, with lumber sourced from Norway or other Nordic countries. The results are not intended to be directly applied to future construction projects, as only one impact category is considered and the design for the wooden bridge is over 20 years old.

LCI and LCIA

For all three studies, the LCI and LCIA are integrated and sometimes implicit in the EPDs and databases used to extract relevant GWP values for the different materials and processes in each life cycle stage. The method and sources for each of the three studies is illustrated here:

(a) In the attributional study, the inventory of emissions for wood and concrete products was compiled using EPDs for Danish products, while for the rest of

materials and processes, as well as for the missing life cycle stages, the Norwegian VejLCA and German Ökobaudat databases were used.
(b) Study "b" uses a consequential version of the Ecoinvent database.
(c) Study "c" uses same database as "b," but also incorporates the "logging effect" model to calculate the emission factors of wood products. In this model, the discounting of carbon follows the factors taken from the CIRAIG Dynamic Carbon Footprinter tool.

3 Results and Discussion

(a) *Attributional Approach*

The results of the LCIA for the first approach, shown in Fig. 4, show that the concrete bridge has the worst performance in terms of GWP impacts.

In the emissions for production and replacement, all wood, including formwork, contributes with a negative sign. The EPDs used for the inventories of the wooden products include the carbon storage of the wood, and for all of them the carbon sink during the growth of the wood more than offsets the emissions caused during logging, manufacturing, and transport of the wooden materials. In the case of the wooden bridge, the negative emissions from the wood more than offset all other construction materials as well, giving an overall negative sign to production.

The production stage accounts for 89% of the total emissions of the concrete bridge, and 89% of the production emissions is attributed to concrete and steel. This is due to their large material quantities and high carbon intensity.

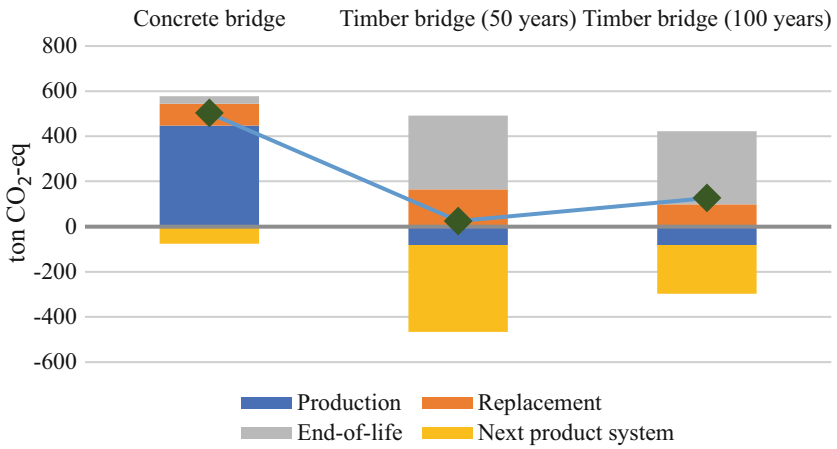

Fig. 4 Attributional approach results

Replacement captures those elements that need to be substituted during the life cycle of the bridge, including their end of life. In the case of the 50-year wooden bridge, this quantity has substantially higher emissions as it takes into account the carbon emitted to the atmosphere by the incineration of the old wood.

The end of life of steel and concrete has a much lower carbon intensity than that of wood, and it generates negative emissions (credits) in the next product system because of recycling. This factor is very low in the case of concrete and significant in the case of steel. The energy produced from wood combustion is credited to the scenario in module D. As the electricity and heat production in Denmark is projected to become greener over the coming years, the credit decreases and becomes very low after year 2050. This means that the benefit of using timber in construction becomes smaller and smaller as the benefit of energy production is being reduced.

It can be concluded that, at a project-level, a wooden bridge has a better carbon profile than a concrete one. It is important to note that this result is not appropriate for considering larger, systemic changes, for example a decision at the national level.

(b) *Consequential Approach*

The overall picture looks similar when using the consequential approach, as the concrete bridge is still the worst-performing in terms of carbon, as shown in Fig. 5.

Its savings in the next product system, however, are larger in all cases. This is because the consequential approach considers the ripple effects of waste recycling and utilization, such as changes in market dynamics, resource allocation, and waste management practices. This holistic approach allows the model to capture indirect impacts that may not be fully accounted for in attributional LCA.

Steel is a particularly good example, as it is observed that in its next product system, the scrap steel's recycling, and subsequent displacement of average steel on the market offsets more than half of the life cycle emissions from steel.

It is interesting to observe that, as in the previous case, the more wood is used, the lower the environmental burdens. An extreme case of this is provided by the 50 year

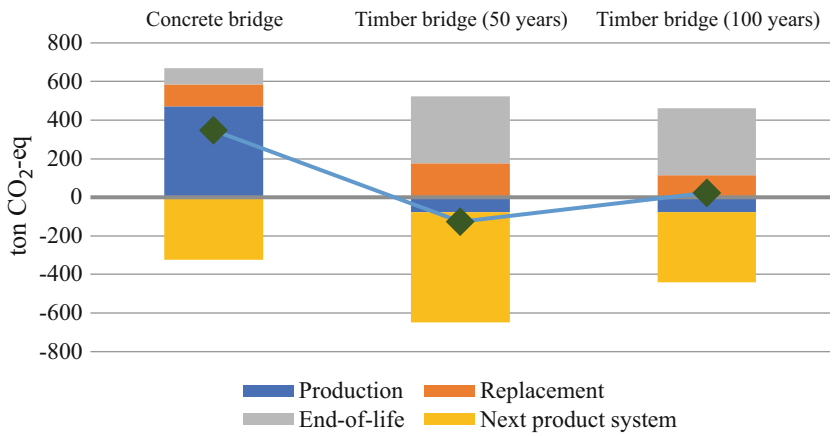

Fig. 5 Consequential approach results

bridge, where the total emissions appear to be negative, suggesting that constructing a shorter-lived wooden bridge would actually result in a net carbon sink of −127 t CO_2-eq, as opposed to 347 t CO_2-eq that the concrete bridge would contribute to.

(c) *Consequential Approach, Logging Effect and Discounting*

The radically different set of assumptions used in this third approach is reflected in the results, which show an entirely new picture compared to the previous two cases. In this case, it appears that the short-lived timber bridge is by far the highest emitter, as it is responsible for the emission of 1961 t CO_2-eq. This can be observed in Fig. 6.

This approach takes into consideration the opportunity cost of not extracting timber, but it also uses some specific assumptions, setting the cut-off at 100 years and carbon discounting until that point. This allows to fully discount all end-of-life and next product system emissions, as they will in fact be responsible for no radiative forcings during the time horizon of the study. The only exception would be the end-of-life of old material after replacement, which is in replacement, and their beyond life cycle impacts found in next product system, in this case only structural wood, which is however discounted by 59% following the carbon discounting rule set up in this study.

This allows to focus on the emissions from the production of all materials, which is similar to the previous studies for the concrete bridge, and entirely different for the wooden ones. This is in turn a direct consequence of the assumptions expressed in the logging effect, which try to represent the opportunity cost of logging as opposed to not extracting wood and letting the forest grow.

From this result, it can be concluded that when considering the opportunity cost of logging and for how long emitted CO_2 will actually cause radiative forcing within the 100-year study period, a timber bridge will cause more global warming than a concrete bridge.

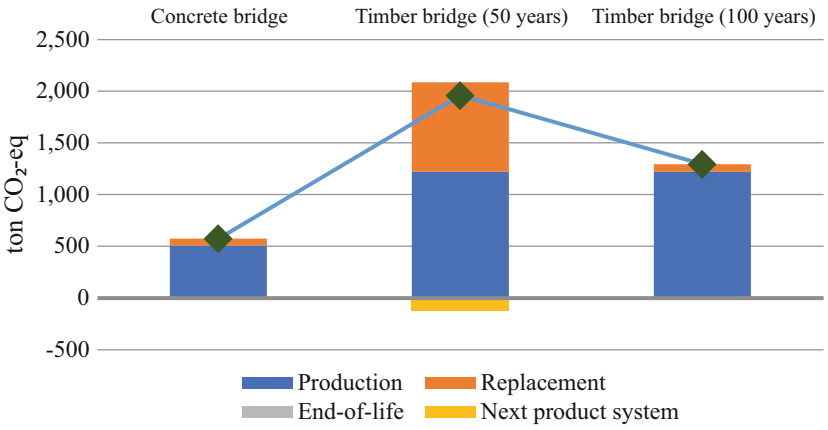

Fig. 6 Consequential approach, logging effect, discounting results

Table 1 Comparison of the results from the three LCAs

	Concrete bridge [ton CO_2-eq]	Timber bridge (50 years) [ton CO_2-eq]	Timber bridge (100 years) [ton CO_2-eq]
(a) Attributional approach	502	25	126
(b) Consequential approach	347	−127	23
(c) Consequential approach, logging effect, discounting	384	2457	1323

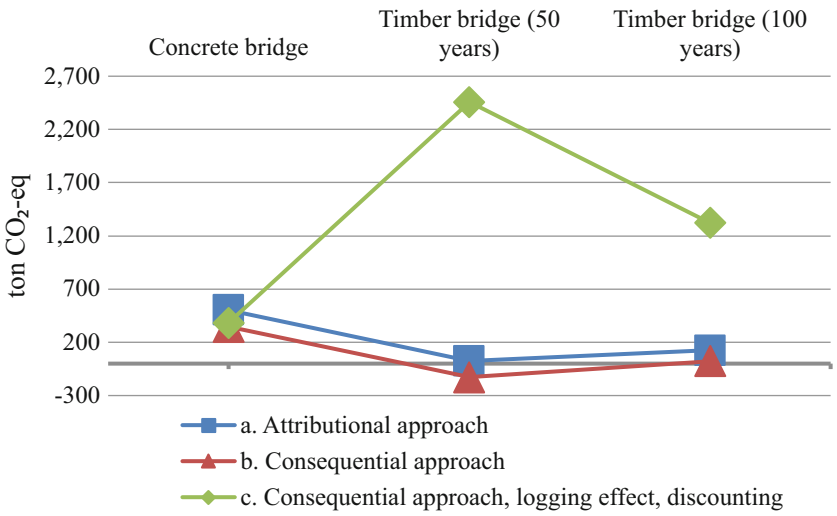

Fig. 7 Comparison of the results from the three LCAs

Comparison

Whereas the embodied carbon of the concrete bridge is comparable across the studies, the 100 years wooden bridge varies by 2 orders of magnitude and the 50 years bridge even changes the sign of its contribution—from carbon sink to huge climate offender. More detail on the results can be observed in Table 1 and Fig. 7.

4 Conclusions

The study successfully conducted all three life cycle assessments. Comparing the first two studies showed that, notwithstanding the deep methodological and conceptual differences between the attributional and consequential approaches, their application to this specific bridge project yielded some overall similar results. In all three

cases, the consequential study tends to provide an overall lower global warming potential, which is due to the consequential approach's ability to include more indirect impacts in its analysis, with a particular emphasis on recycling and waste utilization.

Looking at the results of the study, approach "c" is clearly an outlier. Its importance is to provide an example of how a different framing of the initial research question can lead to wildly different results. The considerations at the base of this approach can help us acknowledge that current carbon accounting practices are varying widely, especially when analyzing biogenic carbon, and that by changing the initial question, the answer might be just opposite.

When looking at a single project like Remmevej, it is common to adopt a framing that is closer to the attributional question: how much carbon is this project responsible for? But when addressing the larger question: what role will wood play in the future of bridges? This question must stem for a deeper reflection on how a substantial increase in the demand of wood will affect its supply and change land use. For this type of analysis, it might be more appropriate to use the consequential approach and to include more impact categories in the analysis to address all relevant impacts on ecosystems, human health, and resource availability.

1 Introduction

The United Nations envision in the Agenda 2030 a roadmap toward a peaceful and prosperous world for people, a planet for today and future generations [1]. The transport sector is an important component for the achievement of this vision. A well-functioning transport sector promotes economic advancement, social inclusivity, and well-being of nations and regions [2]. The transport sector does so by providing services and infrastructures capable to enhance mobility of goods and people in a safe, resilient, accessible, efficient, and affordable way while minimizing the related environmental impact [3]. Countries are aligning with this vision in their respective national transport plans.

Over the life cycle of a road infrastructure, the operational stage is the longest one and requires maintenance and rehabilitations activities to keep the road at a

M. Kioumarsi, B. Shafei (eds.), *The 1st International Conference on Net-Zero Built Environment*, Lecture Notes in Civil Engineering 237,
https://doi.org/10.1007/978-3-031-69626-8_130

satisfactory level of service. Significant national resources are spent every year to keep the infrastructure at the expected levels [4–6]. To maintain and/or rehabilitate the infrastructure, there is the need to monitor and assess the condition of the road network and finally evaluate potential need for maintenance and/or rehabilitation activities. Road monitoring systems can be deployed to inspect the status of the road network. Each monitoring system produces big data that are collected, stored, and analyzed by appropriate Pavement Management Systems (PMS). These PMS can support road decision-makers while prioritizing the road network sections to be maintained and/or rehabilitated. The decision-making process is not trivial as it is a balance among different aspects to be considered simultaneously [32].

The present chapter presents an overview of the decision-making process of road maintenance using as a case study the Norwegian case. At first, this work presents a background on road monitoring systems and pavement management systems, and then it focuses on the decision-making process of road maintenance in Norway. This chapter aims to bring the attention to the opportunities and challenges of maintenance decision-making process in line with the Norwegian national transport plan.

2 Background

2.1 Road Surface Characteristics

There are multiple road characteristics that may be inspected. These characteristics include road friction, texture, smoothness, unevenness, and others. These characteristics are represented by parameters such as road friction, International Roughness Index (IRI) [7], Mean Profile Depth (MPD) [8], rut depth [9], and road defects (e.g., cracks and potholes). By measuring these parameters, it is possible to assess and evaluate the condition of the road network.

2.2 Road Monitoring Systems

Monitoring activities of a road network is an essential task to detect poor road conditions. Different approaches have been developed during the years to monitor roads, from static measurements to continuous measurements [8, 10]. Continuous measurements are typically sensor systems mounted on vehicle platforms (e.g., cars) which may drive at normal driving speed and collect continuous measurements. The main components of these systems comprehend a measurement sensor (laser-based, mechanical, camera-based, etc.), geo-localization sensor (GPS/GNSS), and orientation sensor (IMU) [10, 11]. Vehicle platforms include Unmanned Aerial Vehicles (UAVs) [13, 14]. In recent years, the literature also observes the use of mobile phones to inspect roads [12, 15, 16]. These monitoring systems are adopted from

operators to inspect the roads continuously. Each inspection activity collects a high amount of road information which may be collected multiple times over a period of time (1 or more years). This big data is handled by PMS.

2.3 Pavement Management Systems

The management of the pavement infrastructure is defined as a process which assesses and evaluates with a given priority the maintenance and rehabilitation tasks of a road network, optimizing the relative resources [17, 18]. Through the use of heterogeneous big data (e.g., road conditions, annual traffic, budgets, and policies), PMSs assess the quality of the road network pavement, with the use of engineered indexes [e.g., Pavement Condition Indexes (PCIs)] and designed models. These indexes and models predict the quality and performance of the road network and assign prioritization levels of segments in the road network [19–21]. There are different PMSs that can be adopted from road authorities [20, 22, 23]. The authors [24] investigate the accuracy of the predictive models with their relative consequences in case the actual and predicted values of the investigated models vary, quantifying the budgetary implications of the relative impact. With a focus on highway pavement management, the authors [25] describe the potentialities of the Geographic Information System (GIS) for PMS purpose. In their work, the authors [26] studied and evaluated the potentialities of data mining and knowledge discovery (DMKD) combined with GIS for pavement management purposes. Their approach may provide consistent decisions and optimize resources (time and costs related) by speeding up the decision-making process. However, this approach requires verification in post-processing phases. While [27] describes how the GIS-PMS approach can be a valuable tool for evaluating the quality of pavement condition of road network in proximity to the city of Lisbon, the authors in [28] propose a database management system which might assist small municipalities facing budget constraints. The work [29] presents a model of GIS in PMS integrated with the Life Cycle Analysis (LCA) to predict pavement distresses and support decision-making processes.

3 Case Study: The Norwegian Road Transport Sector

The Norwegian road network comprehended 10,500 km of national roads and 45,000 km of county roads. Prior 2020, Norway comprised 19 counties. The Norwegian Public Road Administration (NPRA) was responsible for the whole Norwegian road network, on behalf of government and counties. In 2020 there was a reorganization of the road transport sector and the NPRA became responsible for the national road network (10,500 km), while the counties (downsized from 19 to 11) became responsible for the county road network (45,000 km) [30].

The budget for the road maintenance is based on the national funding (amount per year designated to the maintenance). Based on the budget, the section of roads within the road network is classified with a given priority. Based on their priority, the budget is allocated to maintain the roads with the highest priority. Technical requirements of the road network, and related level of service, can be found in [31].

3.1 Power Relations in Road Infrastructure Maintenance

Figure 1 shows the power relations between operators, decision-makers, and executors. The below conceptual model contains a color categorization (color boxes) to depict the correlations between the actors and their functions.

Based on the road network they are responsible for, operators (NPRA, counties or consultancies) perform road data collections (or inspections) and store the collected data. Then, decision-makers (e.g., national road authority and/or counties) adopt the stored data to assess and evaluate potential actions to improve the quality of the road network. After it is decided which road sections require maintenance and rehabilitations, executors (e.g., road contractors) require to perform actions oriented to improve the quality of the road sections.

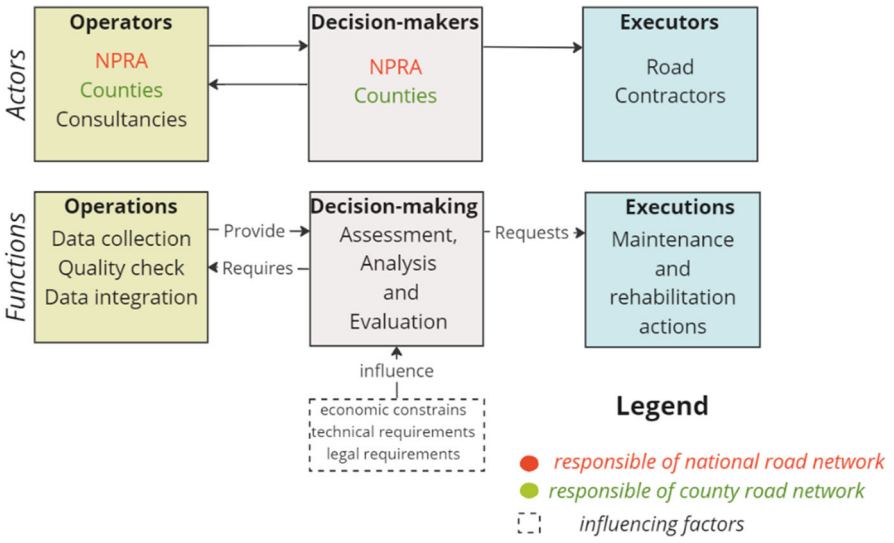

Fig. 1 Power roles, actors, and functions in road maintenance decision-making, inspired from [32]

3.2 Maintenance Decision-Making Process

The process begins with the selection of a desired road characteristic(s) to be assessed over the interested road network. After that, the road network is inspected, and road information is retrieved. After road inspections, reports containing geo-localized road data are generated. The operator generates and stores the reports in the national database, Rosita. Rosita is a data bank system that stores any road characteristics data retrieved from the Norwegian network according to international standard criteria. Rosita includes national road and counties road network information.

Further step is the analysis of road deterioration over the years. The historical reports related to the interested road characteristic(s) are retrieved in Rosita, and the progressive deterioration is analyzed. The PMS analyze, assess, and evaluate the condition of the road network by merging Rosita's data with the annual traffic conditions, technical/legal requirements [31] for the interested road network, and economic yearly budgets. The PMS categorizes each section of the road network based on the severity of the road condition and its potential impact on road traffic. In case the quality level is critical (road characteristic(s) value(s) is near or below requirement(s) legal/technical threshold limits), road maintenance/rehabilitation actions are mandatory. In contrary cases, the prioritization of the road maintenance follows the PMS's categories of priority. NVDB stores road network's information such as geometry, topology, road's constituents (equipment, drainage, etc.), infrastructure layers' properties, traffic volumes, and accidents. NVDB's information is also included in the PMS analysis and evaluations. Figure 2 shows the system constituents to perform a data-driven decision-making, and Fig. 3 shows the roam maintenance workflow.

4 Discussions

The Norwegian transport plan envisions transport infrastructures that are safe, effective, valuable for end user, innovative, and environmentally friendly [35]. This applies also to road infrastructure. Maintenance activities and related decision-making are of primary importance to keep road infrastructure at acceptable

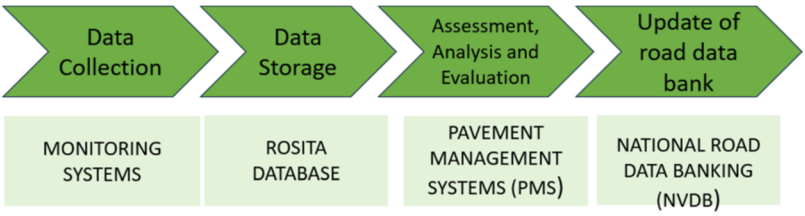

Fig. 2 Systems constituents of road maintenance decision-making process

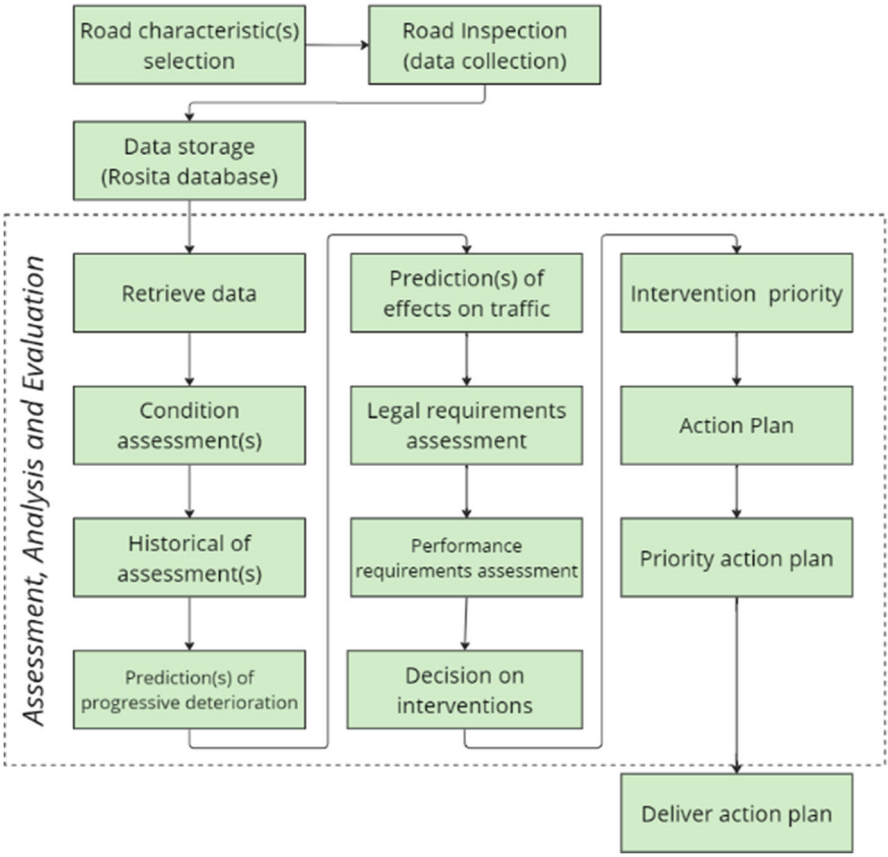

Fig. 3 Road maintenance workflow

level of services enhancing thus the safety, effectiveness, and value for the road end user. However, to align with the national transport vision, it is required to satisfy at the same time its multiple qualities. The environmental sustainability is one of these qualities which needs to be considered in the maintenance decision-making process. Currently, during the decision-making process, the environmental sustainability is indirectly addressed by the executor's operations. To obtain permission for operations, executors need to document their practices and related environmental impact. This is done, for instance, by providing documentation related to their machinery (e.g., electric or fuel-based vehicles) and Environmental Production Declaration (EPD). However, to integrate the quality of environmental sustainability and the other qualities, a more systematic approach into the decision-making process is required [32, 34]. Further development of such management systems may support the systematic integration of the environmental sustainability as the other desired transport system's qualities. This may potentially include considerations related to the environmental impact of winter maintenance practices.

Innovation, technologies with relative (big) data and advanced materials may contribute to the development of a (smart) mobility and (smart) transportation with the mentioned qualities [33]. Implementing innovative technologies in the decision-making process, such as using vehicle-to-vehicle and/or vehicle-to-infrastructure for monitoring purposes, may require an alteration of the data-driven process of the systems constituents shown in Fig. 2.

The reorganization of the transport infrastructure poses an additional challenge to be mentioned. After the reorganization, there was a decentralization of responsibilities from national level to county level. Counties became responsible for keeping the quality of their relative road network at acceptable quality levels, without putting too much stress on their budgets. Yet these counties require competence in road engineering which may be replaced by not-road engineering personnel. The latter needs to make decisions based on highly engineering road technologies and PMS often counterintuitive for those not expert in the field [28]. Systems thinking approaches may support the comprehension of the holistic complexity focusing on the intervention that fit the desired purpose [34].

5 Conclusion

This chapter presents an overview of road maintenance decision-making. The presented Norwegian case describes the maintenance and operations processes for the national road network. The chapter discussed the power relations, the decision-making constituents, and processes in light of the reorganization of the Norwegian transport sector. The chapter observed the need to better integrate the environmental sustainability, as well as other quality, in the road maintenance decision-making process. The alignment of these qualities is a valuable aspect to align the decision-making of maintenance and/or rehabilitation toward the vision of the Norwegian transport plan.

1 Introduction

The global construction industry is responsible for consuming over 30% of virgin resources and is a significant source of greenhouse gas (GHG) emissions and waste generation, contributing 40% and 25%, respectively [1, 2]. Modern road infrastructure (RI) is particularly resource-intensive, requiring substantial amounts of land, steel, asphalt, concrete, aggregates, and energy in construction, thereby contributing significantly to the construction industry's GHG emissions [3]. The industry faces increasing pressure to adopt sustainable practices, spurred by international agreements like the Paris Agreement, the United Nations Sustainable Development Goals, and the European Union's European Green Deal. The shift from the current linear economy, which is marked by a "take-make-dispose" approach, to a circular economy (CE) where resources are utilized to their maximum potential and kept in use for

as long as possible, is globally recognized as vital for achieving and sustaining future environmental sustainability [4]. Given the escalating focus on reducing emissions and limiting resource use, reevaluating how RI is built and maintained is imperative.

The global road network is currently estimated at approximately 16.3 million kilometers, with an expected increase of 25 million kilometers by 2050 [5]. The total emissions from the transport sector since the industrial age account for about 15% of all GHG emissions [6]. In light of these global challenges, this paper focuses on Norway, a country with its own set of challenges and opportunities, in transitioning to CE in RI. Highlighting the massive resource consumption of the current practices in Norway, an average of 50 tons of stone aggregates are used per meter of a new two-lane road [7]. To transition from the traditional linear economy to a more circular one, a fundamental shift in the design, construction, use, maintenance, and eventual decommissioning of RI is required [8].

Although various barriers and drivers for circular infrastructure have been identified across political, economic, technological, social, knowledge-based, and attitudinal categories [9], the most substantial barriers seem to be political and economic. However, these barriers could potentially transform into significant drivers through revised regulations and standards [10]. Facilitating sustainable choices in projects via incentives, emphasizing CE in public procurement, and incorporating CE criteria in tender competitions are some key strategies proposed for this transition [11].

While extensive research exists on isolated components of RI construction or materials (e.g., novel asphalt mixtures and aggregates, electrification of machinery), a systematic overview integrating CE principles into the entire RI is scarce. Research that fully integrates these principles is necessary, particularly in adopting a holistic approach that seeks to reduce not just GHG emissions but also the consumption of virgin resources and land use [12]. This study aims to explore the broader challenges hindering Norwegian actors in transitioning toward more sustainable and circular RI and to identify potential opportunities for circular growth.

2 Methods

This study employs a mixed-methods approach. Initially, a preliminary literature search on the barriers and drivers for CE in the broader construction industry was conducted. The results from the literature were used as a basis to develop a web-based survey targeting specific groups of professionals in the Norwegian road industry. This survey was distributed to 117 actors in the sector, yielding a response rate of 48.7%, with 57 respondents completing the survey. An additional 13.7% of recipients (16 individuals) partially completed it. The survey was designed to gather knowledge from their experiences and was supplemented with six semi-structured interviews to gain further insight.

2.1 Survey

A web-based survey was designed using the program SurveyXact and distributed to various actors working with RI. The surveys were intended to get a clearer understanding of which focus areas the different Norwegian actors themselves perceived as promoting and inhibiting the development of sustainable and CE-oriented RI. The respondents targeted were from various groups with experiences with Norwegian RI, such as developers, contractors, and material suppliers. These groups were selected due to their potential to provide valuable insights and firsthand knowledge, which are essential to reveal how the sector itself perceives sustainability, CE, and the factors that may facilitate or impede the transition toward these themes. Several of the respondents were contacted via an ongoing research project related to sustainable RI.

The survey was divided into three themes: (1) background information on the respondents' roles and the region of their workplace, (2) general views on sustainability and its importance for the construction industry, and (3) perceptions on CE, including barriers and drivers for transitioning to CE in Norwegian RI. A total of 13 questions were asked, structured as multiple-choice questions without requiring free-text responses. However, to capture aspects that might fall outside the provided alternatives, several questions included the option 'other,' where respondents had the opportunity to further explain in their own words.

2.2 Qualitative Interviews

Six semi-structured interviews were conducted, featuring two participants each from developers, contractors, and material suppliers. These interviewees were selected from a group of 11 survey respondents who had indicated their willingness to participate in further interviews. In an effort to maintain equal representation among the different stakeholders, invitations were sent to nine of the respondents to verify their continued availability for an interview. However, due to non-responses from three individuals, the final tally of interview subjects was reduced to six.

The questions used in the qualitative interview were designed to follow up on the initial survey results and to allow the interviewees to provide more depth of understanding than the questions responded to in the initial survey. The survey results were analyzed to identify areas requiring deeper exploration, guiding the formulation of the interview questions. This approach aimed to delve into aspects not fully captured by the survey, such as nuanced experiences and detailed perspectives, thereby enriching the study's findings with a more comprehensive understanding of the participants' views and experiences.

The interview guide consisted of 12 open-ended questions, and the 45-to-60-min interviews were conducted online due to geographical distribution, using web-based

platforms and audio recordings. To ensure confidentiality and data protection, personal identifiers were anonymized. The interviews were transcribed and analyzed using NVivo, assisting in organizing and identifying patterns in qualitative data and ensuring a thorough and accurate representation of the interviewees' insights.

3 Results and Discussion

The combined results from the mixed-methods approach were intended to provide a series of perspectives on the transition toward CE in Norwegian RI. These diverse sources of information reveal consistent themes and challenges, as well as potential pathways for the successful implementation of CE practices.

The survey, which targeted 117 individuals as previously detailed in the Methods section, elicited responses from 57 respondents and partial responses from 16, with their position within the firm presented in Table 1. Due to the varying levels of survey completion, there were some variations in the total number of respondents for specific questions, as indicated in the accompanying figure texts. The respondents were evenly distributed geographically across Norway. Among the "Other" category, eight were researchers, and the remaining four aligned with the "Leader" category (subject manager, COO, and two in administration).

3.1 Motivations

This section will investigate the motivations of the actors to transition toward CE. Figure 1 presents the survey results for the question "*What benefits do you consider circular economy can have in your field of work?*". The perceived benefits identified were predominantly reduced environmental impact, improved resource efficiency, and social responsibility (Fig. 1).

When asked, "*What measures have you implemented to make your projects more sustainable?*" the results highlighted a focus on reducing GHG emissions (72%) in their current projects. Other significant circular economy (CE) measures included

Table 1 Position within the firm of respondents

Position	Number of respondents
Leader	42
Advisor/consultant	7

Engineer	5
Finance/accountant	1
Architect	0
Other	12

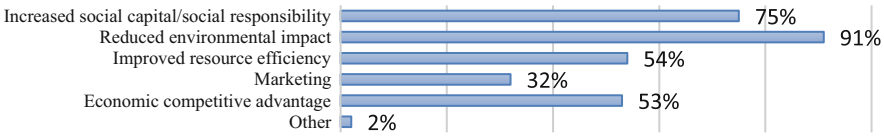

Fig. 1 What benefits do you consider the circular economy to have in your field of work? (multiple choices possible) (Respondents: 57)

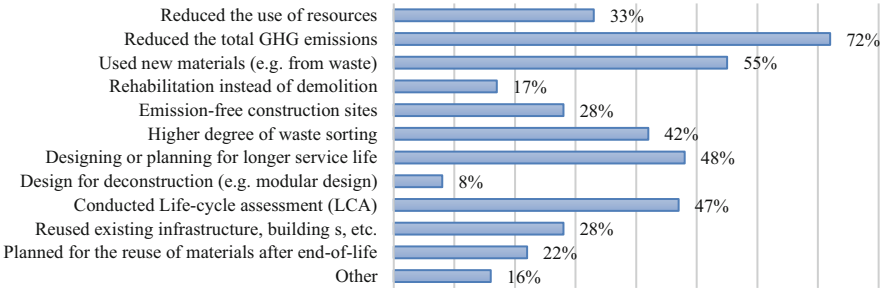

Fig. 2 What measures have you implemented to make your projects more sustainable? (multiple answers possible) (Respondents: 64)

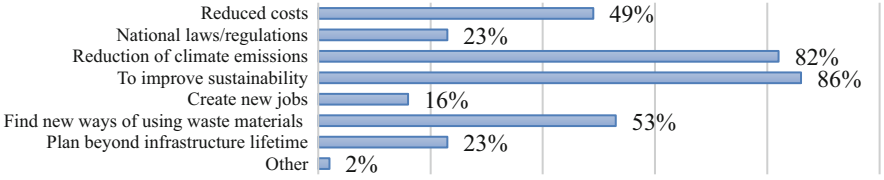

Fig. 3 What is your main objective in adopting a circular economy in your field of work? (multiple choices possible) (Respondents: 57)

using new material types (55%), increasing recycling rates (42%), designing for extended lifespans (48%), and conducting life-cycle analysis (47%) (Fig. 2).

When the respondents were asked to identify what they believe is the sole most effective measure to reduce waste generation from RI, there was an even distribution between planning for the longest possible lifespan (42%) and reusing materials (38%) as the standout choices. The remaining options, "to plan for future maintenance" (9%), "designing for future disassembly" (6%), and "more stringent requirements for the degree of sorting of generated waste" (5%), were not considered to be as effective.

The question "*What is your main objective in adopting a circular economy in your field of work?*" showed that the motivations for implementing CE principles are seen as a way to both improve sustainability (86%) and reduce GHG emissions (82%). Fewer see the possibilities of reducing costs (49%) and closing the resource

loops by using waste materials (53%) as a motivation for change (Fig. 3). The contractors interviewed did not only perceive sustainability as a way to win contracts but as a responsibility to do better.

The transition toward CE in RI is motivated by a combination of environmental, economic, and sustainability concerns [12]. Survey responses reflect a strong awareness of the importance of this transition. However, the prioritization for a transition to CE varied, with an almost linear distribution from no (4%) to high (40%) priority.

Personal interviews reinforce these findings, revealing a general consensus among RI professionals about the importance of resource efficiency and the need to keep used resources in circulation, thereby emphasizing the sustainability aspect of CE.

3.2 Drivers

To reveal what the actors themselves experienced that would drive the transition to CE, the question "*What do you think will be the biggest driver for a transition to a circular economy in your field of work*?" was asked. The results reveal that the most significant driver for CE adoption is identified as regulatory demands (77%), followed by emphasis on CE in tendering processes (61%), and improved profitability (54%) (Fig. 4). The survey results show that regulatory demands and tendering processes can have a significant impact on implementing CE. Some of the interviewees reinforced this result by suggesting that project owners can significantly influence CE adoption through contract criteria.

Drivers for the adoption of CE in RI are complex. Governmental policies and regulations emerge as potential drivers, as indicated by both the literature and interviews, with regulatory demands and policy initiatives identified as key factors influencing CE adoption. The survey data further substantiates this, indicating that regulatory requirements significantly impact the prioritization of CE practices. Economic incentives, such as favorable tendering conditions and financial support mechanisms, are highlighted as crucial in encouraging the adoption of CE practices. Transitioning to CE also has significant economic implications. The survey and literature suggest potential cost savings and long-term financial benefits. For instance, efficient resource use can lead to reduced material costs, while innovative recycling technologies can create new revenue streams.

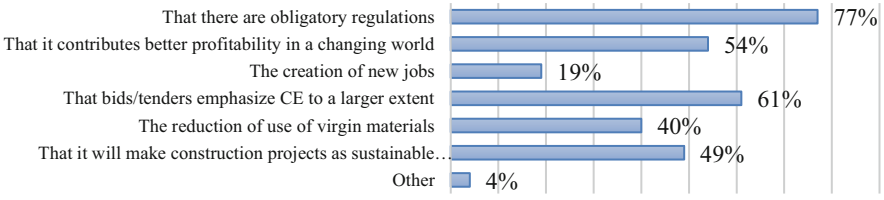

Fig. 4 What do you think will be the biggest driver for a transition to a circular economy in your field of work? (multiple choices possible) (Respondents: 57)

3.3 Barriers

In line with the literature, both the survey and interviews showed that Norwegian RI actors regard political and regulatory frameworks as prominent barriers to CE (Fig. 5). Furthermore, both the survey and interviews highlight economic factors as critical barriers, with a lack of incentive schemes being particularly prominent. However, the economic barriers also hold potential as drivers, should regulatory changes and incentives align favorably (see Fig. 4 and Table 2).

The literature, survey, and interviews all point to attitudinal resistance and a lack of comprehensive knowledge as obstacles [9, 10]. Showing that there is a need for greater awareness and understanding of CE's broader benefits beyond environmental impact. Several of the interviews pointed to encountering attitudinal difficulties when trying to make use of a novel approach or material, which ultimately led to the traditional alternative being chosen.

The survey revealed that CE and sustainability are currently regarded as costs and not as sources of possible cost savings. This is in line with the literature, where the economy is regarded as one of the main barriers to transitioning to CE [9]. A cause of this may be that it has been difficult to illuminate the cost-saving possibilities that a fully integrated CE could bring. A more effective use of available resources can lead to cost savings by not ordering more goods than is necessary. This will mean that the generation of waste that can occur on the construction site is minimized. Once goods and materials have become waste, they no longer have the same value as the costs associated with purchasing them. In other words, there are a lot of materials that today are only transported to the construction site to be transformed into worthless waste. This will mainly result in additional costs being incurred in the projects.

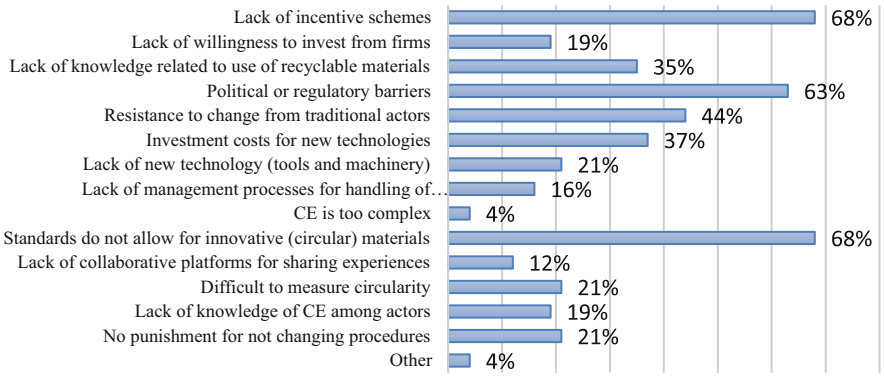

Fig. 5 What will be the biggest obstacles/barriers that could limit a transition to a circular economy? (multiple choices possible) (Respondents: 57)

Table 2 Summary of interview findings

Theme	Findings
Understanding of CE	There was unanimous recognition of CE's sustainability aspect, emphasizing resource efficiency and the necessity of recycling and reusing resources rather than extracting virgin resources. However, the economic and social dimensions of CE were notably absent from the discussions.
Perceived barriers and drivers	One key barrier identified is the rigid regulatory framework and lack of incentives, hindering the adoption of more sustainable alternatives. Conversely, the presence of strong will and desire among industry players to implement greener alternatives was noted as a significant driver, although hindered by current limitations.
Role of competition, and contractual requirements	The importance of the role of project owners in setting contractual requirements for sustainability was highlighted. Some respondents noted a shift toward sustainability when such criteria were included in contracts.
Regulatory framework, manuals, and standards	The existing regulatory framework and standards are seen as the most significant barriers to making sustainable choices. These standards are perceived as far too rigid to accommodate new materials or approaches, making sustainable choices challenging to implement.
Economic considerations	From a private sector perspective, economic viability is a primary consideration. The potential for economic incentives or penalties from project owners is seen as a critical factor in driving sustainable choices.
Technology and innovation	The current state of technology, particularly in electric construction machinery, is seen as not yet mature enough for widespread adoption. Hydrogen technology is considered a more promising alternative for future development.
Attitudinal barriers	Attitudes within the industry are seen as both a barrier and a driver. Conservative approaches often favor traditional methods over newer, potentially more sustainable options.
Political factors	The complexity of navigating various support schemes and the need for more targeted governmental actions and policies to facilitate the transition toward sustainability were emphasized.

3.4 Summary of Interview Findings

This section presents the key findings from the semi-structured interviews, as detailed in Table 2. These interviews yielded deeper insights into the initial survey results. Through analysis in NVivo, themes and patterns were identified.

As shown in Table 2, while there is a clear understanding and willingness within the industry to move toward a more sustainable CE, significant barriers such as rigid regulations, economic considerations, technological limitations, and conservative attitudes need to be addressed. These findings suggest a need for more flexible regulations, economic incentives, technological advancements, and a shift in industry attitudes to fully realize the potential of CE.

3.5 Summary and Discussion of Findings

The results of the survey showed that a large majority of respondents were "Leaders." This may have led to the results being shifted toward the more economic considerations that a change to CE would bring about. Management is often responsible for ensuring that the profitability of the company is considered, and they often make targeted choices so that the allocated budget is kept. This possible bias could have given greater weight to the financial aspects when asked to weigh advantages and disadvantages against each other in a survey.

Owing to the diverse dependencies and fragmentation amongst stakeholders in the broader construction industry, it's challenging to identify a singular action that would optimally facilitate the increased adoption of CE. Researchers advocate for various categories to classify the barriers and drivers, yet these categories are interrelated, making it impractical to focus solely on one as the definitive solution. Barriers may become drivers with altered premises, and inaction could turn current drivers into future barriers. A holistic approach is needed to overcome these barriers and ensure the activation of necessary drivers.

3.6 Further Work

Further research is required to address the broader scope of CE in RI comprehensively. Defining what constitutes a "circular road." This involves establishing a clear, comprehensive understanding of design, materials, and life-cycle impacts. Equally important is the development of methods to measure the circularity of RI projects. Effective metrics and indicators to assess circularity across various life-cycle stages will be instrumental in evaluating progress and shaping policy and practice in RI construction in the CE framework. Additionally, comparing materials and practices aligned with CE principles against traditional methods will yield insights into efficiency, sustainability, and cost-effectiveness.

Moreover, there is a need for increased knowledge and awareness about the full scope of CE, which extends beyond environmental benefits. This highlights the importance of education and information dissemination as drivers for CE adoption.

4 Conclusions

This study underscores the need for a paradigm shift in the RI industry, transitioning from its current linear model, which is heavily resource-intensive and a significant contributor to GHG emissions, to a more sustainable circular approach. Focusing on the Norwegian context, this research highlights that the transitions to CE in RI promise significant environmental benefits, including a minimized carbon footprint,

reduced resource extraction, and waste generation. Economically, it can lead to cost savings through collaboration, efficient resource use, and potentially open new market opportunities. Despite these benefits, several challenges hinder the transition. High initial costs, the need for technological innovation, resistance to change, and a lack of clear guidelines and standards are prominent barriers. Furthermore, the current economic framework often does not incentivize sustainable practices, necessitating policy and regulatory changes. Policy and regulation play a pivotal role in facilitating this transition. Policies encouraging the use of recycled materials, promoting sustainable practices, and standardizing CE approaches are recommended.

In conclusion, the shift toward CE in RI presents a promising pathway toward sustainability. While there are challenges to be addressed, the benefits in terms of environmental conservation, economic savings, and resource efficiency are substantial. Continued research, innovation, and collaboration among stakeholders are essential to realizing the full potential of this transition. This study underscores the urgent need for policy reforms and collaborative efforts in Norway to harness the full potential of a circular economy in road infrastructure.

Acknowledgments This study is financed by the research project "Green Platform—Sustainable Value Chain and Materials in Road Construction," as financed by the Norwegian Research Council grant project number 340901.

1 Introduction

By substituting the traditional linear economic system of raw material usage, a circular economy provides good alternative to the current linear system with a focus on efficient use of resources at all stages of products life cycle where consumption is kept within a circular and technological cycle [1]. Circular economy is a system with a regenerative approach to resource consumption, allowing extended life span and multiple reuse of products [2]. The circular strategies are typically considered in the R frameworks derived from the 3R's strategies, the 9R's as presented by [3] and extended 10R's [4]. The strategies are prioritised upon on the extent in which the value of product is maintained, this implies that keeping a product in its original form results in better resource efficiency than downcycling material for recycling [5], which leads to loss of greater value coupled with required energy and resource for the recycling process. Therefore, the main goal of circularity

in products is to preserve for as long as possible material and components with highest value, with subsequent extension of life of product achieved through repair, refurbishment and remanufacturing [6]. Circular strategies with focus on retaining maximum resource value are focal point in the EU environmental policies [7].

The built environment consumes almost a half of material ever used in human history [8], thereby making buildings at the end of life a likely source of material stock to serve future demand [9]. Previous sustainability practices have fallen short when it comes to effectively handling the end-of-life phase of resources. Hence, most of buildings materials are disposed to the landfills at the end of life because most of the materials used do not have any reuse potential [10]. Therefore, the end of life of buildings becomes the stage with most environmental impact with construction and demolition waste constituting over 25% of land fill waste [11]. The construction industry does not have a clear approach to disassembly of buildings, with primary emphasis on recycling rather than embracing a comprehensive approach that could yield more substantial environmental benefits [12]. The reuse of building components from existing built assets has been recognised as an effective approach from a multiple life cycle perspective to improve waste elimination and resource efficiency within the concept of circular economy in the construction industry [13, 14].

Modular design is an integral method or approach for product designed with multiple lifecycle [15], to enhance recovery and reuse of material and products [15]. Modular design and construction have been adopted in the construction industry, but most are not aimed at multiple life cycle. This is largely attributed to the complex nature of construction products as not all materials and components are suitable for multiple life cycle design [16]. Products that are targeted for multiple life cycles requires material with high inherent value capable of easy collection at the end of life, standardised components, disassembly and reassembly potentials, and modularity function, among others [17]. Design for disassembly also referred to design for deconstruction in the construction industry supports a sustainable reuse and remanufacturing of components at the end of life through effective disassembly or deconstruction [2]. An important element in buildings designed for disassembly or deconstruction to enable reuse at the end of life is the use of prefabricated modular assemblies with reversible connections rather than composite systems that will necessitate demolishing at the end of life [18]. Designing modular buildings for disassembly and reuse can potentially reduce waste and material consumption alongside other sustainability impacts of construction projects in line with the circular economy framework [19]. In recent times, there is an increase in modular approaches in building projects, largely influenced by government policy [20], rather than a systematic performance evaluation of environmental, economic and social impacts. Therefore, to aid this transition, a comprehensive framework to support a holistic evaluation of impacts with the three-dimensional sustainability (environmental, economic and social) approach is required for an effective decision-making support.

2 Methodology

In this study, a systematic review was conducted to analyse the existing literature on modular construction and design for disassembly. The methodology shown in Fig. 1 consists of the following phases: (i) defining the research question, (ii) determining the search process, (iii) defining the article selection criteria, (iv) result classification and analysis, and (v) developing the proposed framework.

2.1 Search Process and Selection

The study was conducted to identify the current trends in studies and application of modular buildings designed for disassembly and identify the sustainability goals as well as various indicators applicable to the studies. The evaluation of various types of material inputs for these strategies was conducted to identify the extent to which it

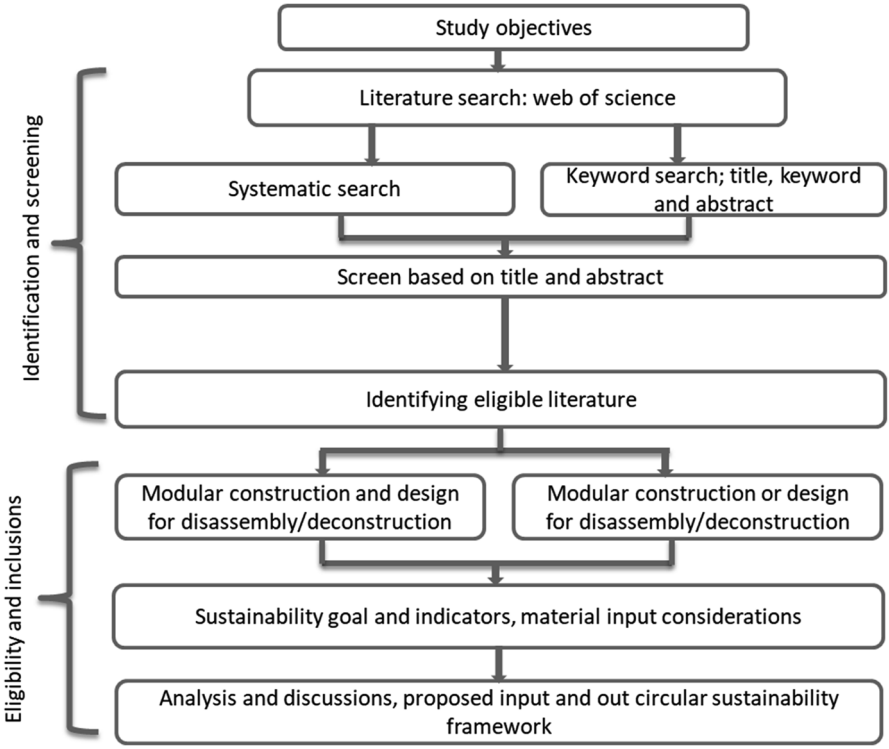

Fig. 1 Adopted methodology for the study

affects the sustainability performance. The study further evaluates the extent to which the existing literature addresses these circular approaches from the three-dimensional sustainability perspective.

Relevant key words for the literature search were developed based on preliminary search in the subject area from the web of science data base in the field of construction building technology base on title, keyword and abstract. The theme based specific key words are circular*, modular* build* or construct*, 'design for disassembly' or 'design for deconstruction'. The search yielded a lot of studies in general fields, but 35 research articles were considered in the field of construction building technologies. The selection of relevant article was based on certain criteria; the study most have a case study application/analysis, framework, or experimental test for at least design for disassembly/deconstruction or modular design/construction processes or both.

3 Result and Analysis

3.1 Temporal and Geospatial Trends

The study reveals a rapid increase in studies and applications of modular buildings and design for disassembly from 2003 to 2023 (see Fig. 2). This can be largely attributed to the rapid increase on the need to develop effective circular solutions to the resource-intensive construction industry, as the industry has a great potential for implementation of these solutions to solve the problems of resource efficiency, waste management, energy and emissions problems.

From the review of literature highlighted in Fig. 3, more studies and applications are found in Europe with 51%, followed by North America with 16%, 14% in Asia and 8%, 5%, 3% and 3% in Australia, Africa, South America and Middle East, respectively. Although there is a rapid increase in the studies in the area of circular modular buildings designed for disassembly, this study reveals significant regional

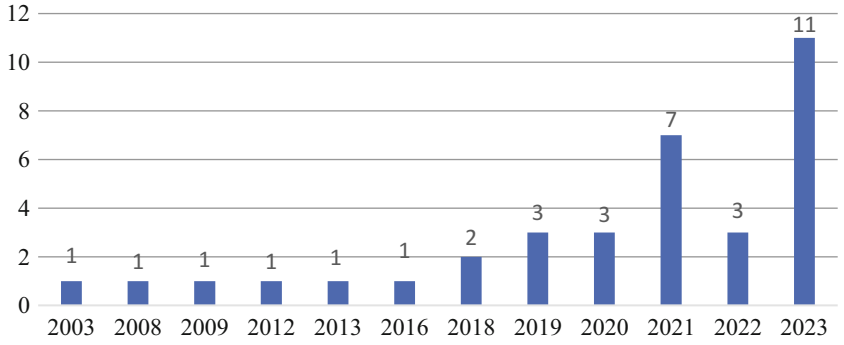

Fig. 2 Temporal trend

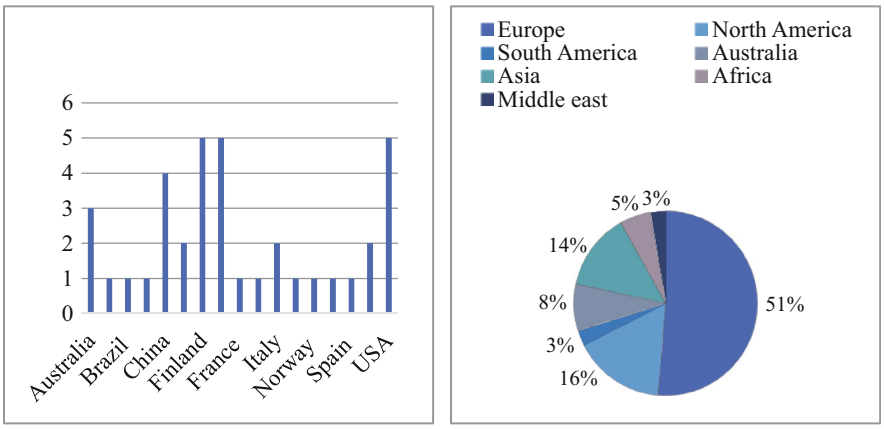

Fig. 3 Geospatial trend

imbalance with fewer research and applications in developing countries (Africa, Asia, Middle East) where infrastructure deficits and construction demand are high. The European countries have already established national circular specific legislations such as the EU-Action plan which supports a top-down implementation of these strategies. Whereas in the USA and other parts of the developing world are yet to develop such a top-down approach. Hence, the bottom-up efforts from stakeholders is the main driving force towards this progress [21].

3.2 Sustainability Goals and Indicators

The analysis of literature shows that studies in modular construction and design for disassembly/deconstruction mostly focus on environmental sustainability (ENV) as the main goal, highlighting indicators such emissions and energy reduction [18, 22, 23], raw material and waste reduction and material circularity [24–26]. Some studies featured a combination of environmental and economic (ECO) goals with cost performance being the main economic indicator [20, 27, 28]. Few studies embraces the triple bottom line sustainability approach [20] having environmental, economic and social (SOC) aspects of energy and waste reduction, cost, as well as safety and welfare. In summary, 71% of the reviewed studies focused on environmental aspects as the only sustainability goal, 26% featured environmental and economic goals, and only 3% addresses all the three aspects of environmental, economic and social impacts as shown in Fig. 4. Sustainability goals are strongly interconnected, and hence, the achievement of sustainable development in the built environment requires a holistic three dimensional approach impact evaluation and determination of appropriate solution.

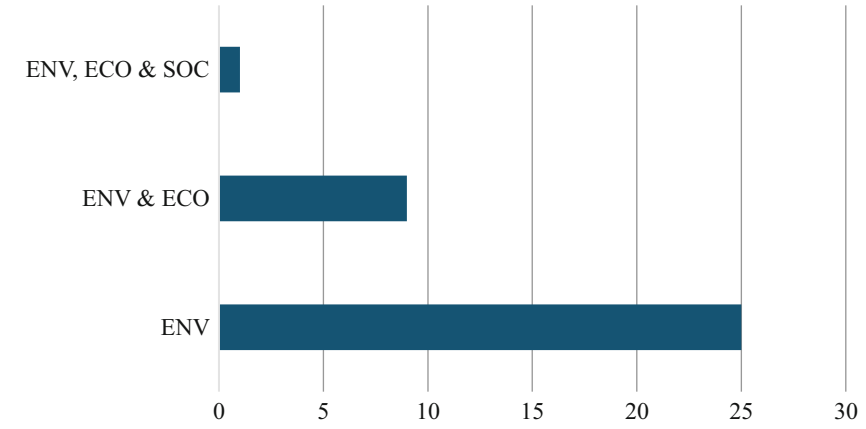

Fig. 4 Sustainability goals

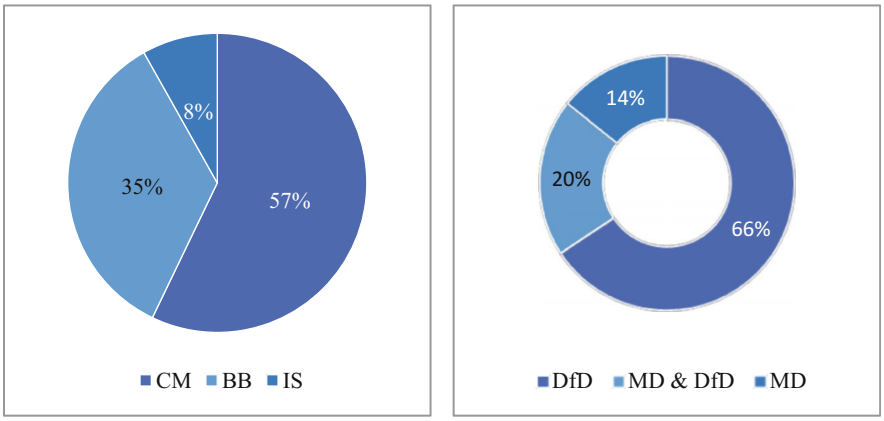

Fig. 5 Material inputs (left), design and construction strategies (right)

3.3 Material Inputs for Modular Buildings and Design for Disassembly

The analysis of the review reveals that the concepts of modular building construction and design for disassembly/deconstruction are often considered separately in most studies although the application of the two concepts presents more benefits from circularity and sustainability perspectives. Design for disassembly/deconstruction application remains the most popular from multiple lifecycle consideration representing 66% of the studies. Modular design/construction application present 14% followed by the combination of both presenting in 20% of the studies.

The result of this review showcases several types of material inputs (see Fig. 5), some of which highlighted benefits from reuse and circular perspective [25, 26, 29, 30], others from pollution, waste elimination and health safety indicators [20, 31–33].

3.4 Conventional Materials (CM)

The use of conventional building material such as concrete and steel used for modular prefabricated construction provided as reinforced concrete modules or steel framed structures, offers great resource efficiency, durability and reuse/recyclability potentials of buildings [20, 34]. Concrete and steel composite building elements base on experimental tests also provides effective deconstructability potentials [21], as well as material and component recoverability during disassembly at the end of building lifecycle [25]. Brick as a building component has a great reusability and flexibility potential with effective design and construction targeted at multiple life cycles [35]. High durability characteristic of bricks as a building material gives a good environmental payback over a period of life cycles with high potential of upcycling for multiple life cycles [35].

3.5 Biobased Material (BB)

The use of wood materials to promote reuse and increase lifetime of elements in panelised timber frames with reversible connections in prefabricated modular building assemblies enables effective reuse and adaptability of panels, with emission and raw material reduction and enhanced circularity [26, 36]. The use of wood/timber concrete composite elements designed for disassembly supports circularity from reuse, remanufacturing and recycling perspective [37, 38]. Biobased material used as design inputs at the early design stages provides a great control over the environmental impact of the building material as well as the possible end of life scenarios [39]. The use of other forms of natural materials such as stones, sand, clay, lime and straw has mostly been proven to have high environmental and economic benefits. Stone and gabions used as structural element designed for deconstruction with simple construction methods also provided high environmental and economic benefits [33].

3.6 Industrial Symbiosis Material (IS)

Material from industrial symbiosis, i.e. materials from other industrial waste/by products as building material presented in studies can lead to improved circularity across all industries. The use of recycled aggregate designed from reuse and recycling perspectives in structural elements [22, 30] offers sustainable solutions to concrete waste generation and embodied carbon emission over lifecycle. The use of organic agricultural waste like rice husk as building materials in modular green wall enhances circularity goals as well as reduced environmental impacts and offer economic benefits [40]. Also sheet metal waste from automobile bodies production

adopted for modular living walls system results in positive effect with reduced greenhouse gases emission and energy usage from traditional metal recycling processes [41]. Other industrial symbiosis application includes partition walls from recycled plastic bottles, recycled carton pipe from waste stream [39] and many more offers long term circular and sustainable solutions.

4 The Proposed Framework

In the quest to improve sustainability performance of buildings, a holistic evaluation of impacts in all phases of lifecycle from all the three sustainability dimensions (environmental, economic and social) becomes necessary for effective decision-making. Previous sustainability studies in the built environment have fallen short of providing a comprehensive evaluation from all the three sustainability aspects. The proposed input–output circular sustainability framework shown in Fig. 6 supports holistic evaluation from the triple bottom line sustainability point of view as well as circularity assessment to ensure effective plan is made for end of life the building. The proposed framework put forward material selection as the main input driver at early design stage. Typically, material consideration follows design stage thereby making it more complex to implement the circular strategies.

The framework gives preference to low carbon building materials to achieve reduced output of greenhouse gas emission and waste, considering biobased material and reusable material from the building industry and cross other industries. The framework presents circular design and construction strategies (design for disassembly and modular construction) to ensure adaptability for extended lifecycle and suitable end-of-life scenario to achieve highest level of value through recovery and reuse of building components and modules.

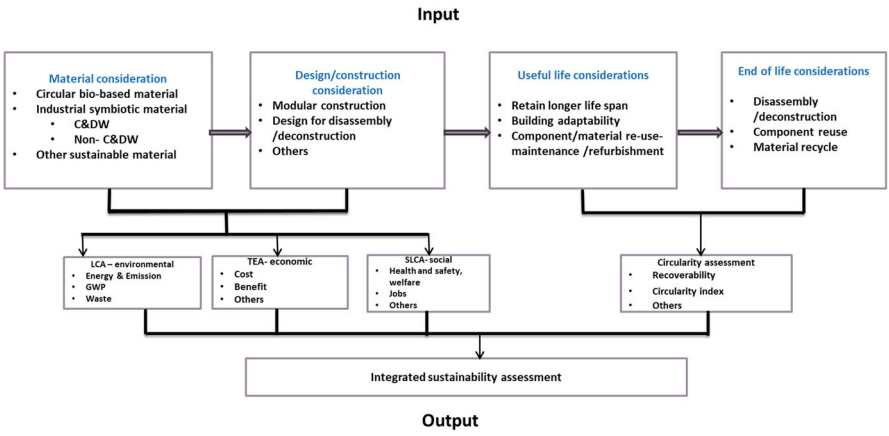

Fig. 6 An input–output circular sustainability framework

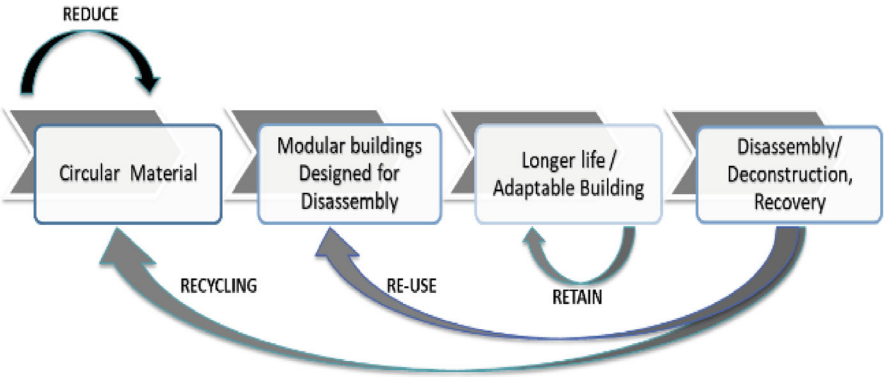

Fig. 7 An input–output circular sustainability framework within R- strategies

From the proposed framework, the adoption of circular low carbon reused/ upcycled or recycled material will potentially reduce raw material usage and reduce embodied carbon. The design and construction strategies can support reuse at the end of life and retain longer building life through adaptability as shown in Fig. 7.

5 Conclusion

This study presented a systematic literature review on modular construction and design for disassembly in relation to material inputs and sustainability targets (environmental, economic, social). The outcome of the review shows that studies within this scope mainly focused on addressing environmental sustainability issues then environmental and economic. Few studies address all the three sustainability dimensions, and hence, the social sustainability aspect largely suffers neglect in research. Sustainable building construction presents numerous social sustainability benefits including up to 50% and 80% risk reduction in concrete and steel modular building construction respectively [20]. Material consideration is an integral aspect in achieving improved ecological impacts of building from reduce, reuse and recycle perspectives [39]. Modular construction and design for disassembly applications mostly adopts conventional material inputs rather than more sustainable circular material. Designing building with circular material reduces raw material inputs and emission output and hence, supports effective circularity and successful transition to sustainable built environment and net-zero. Modular building and design for disassembly are promising circular concepts and they are becoming popular in research and application, but mostly in Europe and North America, therefore this present significant regional imbalance. Despite the potential benefits of adopting modular buildings design for disassembly, the concepts are mostly applied separately. Hence the study presents a comprehensive circular sustainability evaluation framework, with triple bottom line sustainability approach. Sustainability performance is site

specific, therefore critical evaluation of environmental alongside socio economic impacts of circular solutions will be beneficial especially in developing countries with high demand of infrastructure projects. Hence, further studies can be conducted to implement the proposed framework at early design stage for effective decision-making support.

1 Background

The built environment is currently in a dire moment of change to achieve further sustainable solutions and to reduce the carbon footprint [1–3]. The Linear economic model has been predominantly adopted in the construction industry, in addition to the introduction of recycling of construction waste. In alignment with the findings in UNEP [4] where the built environment was found to account for 39% of the global carbon emissions. Giorgi et al. [5] stated that linear economic models and recycling are no longer a solution due to limited resources available. The concept of the CE is relatively new and generating further recognition across many respective fields, including the construction industry [6]. Some existing challenges interluding the further adoption of CE principles within the AEC industry include but not limited to;

the traditional construction and design strategies, construction and demolition waste management, poor supply chain management, Ignorance of End-of-Life (EOL) principles, lack of regulations and strategies to encourage the adoption of the CE principles, lack of collaboration, and lack of information exchange of CE practices (Al [7, 8]).

Building Information Modelling has been a vital element in the construction industry allowing for improved communication, collaboration, and interoperability in construction projects. Digitalisation, especially BIM as a promising tool, facilitates the collaboration between project teams to incorporate and manage information of building processes that may lead towards more sustainable construction projects, and reinvents contemporary design [9]. This paper aims to assess the potential utilisation of BIM as an enabler to achieve further implementation of CE principles within the built environment. BIM's role, when aiming to achieve CE-related goals within construction projects, is to be clarified, showing the emerging challenges and barriers, recommendations, and key findings.

2 Concept of Circular Economy

Ellen MacArthur Foundation [10] founded the 3Rs principles that describe circular economy processes to facilitate the transition towards more circularity: reduce, recycle, and reuse. Stated in the works of Ellen MacArthur Foundation [11], CE is a regenerative economy where the target is to retain the highest values for products and materials in a permanent circular system for their optimal reuse, recycling, remanufacturing, and refurbishment. In general, CE illustrates the impact on the economy that natural resources sustain, and give further insight into waste, production, economic systems, and waste within the construction industry [12]. Xue et al. [13] proposed the alignment of CE principles and the technical requirements within the construction industry in terms of resource mass consumption. Similarly, Suárez-Eiroa et al. [14] found supporting evidence that the adoption of CE concept maintains the economic growth, creates further job opportunities, and reduces CO_2-emissions. Conclusively, CE maintains and retains added high value in materials, products, and components in a restorative and regenerative design system until their EOL [15, 16].

2.1 Digitalisation and Enabling CE Adoption

Digitalisation is considered as one of the key enablers of CE as it offers improved intelligence, information management, design and construction process visibility, and condition of assets and products. This in turn assists in managing resources and the facility information and reduces the uses of resources [17, 18]. Another key enabler is the 3DR index coined by O'Grady et al. [19]: Disassembly,

Deconstruction, Resilience. Enabling the principles of 3DR generates increased knowledge on implementation of CE in the context of transforming waste into new suitable resources. Furthermore, O'Grady et al. [19] found emerging benefits in all stages within a project's lifecycle when 3DR is applied. Digitalisation could hold a significant role in empowering the 3DRs, because these principles require strong information management which could be missed or mis-coordinated if the traditional tools/practices used for managing the information is required. Depending on the traditional tool of storing and managing information could lead to more errors in the 3DRs processes, that results in extra cost and more waste.

2.2 Challenges Facing CE

The biggest challenges facing the adoption of CE in the construction industry, is the lack of knowledge and awareness among project parties, lack of clear design incentives for reuse of assets and materials' EOL, and lack of the concept of design for disassembly [20–22]. Purchase et al. [23] found other challenges prohibiting the further adoption of CE principles that include poor governance, high cost, lack of awareness and poor information management, and lack of clear specifications on recycled assets and materials.

The existing structure and characteristics of the construction industry were mentioned by Adams et al. [20] as leading to the fragmentation within the supply chain, which is again one of the key barriers facing the CE implementation [24]. Fulford and Standing [25] found that the efficiency and productivity are severely impacted by the supply chain fragmentation within the construction industry and the lack of standardisation. To obtain a comprehensive understanding of standardisation and apply it properly into projects, BIM emerges as a tool to meet the continuous improvement that standardisation acquires. Bradley et al. [26] found BIM use is commonly applied for any standards in projects where the BIM model is utilised for design purposes, rather than using 4D and 5D BIM model for cost and programme management. It is a requirement in the construction industry for standardisation regarding BIM, which is found within the exchange information between used software applications [27]. BIM's flexibility could provide the tools to monitor and manage the required sustainability measures in terms of waste reduction during the building's entire lifespan [28].

2.3 Synergies Between BIM and CE

The current use of BIM during an asset's life cycle could enhance the possibility of recovering the asset's history in the events of partial or whole destruction in an asset refurbishment, which is one of the current existing synergies between BIM and CE [29]. It is argued by Göswein et al. [30] that dependent factors already in use within

the built environment, such as facility and design management, resource management, and waste management, altogether sustain the synergy currently between BIM and CE. BIM utilisation for waste management is already enabling some of these factors such as quantity take-off, site utilisation planning, 3D coordination and planning, digital fabrication, phase planning, and design review [31]. Performing a BIM-Deconstructability Assessment Score allows for the further enabling of BIM as a tool for Circularity to prolong the EOL of materials, additionally with the use of as-built BIM models for building operations and maintenance using laser scanners [32, 33]. Previous research could identify the as-built BIM models as tools for cost analysis for demolitions plans in selected waste systems including design for disassembly, assets, and waste management [34, 35].

2.4 Barriers and Opportunities of Current BIM-Enabled CE Principles

To help the Built Environment shift from the linear economic model to the circular economic model, Hai et al. [36] suggested assessing benefits such as increased CE awareness and improved recycling rates to aid this shift. Enhancing the building's performance by encouraging further usage of BIM to match EOL assessments of projects, will reduce waste and help preserve the embodied energy in construction projects [37]. Xue et al. [13] found in general that the widespread use of BIM and LCA within the construction industry to not being fully applied. Existing concerns regarding BIM-enabled CE revolve around the whether industry professionals obtain sufficient BIM knowledge, BIM competency, and BIM software training, and the BIM documentation and models in cloud-share collaboration [6]. However, Göswein et al. [30] purport that the main challenges facing BIM-enabled CE are lack of data, poor procedures, and interoperability issues. It is clear that several studies referred to the potential relations between BIM features and the principles of the CE. This will be further explored in this paper.

3 Research Methodology

The research methodology adopted in this study was a simple mixed methodology consisting of a quantitative and qualitative approach to obtain the primary data through two stages: (1) A questionnaire survey and (2) An interview. A pilot study was carried out to validate both the questionnaire survey questions and interview questions. The questionnaire survey was employed to obtain professionals opinion on the current use of BIM in the industry, its use with link to sustainability practices, and its potential use to enhance CE principles. Thirty-seven questionnaire responses were received where the 3 biggest positions at 20% each were identified as working as BIM Modeller or Coordinator, Architects, and Engineers as shown in Fig. 1.

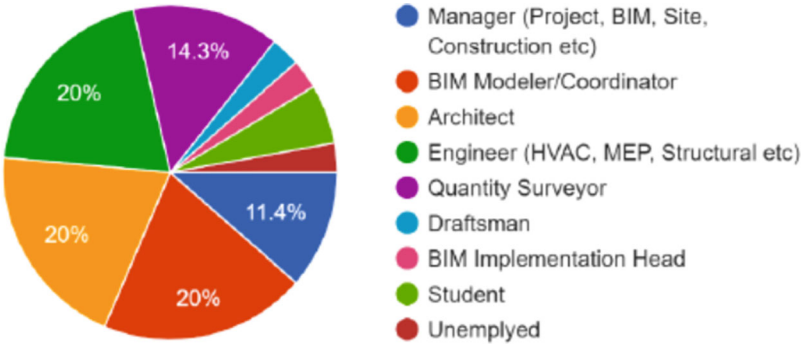

Fig. 1 Participants' current role within their organisations

Then, five interviews were carried out with experts (i.e. 2 BIM Managers, 2 BIM Coordinators, and 1 Asset Manager) to explore in depth the potential utilisation of BIM in facilitating the adoption of CE in the AEC industry. The collected data from the questionnaire survey was statistically analysed to demonstrate the significance of various variables in each theme. Then, thematic analysis was employed to analyse the data collected from interviews. Then, a conceptual framework is produced to show the potentials of BIM in facilitating the CE in the AEC industry.

4 Data Analysis and Findings

4.1 Current BIM Practices

Invaluable BIM insights were provided by the participants as a total of 62% of the participants were revealed to be directly involved in the daily utilisation of BIM, and they could reveal the main utilisation of BIM is for design purposes as shown in Fig. 2. However, the use of BIM for waste recycling, reuse of building components, and deconstruction receives less importance and understanding on how to use BIM for these practices.

4.2 Awareness of CE

In general, the participants' perception of the CE was for recycling and reuse of construction elements and materials. It can be seen from Fig. 3 that there is significant awareness of the participants with a score of 77% on the utilisation of the 3Rs (recycle, repurpose, reuse) which is already applied in construction projects, with the other common CE principles such as design for lessened energy consumption and prefabrication of elements.

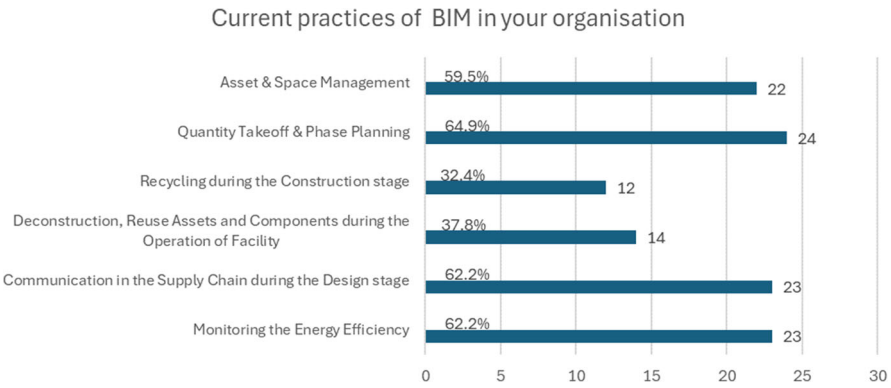

Fig. 2 Current practices of BIM in your organisation

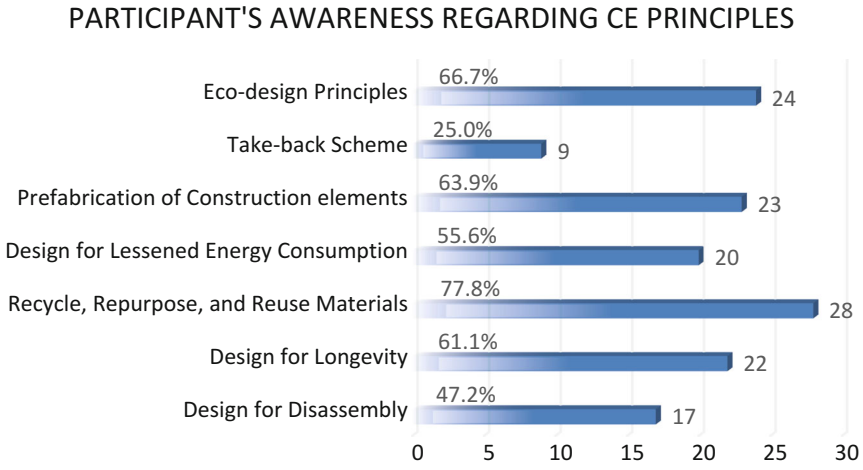

Fig. 3 Participant's awareness regarding CE principles

4.3 Perceived Benefits from Utilising BIM as a Tool for Circularity

Figure 4 demonstrates the participants' perceived benefits for construction projects adopting BIM for facilitating the CE principles include; improved interoperability and communication within the supply chain, improved life cycle cost estimation of assets, and standardisation using BIM in projects. The general recommendation is the need for a general shift in the paradigm in addition to complete EOL review when BIM is used. This is aligned with 3 out of 5 interviewees who stated that BIM has high potential in facilitation circularity as quoted by one professional: '*We've had success applying principles such as Design for Disassembly, mainly due to the*

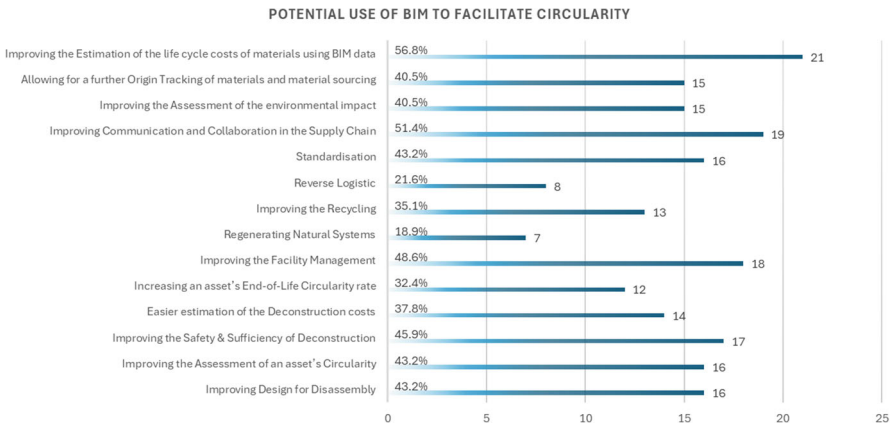

Fig. 4 Potential use of BIM to facilitate circularity

central origin of data and information BIM provides'. And another quoted*: 'We used BIM in a recent project to develop digital twin to optimise and stimulate the building energy performance. Due to the creation of that digital twin. It allowed us to alter the design swiftly and assess the sustainability metrics. This resulted in the achievement of a LEED Platinum certification for our organisation*'.

The results reveal there is a reasonable awareness on the potential use of BIM to facilitate circularity within the AEC industry. However, there are some barriers such as the absence of demands to apply the CE principles from clients, professional bodies, and the government. This is aligned with Charef's [6] finding. Additionally, the client was identified as holding the main responsibility for the encouragement and development for adopting CE within built environment projects. It was suggested that stakeholders might not comprehend the desired awareness and knowledge of the CE principles to enable it.

5 Discussion

BIM utilisation was identified by all interviewees to foster stakeholders' communication and collaboration that yields a sustainable work environment for improved, sustainable construction projects, which aligns with Kuzina's [38] suggestion of enabling BIM for life cycle management. 4 out of 5 of the interviewees reported on BIM generated benefits includes material and energy efficiency, energy simulation, risk analysis, cost savings, improved design and decision making. Sustainability efforts emerging from their organisations BIM use was energy analysis, data integration, resource management, and design optimisation.

In terms of stakeholder engagement and perception of BIM's sustainability potential, 80% of the interviewees could acknowledge that the perception among

stakeholders varies due to differences in knowledge, willingness, and adjustment to adopt BIM completely for sustainable procedures. Among the identified barriers were legal concerns, change resistance, high cost, and complete knowledge of BIM. Designers, engineers, and architects demonstrate a high interest in enabling the complete sustainable potentials that BIM offers. One of the interviewees suggested that to combat stakeholders' reservations, BIM specialists could display the benefits to gain further support from stakeholders. One of the interviewees suggests the identified barriers could be solved by organisations introducing proper data integration and BIM training.

Sixty per cent of the interviewees agreed to the existing alignment between the CE principles and the BIM features in the construction industry that can be found in procedures such as resource efficiency, and material consumption, selection and tracking. BIM was particularly identified as an enabler for practices of Design for Disassembly (DFD), with an interviewee describing the emerging success within a project with DFD was solely due to the central origin of project information data provided by BIM. Although, another interviewee stated that BIM in 4D which is very useful for resource utilisation in various locations in construction projects, is a level of BIM maturity yet to be seen. Eighty per cent of the participants stated that increased building performance and waste reduction are the two commonly witnessed BIM enabling the CE principles. Interviewee 4 particularly stated that their use of digital twin allowed for quick design alterations and assessment of sustainability metrics yielding their organisation's a LEED Platinum certification.

A total of 60% of the interviewees identified security, management, quality, and data interoperability to be the most common areas to causes challenges when BIM was promoted for sustainability efforts and CE procedures. One interviewee stated the main issue was still resistance and sceptics among stakeholders. Interviewee 4 provided valuable insight of the further need of complete demonstration of BIM's advantages to combat these challenges, that aligned with Charef's [6] common user concern including the lack of BIM expertise and knowledge within the project team.

Applicable demonstration of BIM's benefits will gain further awareness and decrease the occurrence of challenges. This concern was discovered by Xue et al. [13] on how BIM in coordination with a LCA is not utilised to its desired outcome. Applying standardisation and BIM training was suggested by 20% of the interviewees to prevent these challenges, where standardisation was found promising in Poljanšek [27] for exchange information in the application of different software.

Emerging examples of BIM-enabled CE principles, also found by Kevin van Langen et al. [39], are reported by all interviewees, including economic growth, reduced carbon footprint, lessened energy consumption, lessened environmental impact, and reduced costs on a material, operational, and constructional level. This theme is in accordance with what was purported by Manzoor et al. [40], that BIM offers a vast selection of tools to enhance that sustainability in construction projects. Based on the above findings, in the following section a proposed conceptual framework is produced to demonstrate the potential relationship between BIM features and circularity principles within the built environment.

6 Conceptual Framework

A proposed framework presented in Fig. 5 is developed in combination with the analysis and results emerging from the above existing literature and data analysis, in order to display how the competencies of BIM can aid the further adoption of the CE principles in the BE. The various BIM competencies are highlighted in colours on the left, and the CE principles are located on the right hand side in non-coloured segments. Highlighted texts in red within the links between BIM competencies CE principles show the faciliated outcome that in the link could achieve sustainable aspects within the CE principles.

The conceptual framework in Fig. 5 sheds light on the existing gap between the competencies of BIM and the CE principles, in exhibiting an interconnection that could aid further sustainable approaches, resilient projects, and resource efficiency within the BE. BIM's data driven capacities aligns with procedures to achieve CE, and the framework can be used as a practical tool by industry professionals and stakeholders to analyse and navigate for more sustainable, net-zero carbon projects. For example, 'data and information management' as one of the key BIM

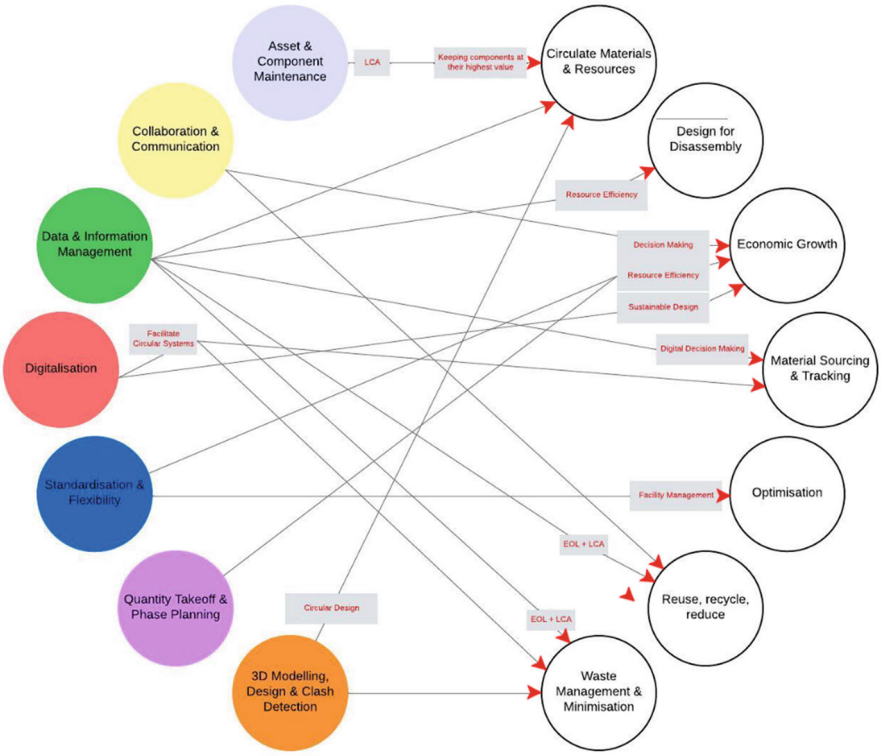

Fig. 5 Links between BIM Competencies and the CE principles

competences plays a crucial role in enabling 'Design for Disassembly', 'tracking materials and provide information on life span and circularity', and updating the data on 'reuse, recycle, reduce principles' which in turn enable waste management and minimisation. No doubt DfD and Standardisation goes hand in hand, which are essentials for circularity, reuse, repurpose and waste minimisation. The potentials of using BIM to enable circularity principles are many and difficult to cover them here.

Vital synergy, patterns, and themes between the BIM competencies and the CE principles can be identified when applying the framework which facilitates through knowledge of current synergies and challenges within the AEC sector. Critical insight emerging from the framework: circular strategies, collaboration & communication, design for adaptability, decision-making, efficiency gains, interdependence of competencies and principles, and lifecycle perspectives.

7 Conclusion

The most vital role as an enabler can be found in stakeholders and their resilience to apply BIM requirements that facilitate and foster sustainable procedures, and the shared BIM model's data allows for sufficient interoperability between stakeholders. To achieve BIM-enabled CE principles within the BE, it is crucial that stakeholders, and mainly the client, encourage various construction project participants to increase their training of BIM's use and explore its wide potentials. These findings align with both relevant literature and the suggested growing interest of BIM-enabled CE principles for preservation of embodied energy and waste reduction, and reports of increased recycling rates that occur when shifting to a Circular Economic Model.

Some of the frequently used BIM competencies emerging from the data include asset & space management, communication & collaboration in the supply chain, energy efficiency management, phase planning, and quantity take-off. These competencies enable the possibility of design and resource optimisation, deconstruction, energy analysis for operational costs and waste reduction, material sourcing and tracking, and displays the interconnection between BIM and CE principles. As seen in the conceptual framework, these links can facilitate the proper adoption of circularity in construction projects. Emerging from the qualitative data, most frequent principles of CE currently utilised within the BE include the 3Rs, design for eco-principles, design for lessened energy consumption, design for longevity, and prefabrication of construction elements. Furthermore, the findings of this research and the proposed conceptual framework could be used as a basis for further research and investigation, where some case studies could be used to demonstrate the most significant contributions of BIM towards enhancing circularity and sustainability within the built environment.

1 Introduction

Concrete stands as not only the most utilized building material globally but also ranks second in overall material usage, following only water—an unsurprising status given its abundance, affordability, and widespread availability. Its versatility allows for a myriad of applications, rendering it indispensable in various construction projects. Cement serves as a binding agent utilized in concrete and other construction materials. The total volume of cement production worldwide amounted to an estimated 4.1 billion metric tons in 2022 [1]. At present, China stands as the foremost producer of cement globally, with an output of approximately 2.1 billion

tons in 2022 (more than half of the global production) [2]. Following behind, India emerges as the second-largest producer of cement with its production reaching 370 million tons. Vietnam secures the third position, with 120 million tons in 2022. Among the remaining cement-producing countries, none surpasses the threshold of 100 million tons.

Steel, as a construction material, offers advantages in sustainability when compared to concrete. While both materials are widely used in construction, steel's recyclability stands out as a key factor contributing to its sustainability. Unlike concrete, which relies heavily on cement production—a process associated with significant carbon emissions—steel can be recycled infinitely without loss of quality, reducing the need for raw material extraction and minimizing environmental impact. On the other hand, the production of crude steel also has a significant cost to the environment. One of the primary contributors to environmental degradation is the extraction and processing of raw materials, particularly iron ore and coal, which are essential inputs in steelmaking. Moreover, the manufacturing process itself involves high energy consumption and emissions of greenhouse gases, such as CO_2 and CH_4. Overall, the environmental cost of steel production underscores the urgent need for sustainable practices and technological innovations to mitigate its adverse impacts [3]. In 2022, global crude steel production reached nearly 1.89 billion tons [4]. China emerged as the largest steel-producing country, contributing approximately 1 billion tons, accounting for approximately 54% of the world's production.

Figure 1 illustrates the annual cement and steel production worldwide from 1995 to 2022. Comparatively, in 1995, global cement output was a modest 1.39 billion tons, or 34% of the 2022 production. Similarly, crude steel production in 1995 totaled 753 million tons, representing 40% of the output witnessed in 2022. These statistics underscore the recent expansion experienced in the construction sector globally.

Despite the finite nature of the planet's resources, both concrete and steel production continue to escalate annually. This trend underscores the urgent need for responsible resource management and sustainable construction practices. In the face of burgeoning demand, it becomes imperative to utilize these materials efficiently and judiciously, avoiding wastage wherever possible. Furthermore, it is

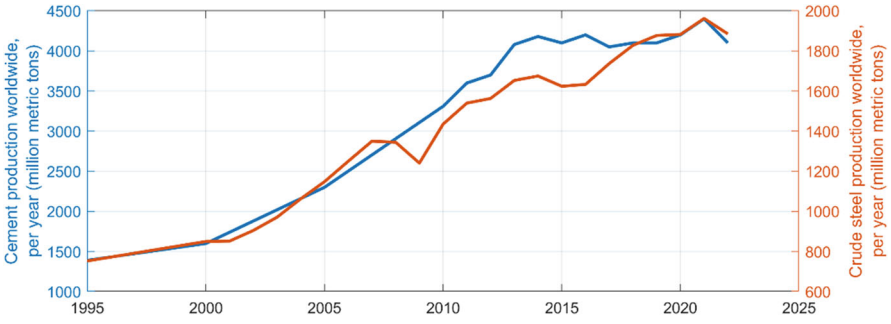

Fig. 1 Cement and steel production worldwide, per year (1995–2022) [1, 4]

essential to acknowledge that the building sector in general consumes approximately 40% of the world's energy, 25% of its water, and 40% of its resources, while also serving as the leading contributor to global greenhouse gas (GHG) emissions, accounting for 30%. Additionally, the construction industry is a significant source of waste generation [5].

2 Structural Optimization and Sustainability

Structural optimization emerges as a vital tool in the quest for sustainability in our constructions, offering a pathway toward constructing structures that maximize efficiency while meeting stringent safety standards. Structural optimization involves applying optimization techniques to the design of load-bearing engineering structures such as buildings, bridges, and others. Before the adoption of computer-assisted optimization procedures, structural elements like beams and plates were designed optimally using manual trial-and-error methods, which were time-consuming. Today, by leveraging advanced optimization techniques, engineers can design buildings and infrastructures that require minimal material inputs without compromising structural integrity or performance. In doing so, structural optimization paves the way for a more sustainable future, where our constructions are not only resource-efficient but also resilient and environmentally conscious.

2.1 Literature Review

Structural optimization has emerged as an innovative technology in recent decades, as demonstrated by the wealth of research articles dedicated to the subject in the literature. A search on Scopus conducted on March 16, 2024, using the query "TITLE-ABS-KEY ("structural optimization") "AND PUBYEAR>1994 AND PUBYEAR<2024" yielded a total of 52,404 published documents from 1995 to 2023. By limiting the search to engineering only, using the additional instruction "AND (LIMIT-TO (SUBJAREA, "ENGI"))" we similarly get 33,670 published documents. Figure 2 depicts the trend of published papers on structural optimization according to Scopus for the period 1995–2023, both overall and within the engineering field. Within the engineering domain, the figure reveals a consistent increase in the number of papers published each year, from 117 papers in 1995 to 1365 papers in 2009 and 3439 papers in 2023.

Lagaros [6] sought to demonstrate the profound environmental benefits and economic advancements achievable through the adoption of optimization-based design procedures within the construction industry. Russo and Rizzi [7] introduced a computer-aided methodology, which integrates Structural Optimization and Life Cycle Assessment (LCA) tools. They used optimization strategies that convert environmental objectives and constraints into structural and geometrical parameters, enabling the generation of alternative green scenarios based on shape, material, and

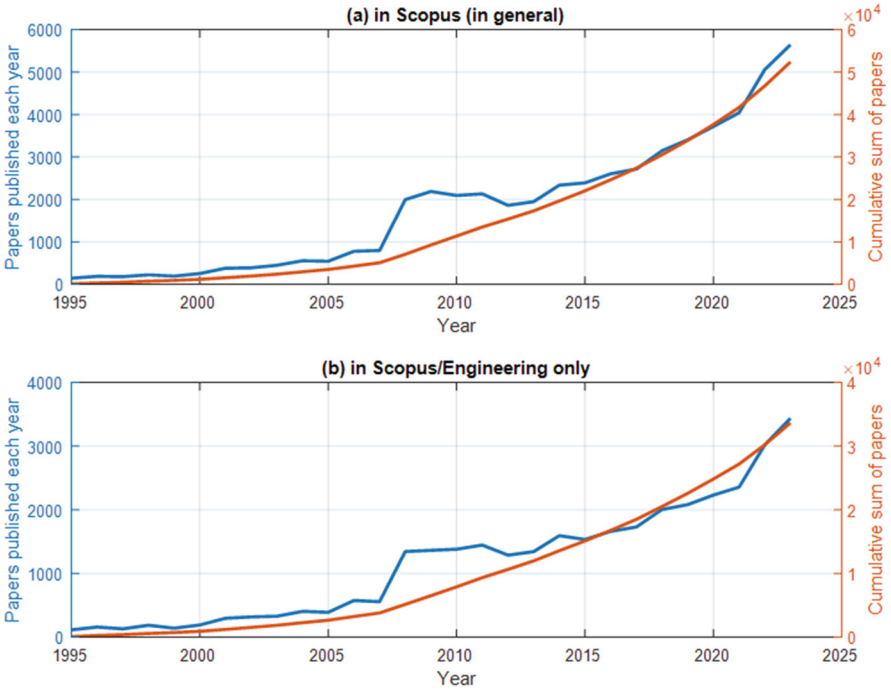

Fig. 2 Published papers in "Structural Optimization," according to Scopus (1995–2023)

production. Rempling et al. [8] attempted automatic structural design by combining set-based design, parametric design, finite element analysis (FEA), and multi-criteria decision analysis. The method was tested on three existing bridges. Tien and Van Tung [9] used building information modeling (BIM) for the multidisciplinary design optimization of sustainable structures, employing the Non-dominated Sorting Genetic Algorithm II. Islam et al. [10] described an optimization approach for balancing life cycle cost and environmental impacts for typical Australian houses, employing single- and multi-objective optimization techniques. Afzal et al. [11] investigated the potential of BIM and optimization algorithms to optimize structural systems and improve design outcomes, following the PRISMA systematic review methodology.

3 Optimization Problems, Algorithms, and Objectives

3.1 Types of Structural Optimization Problems

The basic types of structural optimization problems encompass topology, shape, and sizing optimization, as shown in Fig. 3. Topology optimization is a computational method that aims to determine the optimal distribution of material within a given

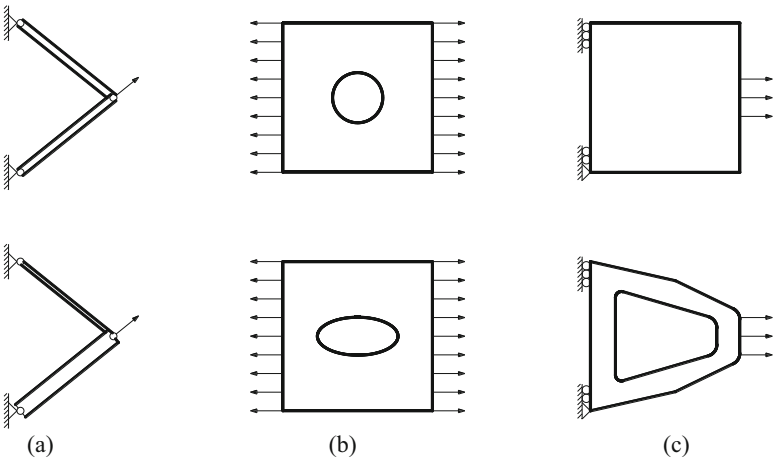

Fig. 3 Basic types of structural optimization problems [16] (Top: Original structure, Bottom: Optimized structure): (**a**) Sizing, (**b**) Shape, and (**c**) Topology optimization

design space to achieve predefined performance objectives while minimizing material usage [12]. By iteratively removing unnecessary material and redistributing load paths, topology optimization enables the creation of structurally efficient designs with optimized strength-to-weight ratios. This approach allows engineers to explore unconventional complex geometries, leading to the development of lightweight and resource-efficient structures that can meet stringent sustainability criteria.

Shape optimization focuses on refining the geometry of structural components to improve their performance characteristics, such as stiffness, strength, or aerodynamic efficiency [13]. By adjusting the shape of individual elements or entire structures, engineers can achieve desired functional requirements while minimizing material usage and environmental impact. Shape optimization techniques often involve parametric modeling and FEA to explore a vast design space and identify the most efficient geometric configurations. This approach facilitates the creation of streamlined and aerodynamic structures that enhance sustainability by reducing energy consumption and material waste.

Sizing optimization involves determining the optimal dimensions of structural members, such as beams, columns, or trusses [14, 15], to maximize performance while minimizing material usage and cost. By systematically adjusting the cross-sectional properties of components based on loading conditions and design constraints, engineers can achieve optimal structural efficiency. Sizing optimization techniques consider factors such as strength, stiffness, and stability to ensure that the resulting structures meet safety standards and functional requirements. This approach allows for the creation of lightweight and resource-efficient designs that contribute to overall sustainability by reducing material consumption and carbon emissions.

3.2 Optimization Algorithms

Optimization algorithms can be broadly categorized into mathematical and metaheuristic ones. *Mathematical algorithms*, also known as deterministic algorithms, are systematic procedures that rely on mathematical principles to find optimal solutions. One of the most widely used mathematical optimization techniques in structural optimization is the gradient-based optimization method. Gradient-based algorithms, such as the method of steepest descent and Newton's method, iteratively update the design variables in the direction of the gradient of the objective function to converge toward the optimal solution. These algorithms are efficient for convex optimization problems with smooth, continuous objective functions.

On the other hand, *metaheuristic algorithms* [17] are stochastic search techniques inspired by natural phenomena or human behavior [18]. These algorithms explore the solution space using randomized search strategies, making them well-suited for non-convex, multimodal optimization problems commonly encountered in structural optimization. They can be broadly classified into the categories shown in Table 1 which also includes some example algorithms for each class. The list is not exhaustive.

In structural optimization, mathematical algorithms are often preferred for problems with well-defined objectives and constraints which can be often expressed analytically. Gradient-based methods are particularly effective for problems with smooth, continuous objective functions and explicit constraints. However, for more complex, non-convex optimization problems with discontinuous or non-smooth objective functions, metaheuristic algorithms offer a more robust and versatile solution approach due to their ability to effectively handle non-convex, multimodal

Table 1 Categories of metaheuristic optimization algorithms

Category	Examples and related works
Evolution-based algorithms	Genetic algorithms (GA) [19, 20]
	Differential evolution (DE) [21, 22]
Swarm intelligence-based algorithms	Particle swarm optimization (PSO) [23]
	Firefly algorithm (FA) [24]
	Grasshopper optimization algorithm (GOA) [25]
	Cuckoo search (CS) [26]
	Whale optimization algorithm (WOA) [27]
Physics-based algorithms	Simulated annealing (SA) [28]
	Lightning search algorithm (LSA) [29]
	Gravitational search algorithm (GSA) [30]
	Electromagnetic field optimization (EFO) [31]
Human-related algorithms	Teaching-based learning optimization (TBLO) [32]
	Sharing knowledge-based algorithm (GSKA) [33]

objective functions and complex design spaces. Hybrid methods can also be employed, aiming to harness the strengths of both categories. Typically, these methods utilize a metaheuristic algorithm for global exploration, followed by a mathematical optimizer for fine-tuning through localized search around the global optimum [23].

3.3 Optimization Objectives

Optimization criteria, also known as objective functions, play a critical role in structural optimization by defining the goals and performance metrics that guide the design process. In optimum structural design, these criteria typically encompass various factors such as structural efficiency, safety, cost-effectiveness, and environmental sustainability. Structural engineers often aim to maximize structural performance while minimizing material usage, weight, or construction costs. Additionally, considerations may include constraints related to permissible stress levels, deflection limits, and geometric configurations. By carefully selecting and formulating optimization criteria, engineers can effectively balance competing objectives and tailor designs to meet specific project requirements, ultimately yielding more sustainable structures.

In *single-objective optimization* (SOO) within structural engineering, the focus is on optimizing a single performance metric or objective function, such as minimizing material usage or cost, maximizing structural strength, or minimizing deflection under load. Engineers typically formulate the optimization problem as a mathematical function, seeking the optimal solution that satisfies predefined constraints while optimizing the chosen objective. SOO techniques, such as gradient-based methods or evolutionary algorithms, facilitate the exploration of design alternatives to achieve the desired performance targets. While SOO provides a straightforward approach for addressing specific design goals, it may overlook trade-offs between conflicting objectives and fail to capture the full spectrum of design possibilities.

In contrast, *multi-objective optimization* (MOO) considers multiple conflicting objectives simultaneously, aiming to identify a set of solutions that represent trade-offs between competing criteria [34]. These objectives often encompass diverse aspects such as structural performance, cost, sustainability, and aesthetic considerations. MOO techniques enable engineers to explore the trade-off space and generate a range of design alternatives known as the Pareto front [35]. By evaluating trade-offs between different objectives, MOO facilitates informed decision-making and helps identify design solutions that offer superior overall performance across multiple criteria. This approach is particularly valuable in complex design scenarios where conflicting objectives must be balanced to achieve optimal outcomes.

4 Benefits of Optimization in Structural Design

Optimization in structural design offers numerous benefits that contribute to the development of efficient, cost-effective, and sustainable structures. By leveraging advanced computational techniques and mathematical algorithms, engineers can systematically refine designs to enhance performance, reduce material usage, and minimize environmental impact. Optimization enables the exploration of a vast design space, leading to innovative solutions that prioritize structural integrity, safety, and functionality. It facilitates informed decision-making by quantifying trade-offs between conflicting objectives, allowing engineers to achieve optimal outcomes tailored to specific requirements. Ultimately, the adoption of optimization methodologies empowers engineers to push the boundaries of structural design, resulting in more resilient and resource-efficient built environments.

Efficiency Optimization improves the efficiency of structural systems by maximizing performance while minimizing resource consumption and waste. Through iterative refinement of designs, engineers can achieve higher structural efficiency, leading to lighter, more streamlined structures that require fewer materials and resources to construct. This enhanced efficiency translates to reduced construction time, lower energy consumption, and improved overall sustainability.

Cost Savings Optimization helps to reduce construction costs by optimizing material usage, minimizing the need for expensive materials, and streamlining construction processes. By identifying cost-effective design alternatives and eliminating unnecessary elements, engineers can realize significant savings in material procurement, labor costs, and project overheads. Furthermore, optimized designs often require less maintenance over their lifespan, further reducing life-cycle costs and enhancing long-term affordability.

Sustainability Optimization plays a crucial role in promoting sustainability in structural design by minimizing environmental impact and resource depletion. By optimizing material usage, structural configurations, and construction methodologies, engineers can reduce the carbon footprint of buildings and infrastructure projects. Additionally, optimization enables the integration of sustainable materials, renewable energy systems, and passive design strategies, further enhancing environmental performance and resilience to climate change.

Innovative Designs Optimization fosters creativity and innovation in structural design by pushing the boundaries of conventional practices and exploring new possibilities. By leveraging advanced computational tools and generative design techniques, engineers can generate novel structural forms and geometries that maximize performance and visual appeal. Optimization encourages experimentation with unconventional materials, fabrication methods, and construction techniques, leading to the realization of iconic and landmark structures that inspire future generations.

Safety Optimization can enhance structural safety by optimizing designs to withstand a wide range of loading conditions and environmental hazards. By conducting rigorous analysis and optimization iterations, engineers can identify potential weaknesses, improve structural robustness, and mitigate risks of failure. Optimization also allows for the incorporation of safety factors and design redundancies, ensuring that structures meet or exceed regulatory standards and withstand unforeseen challenges throughout their lifespan.

5 Challenges and Limitations

Optimization in structural design, while offering significant benefits, also presents various challenges and limitations that engineers must navigate to achieve successful outcomes. Below we examine and analyze some of these obstacles in detail.

Computational Intensity One of the primary challenges in optimization-driven structural design is the computational intensity required to solve complex optimization problems. The iterative nature of optimization algorithms and the need for detailed FEA in each step contribute to significant computational demands, requiring substantial computing resources and time. As a result, engineers must carefully manage computational resources, employ efficient algorithms, and leverage parallel computing techniques to overcome this challenge and expedite the optimization process without compromising accuracy. For instance, if a single FEA iteration of a building requires approximately 5 s to finish, and an optimization algorithm demands 10,000 iterations to reach convergence, then the optimization process could potentially consume up to 14 h to complete—a substantial duration of time.

Multiple Objectives Balancing multiple conflicting objectives and constraints poses a significant challenge in structural optimization, particularly in real-world construction problems. Engineers must navigate trade-offs between competing design criteria, such as performance, cost, sustainability, and aesthetics, to identify Pareto-optimal solutions that represent acceptable compromises. Achieving consensus among stakeholders and reconciling conflicting preferences can further complicate the optimization process, requiring robust decision-making frameworks and stakeholder engagement strategies to address diverse perspectives and priorities effectively.

Inherent Uncertainties The existence of uncertainties in material properties, loading conditions, and modeling assumptions introduces challenges to the accuracy and reliability of optimization results [36]. Sensitivity analysis techniques are essential for assessing the sensitivity of optimized designs to input parameters and identifying sources of uncertainty that may affect performance and safety. Engineers must employ robust probabilistic methods, such as Monte Carlo simulation [37] or stochastic optimization, to account for uncertainties and optimize designs that

exhibit resilience and robustness [38] in the face of varying operating conditions and environmental factors. Consequently, this introduces further computational complexities to the optimization process [39].

Constraint Handling Handling constraints presents a significant challenge in optimization-driven structural design, as balancing optimization objectives with real-world constraints can be complex and difficult to fully automate. Structural engineers must navigate a diverse array of constraints, including fabrication limitations, regulatory requirements, material availability, and construction logistics, which can significantly impact the feasibility and practicality of designs. While optimization algorithms excel at finding solutions that optimize specified performance metrics, integrating constraints into the optimization process requires careful consideration and often involves trade-offs. Engineers must strike a delicate balance between achieving optimal performance and adhering to practical constraints, such as budgetary limitations, site-specific conditions, and safety standards. Furthermore, constraints may vary in nature and complexity across different projects, necessitating customized approaches and expert judgment while optimizing structural designs for sustainability, efficiency, and safety. Despite these challenges, advancements in constraint handling techniques, continue to enhance the capabilities of optimization algorithms to accommodate diverse constraints and facilitate the development of innovative and practical structural solutions.

6 Conclusions

In conclusion, structural optimization emerges as a pivotal asset in contemporary engineering, offering a pathway toward the creation of stronger, more efficient, and sustainable structures. By harnessing the power of optimization algorithms and computational tools, engineers can unlock innovative design solutions that maximize performance while minimizing environmental impact. Optimization techniques enable the strategic allocation of materials and resources, resulting in structures that exhibit superior resilience, structural integrity, and resource efficiency. Moreover, optimization has the potential to revolutionize the construction industry by streamlining design processes, reducing material waste, and enhancing project cost-effectiveness.

With advancements in technology, hardware, and software, coupled with the increasing availability of computational resources, the field of structural optimization is poised for significant expansion. The integration of cutting-edge computational methods and predictive modeling techniques promises to propel structural design into a new era of unprecedented creativity and efficiency. By leveraging these technological advancements, engineers can explore complex design spaces, optimize structural configurations, and push the boundaries of conventional construction practices. As a result, the forthcoming era of structural design holds the promise of

seamlessly blending artistic ingenuity with scientific precision, yielding structures that not only meet functional requirements but also embody ecological mindfulness and cost-efficiency.

In essence, structural optimization represents a transformative paradigm shift in the built environment, offering a harmonious convergence of engineering excellence and sustainable design principles. By embracing optimization methodologies, engineers can catalyze positive change in the construction industry, fostering the development of resilient, adaptable, and environmentally conscious structures. As we embark on this journey toward a more sustainable future, structural optimization stands as a beacon of innovation, driving the evolution of architectural design toward a greener, more efficient, and harmonious built environment.

1 Introduction

AI's ability to analyze vast data sets, predict trends, and automate tasks presents a promising avenue for smarter, more sustainable urban planning [1].

Moreover, AI's potential in discovering environmentally friendly materials and methods is still being explored [2].

A significant overlooked opportunity is the use of AI to identify innovative collaborators for building sustainable cities [3]. This article aims to illuminate how AI can revolutionize urban planning and design, exploring strategies to overcome these barriers and maximize AI's benefits.

By simplifying complex concepts and focusing on practical applications, we aim to make the discussion about AI and sustainable cities more engaging and comprehensible.

2 Theoretical Framework

Artificial Intelligence (AI) has significantly transformed our interaction with the environment, evolving from basic computational tools to advanced systems capable of tasks like language and image recognition. Originating from Claude Shannon's work in the 1950s, AI has progressed through remarkable milestones, now operating predominantly in the realm of Artificial Narrow Intelligence (ANI), excelling in tasks like powering voice assistants and chatbots. The ambition extends to Artificial General Intelligence (AGI) and Artificial Superintelligence (ASI), aiming to match or exceed human cognitive abilities, thus potentially reshaping societal norms [4]. AI's applications extend across healthcare, finance, and transportation, driven by advancements in Natural Language Processing (NLP), Computer Vision, Machine Learning (ML), and Deep Learning (DL), enhancing our problem-solving capacity and fostering innovation [5].

In sustainable urban planning, AI plays a pivotal role, leading the development of smart cities that integrate environmental sustainability with technological advancements [6].

AI enhances urban efficiency by optimizing energy use, improving waste management, and refining public transportation through detailed analyses, with cities like Stockholm, Copenhagen, and Amsterdam exemplifying AI's ability to support sustainable, resilient urban areas [7]. Nonetheless, challenges persist, including misconceptions about AI's capabilities, data privacy concerns, financial costs, and potential biases in AI algorithms. Overcoming these obstacles requires targeted educational efforts, transparent data governance, cost mitigation collaborations, and a dedication to ethical AI practices [8].

AI's impact on sustainable urban planning is profound, especially in introducing innovative materials and methods, such as machine learning for land use optimization and energy-efficient building designs. Supported by sensor and satellite data, this global research and development collaboration underscores AI's vital role in fostering sustainable, livable cities [9].

In procurement within urban planning, selecting the right suppliers is crucial. Decision-making models like Multi-Criteria Decision-Making (MCDM) and techniques such as ELECTRE and PROMETHEE help evaluate suppliers based on various criteria, including environmental impact. Generative AI further revolutionizes procurement by enabling the rapid production of high-quality content for supplier evaluation, marking a new procurement era and enhancing selection strategies [10].

2.1 Case Study: AI in Amsterdam's Urban Planning

Amsterdam's AI application in urban planning, particularly in flood prediction and green infrastructure planning, showcases AI's potential to address specific challenges. AI algorithms allow for accurate flood pattern forecasting and the design of urban initiatives aligned with natural water systems, highlighting a sophisticated approach to integrating technology with environmental sustainability. This not only demonstrates AI's problem-solving capabilities but also contributes significantly to the city's climate resilience [11].

3 Methodology

This investigation explores Artificial Intelligence's (AI) role in evaluating and selecting innovative contractors and suppliers for sustainable urban planning. Using a scoping literature review, based on Arksey and O'Malley's framework [12], it examines AI's integration in supplier selection and urban design supply chain management. This methodological approach is ideal for the evolving field of AI, which spans diverse methodologies and outcomes. Our methodology commenced with formulating a research question to explore AI's potential in sustainable urban design. A rigorous literature search followed, employing databases like Semantic Scholar, Google Scholar, and ABI/INFORM, and using Boolean operators for precision (Table 1).

This strategic search, favoring Semantic Scholar for its relevance to our objectives, aimed to cover the last 25 years, capturing AI's advancements and seminal contributions to the field. We prioritized peer-reviewed articles relevant to AI in supplier selection, deliberately excluding unrelated studies. The Elicit tool was instrumental in filtering over 126 million papers, identifying 32 articles crucial for our study. These selections were based on their methodological rigor and innovative insights into AI's procurement role within urban planning. This process allowed for a focused review, ensuring comprehensive coverage and relevance.

Our refined strategy involved specific inclusion and exclusion criteria, streamlining the review process. The choice of individual search terms over a combined string enhanced the breadth of our exploration, enriching the study's depth. This meticulous approach facilitated the identification of 32 articles that

Table 1 Result of our Boolean operators from Semantic Scholar

Boolean operators	Number of articles
AI and Urban Design	Approximately 49,400 articles
AI and Supplier Selection	Approximately 10,200 articles
AI and Order Allocation	Approximately 29,500 articles
AI and Supply Chain Management	Approximately 4240 articles

were pivotal due to their focus on AI in procurement, showcasing methodological sophistication and global applicability.

Data charting adhered to Arksey and O'Malley's [12] framework, summarizing findings to offer a structured overview of AI's role in sustainable urban planning. The final stage collated and summarized results, presenting a synthesized view of the research on AI's transformative potential in sustainable urban development. This methodology, detailed for clarity and depth, and leveraging a Large Language Model (LLM) for textual refinement, maintained scholarly integrity while enhancing readability.

By outlining the use of Boolean operators and strategic database choices, the revision underscores the selection process's rigor. Discussion on methodology reflects transparently on the applied criteria, offering a systematic review that integrates references [13], ensuring the academic integrity of our concise exploration (Fig. 1 and Tables 2, 3, 4 and 5).

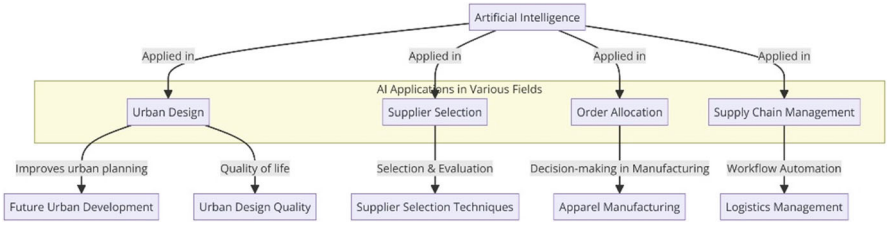

Fig. 1 Relationships between the topics of artificial intelligence (AI) applications in various fields

Table 2 Articles on artificial intelligence and urban design

Title	Abstract summary
AI for Future Urban Development	Highlights AI and machine learning's role in enhancing urban planning through advanced data analysis and inference [14]
AI's Impact on Urban Design	Discusses AI's contributions to urban planning and design, with an emphasis on improving city life quality [15]
Urban AI: Interdisciplinary Research Agenda	Calls for a dedicated research community at the AI and urban design intersection [16]
AI in Urban Design: The Egypt Case	Investigates the potential and challenges of employing AI in urban planning, focusing on Egypt [17]
AI in Australian Urban Planning	Analyzes the adoption and effects of AI technologies in urban planning and development in Australia [18]
Review of Urban Planning and AI	Reviews methods of applying AI to tackle urban dynamics [19]
Hybrid AI Systems in Urban Planning	Describes the development of a hybrid AI system for automating urban planning decisions [20]
Urban-GAN: AI for Urban Design	Introduces a system that uses AI to create distinctive urban designs, showcased in cities such as Manhattan, Portland, and Shanghai [21]

Table 3 Articles on artificial intelligence and supplier selection

Title	Abstract summary
AI and Optimization in Supplier Selection	Develops a system that uses AI and particle swarm optimization for precise supplier selection based on both qualitative and quantitative factors [22]
Neural Networks in Supplier Selection	Explains how the integration of neural networks with the analytic hierarchy process can reduce the amount of training data needed for supplier selection [23]
Intelligent Management at Honeywell	Showcases how Honeywell Consumer Product (Hong Kong) Limited utilized an intelligent system to reduce outsource cycle times [24]
Predictive Model for Supplier Negotiations	Introduces an ANN-based model to improve the supplier selection negotiation process [25]
Green Supplier Selection in a Fuzzy Environment	Combines data envelopment analysis and genetic programming for evaluating supplier efficiency in uncertain conditions [26]
Supplier Management for Product Development	Highlights the effectiveness of Honeywell's intelligent system in reducing outsource cycle times for new product development [27]

Table 4 Articles on artificial intelligence and order allocation

Title	Abstract summary
Cloud-Based System for Apparel Manufacturing	Developed to streamline order tracking and allocation across multiple apparel manufacturing sites [28]
Intelligent Order Allocation	Utilizes fuzzy numbers to enhance decision-making for order fulfillment amid changing customer demands [29]
Symbiotic AI for Order Picking	Introduces an egocentric Symbiotic AI that uses ambient sensing for agent training, improving order picking efficiency without direct supervision [30]
AI in System Order Discrimination	Employs learning machines to identify features for discriminating the order of multivariable systems [31]
Intelligent Warehouse Management Algorithms	Optimizes warehouse order picking by reducing picker travel distance through intelligent algorithms [32]
Carbon Tax-Conscious Order Allocation	Evaluates the economic and environmental impacts of order allocation within online freight platforms under carbon tax constraints [33]
Autonomous Warehouse Robots	Investigates the use of robots for uninterrupted order collection in large warehouse environments [34]
Order Placement and Resource Allocation	Studies the influence of different order placement strategies on resource allocation and processing times in multi-user warehouses [35]

The study highlights the significant role AI plays in supplier management and urban planning, with particular emphasis on innovative systems and models, like Urban-GAN, and focuses on geographical or unique research areas. Notable mentions include the methodologically rigorous and innovative applications of AI, especially in Honeywell's operations in Hong Kong, demonstrating AI's potential

Table 5 Articles on artificial intelligence and supply chain management

Title	Abstract summary
AI in Logistics and SCM	AI enhances automation in logistics and supply chain workflows [36]
AI's Role in Logistics and SCM	Highlights AI's potential in improving decision-making and efficiency in logistics and SCM [37]
AI Solutions for SCM	Discusses AI's emerging portfolio of solutions for supply chain management [38]
AI in SCM: An Exploratory Case Study	Examines the importance of AI-driven research and applications in SCM [39]
AI, SCM, and FinTech	Explores AI integration into analytics and CRM for better customer service in SCM [40]
AI and Blockchain in Digital SCM	Advocates a strategic approach to adopting AI and blockchain for SCM benefits [41]
AI for SCM Execution	Applies AI approaches to improve supply chain execution [42]
Systematic Review of AI in SCM	Reviews current and potential AI techniques for enhancing SCM studies and practices [43]

to enhance efficiency and decision-making in supply chain management. Through a combination of automated and manual screening, the research navigates a vast literature landscape effectively. By employing Arksey and O'Malley's framework, the research develops comprehensive tables summarizing the collected articles, addressing how AI aids in evaluating and selecting contractors and suppliers for sustainable urban development. This synthesized overview provides a concise, yet informative look at AI's current state in supplier selection and order allocation, including the sustainability criteria addressed by AI tools.

Additionally, this research integrates the use of a Large Language Model (LLM) for the refinement of linguistic expression within our materials, enhancing the clarity and accuracy of the content. This careful enhancement ensures that the dissemination of findings remains both comprehensible and adherent to scholarly standards. Such detailed attention to linguistic quality not only elevates the coherence of the presented research but also enriches the discourse on the influence of AI in advancing sustainable urban planning initiatives.

4 Findings and Conclusion

Our study provides a synthesized overview of the pivotal role of artificial intelligence (AI) in the evaluation and selection of innovative contractors and suppliers within the sphere of sustainable urban development. This summary distills key insights into the methodologies, applications, and overall impact of AI technologies on sustainable urban planning and supply chain management, highlighting its essential role in propelling toward a more sustainable future (Table 6).

Table 6 Synthesized overview of findings

Field	Capabilities	Methods/usage	Advantages/impact	Innovations
AI in Urban Design	Enhances urban planning through data analysis and promotes interdisciplinary research	N/A	Automates decision-making and fosters innovative designs across diverse areas	N/A
AI in Supplier Selection	Streamlines the selection process with sophisticated methods	Employs artificial neural networks, genetic algorithms, and fuzzy neural networks	Enhances supplier evaluation and management; supports green procurement decisions	N/A
AI in Order Allocation	Optimizes order allocation and fulfillment in logistics and manufacturing	AI-driven systems improve operational processes	Enhances efficiency, sustainability, and resource allocation	N/A
AI in Supply Chain Management	Automates workflows and enhances decision-making	Ranges from logistics to integrating financial technology	Improves operational efficiency	Utilizes analytics and blockchain to revolutionize supply chain practices

These findings highlight AI's transformative impact across various domains, advancing theoretical understanding and showcasing practical applications, especially in optimizing supplier selection and management processes, affirming AI's contribution to sustainable urban development. The integration of AI in urban design and supply chain management marks a significant transformation toward enhanced efficiency, sustainability, and resilience. However, leveraging AI's full potential requires the development of scalable, ethically responsible solutions. The need for comprehensive strategies to enhance supply chain resilience, efficiency, and sustainability is underscored by the absence of systematic reviews addressing the intricacies of supplier selection and order allocation processes [6]. This gap represents an opportunity for research that enriches our understanding and addresses the challenges of urban logistics and sustainability [44].

Future research should focus on developing specific AI algorithms and conducting empirical studies to assess their real-world applications and challenges. Investigating the ethical, social, and regulatory dimensions of AI deployment is essential for ensuring its widespread acceptance [45]. Additionally, understanding geographic and cultural differences is crucial for creating adaptable AI solutions for diverse urban settings [46].

In conclusion, this analysis presents a strategic roadmap for stakeholders committed to fostering more sustainable, efficient, and resilient urban and supply chain systems through AI. This pursuit enriches both the theoretical and practical understanding of these areas, preparing them to thrive amidst the future's dynamic changes.

1 Introduction

In recent years, active travel has seen increased interest in research, policy and practice, presented as a vehicle for improving health, liveability, safety and sustainability in cities by altering the way we move within them [1]. These changes are typically approached through alterations to the built environment, not least through street space reallocation projects to create desirable spaces for alternative mobilities from previously unclassed road space [2]. However, in attempting to create structural change in mobility norms, practisers encounter significant barriers execution of plans [3]. A proposed solution lies in institutional mobilisation of tactical urbanism and associated concepts, which utilise designed temporariness to test and softly introduce new layouts for urban space for alternative uses [4].

Institutional mobilisation of temporary and tactical interventions in the urban realm increased in relevance during the COVID-19 pandemic in response to changes in the demand for intra-urban movement [5, 6]. The conditions of the pandemic provided a unique opportunity for expanding provision for walking, wheeling and cycling, where lower demands for street space for mobility permitted the introduction of new temporary measures under the legitimation of the acute emergency [7, 8]. The increased interest in tactical urbanism in practice has been accompanied by a similar, co-constitutive trend in research [9–11].

However, the transformative potential of tactical urbanism remains unclear. Rather, instead of acting as precursors to permanent or systemic change, interventions are often removed with the previous street design and mobility norm reinstated. This suggests that in practice, tactical urbanism is not yet able to achieve results that proponents describe. This chapter examines this problem across case studies from international practice in order to determine where difficulties remain and what changes may then lead to more effective utilisation. To structure findings, cases are weighed against five assessment criteria derived from Bertolini [12]: characteristics which must be present in street-based experiments that possess transitionary potential.

The following research questions are approached:

1. What are the main drivers behind short-termism in tactical urbanism planning?
2. To what degree can planning be generalised or is otherwise dependent on local structural conditions?
3. (How) can planning process be adapted to account for these blockages?

The chapter confirms earlier suggestions of a barriers in practice to radical change, where pressure is not placed on the existing regime while supporting the intended norms, and instead, decision-makers still display risk aversion found in permanent planning [13]. Rather, in practice, it is more typical for interventions to follow a path of least resistance in efforts to avoid conflict, finding 'spare space' where demand is lower [14]. Under the COVID-19 pandemic, demand for mobility initially dropped, providing room for experimentation without significant risk to decision-makers, an opportunity exploited by city authorities, particularly in North America and Europe [8, 15, 16], but increasingly in South America and Oceania [17–19]. The critical point then comes during recovery, when demand for space by other modes returns and temporary changes must find additional justification for remaining.

The findings indicate long-term goals have not universally been incorporated into the development of temporary projects. Temporary interventions, while more feasible to implement, remain vulnerable to removal in response to public and political will [20].

Finally, a note on language. Success and failure of projects in this context are measured against their ability to expand and continue along a trajectory which supports uptake of active travel modes, but this is not a definition used across cases. Many cases address short-term issues via short-term means, with little atten-

tion to upscaling, achieving their goals without further development. Success measures across cases are more diverse than the one implemented here and is, as such, not a blanket judgement of subjective quality.

2 Theoretical Framework

This review is grounded in insight from transition studies, including the concept of transition management (TM), which provides basis for determining necessary inputs and dynamics for temporary public space interventions to set into process long-term and potentially permanent changes [21].

Tactical urbanism itself has evolved greatly from its conceptual origins as citizen-initiated alterations in the local environment, based upon collective problematisation and dissatisfaction with official channels of orchestrating change, as described by Lydon & Garcia [22]. Rather, the term has been arguably co-opted for use by the very structures the concept aimed to find alternatives to. However, the usefulness of temporary and inexpensive design in supporting change towards active travel is increasingly recognised, particularly during a period of widespread austerity putting spending under scrutiny [19, 23]. Temporariness as used by official authorities allows for testing of uncertain concepts before committing to a redesign, supporting a strategic transition going beyond the local area. While doing so, socio-political change can be initiated to challenge and disrupt existing norms. Therefore, critics argue only urban experimentation at the institutional scale can drive a long-term transition [24].

Much of the understanding behind the role of tactical urbanism as enabling transition derives from the multi-level perspective (MLP) framework, used for analysing (potential) system change [21, 25]. Previously, a common public space catering to diverse uses, automobility has dominated the mobility system as the primary mode and use for space: remaking the public in its own image, designed to serve a singular purpose in moving vehicles as efficiently as possible. Alternative modes of different speeds, sizes and directionality come into conflict with this goal [26].

Transition studies propose that change is possible via breaks in the third level of the MLP, the landscape. The landscape is external and encompassing, but periodical breaks and crises provide space to undermine the hold of the regime. In this context, the key landscape opportunity is the pandemic. The sudden and widespread challenge of the COVID-19 pandemic had such a radical effect on patterns of urban mobility that it both forced the hand of policymakers to experiment and provided space to do so under exceptional conditions.

With experimentation in mind, Roorda et al. [27] developed a guidance manual for transition management derived from case studies in Western European cities. The characteristics used here to assess transitional capacity in practice are derived from this and assembled by Bertolini [12]: radical; challenge driven; feasible; strategic; communicative/mobilising. A degree of reinterpretation of certain characteristics in light of lessons from the pandemic is applied during discussion of results.

3 Methodology

The review was conducted semi-systematically using thematic analysis based on the pre-established research questions. Search terms were established through a precursive review. Strings using Boolean operators (Table 1) were used to ensure a focus on (active) mobility and to include articles identifiable only through temporariness and types or focus of intervention. Literature was collected and assembled in NVIVO, with further exclusions made during the initial read-through. Ninety-two works were included.

Search terms were chosen to provide as broad an interpretation as possible in order to include results not under the Euro-American vocabulary used to describe temporary active travel projects. Geographic bias is present in the included literature but is reflective of the field. In a recent commentary, von Schönfeld [28] highlights this bias as one connected to expectations about development in planning. In the Global North view mobility experiments as undoing perceived mistakes of a modernism which was never universal. In further development of the field, inclusion of diverse forms of southern urban informality can offer a more holistic view of utilising temporariness.

4 Results

As noted by Stevens, Awepuga & Dovey [19], temporary and tactical urbanisms, when referred to as such, are centred in Europe and North America within the English-language academic literature. Case studies featured in the collected literature reflect this, with the highest number of case studies based on Paris (6), London (6), Berlin (5), Milan (5) and San Francisco (5). A geographical shift can be noted, however, as the focus interest in tactical urbanism moved from bottom-up instances,

Table 1 Boolean operators used in literature search

Main term	Operator	Cycling terms	Operator	Walking terms	Operator	General terms
'tactical urbanism'	AND	'cycling' 'bicycle' 'bike'	OR	'pedestrian' 'walking'	OR	'active travel' 'mobility'
'street experiments'	AND	'cycling' 'bicycle' 'bike'	OR	'pedestrian' 'walking'	OR	'active travel'
'temporary'	AND	'bike lane' 'bike path' 'cycle path'	OR	'walkway' 'pavement' 'sidewalk'	OR	'active travel'
'pop-up'	AND	'bike lane' 'bike path' 'cycle path'	OR	'walkway' 'pavement' 'sidewalk'	OR	'active travel'

of which San Fransisco was a hotspot as the origin of the *parklet* concept, towards municipalities actively working to expand active travel networks and reorient space via tactical means, particularly during the pandemic [22, 29].

A key finding of the review is that municipalities and planners have, in practice, still limited capacity to position temporary projects towards supporting long-term mobility transitions locally. Public support is vital in justifying political decisions. Authorities employ varying participatory processes, from none at all under the 'emergency' mandate of the pandemic [7, 30], to co-creative strategies intending to provide citizen ownership over the projects throughout the entire development process [18].

4.1 Radical

Radical character is essential to socio-technical transitions of all kinds, as it represents a clear break with the existing status quo or dominant regime. Radical interventions in mobile space not only provide facilitation for active travel but also destabilise the automobility's dominance over space.

Using tactical urbanism to initiate changes in street space can permit more radical changes to occur, compared to their permanent counterparts, which can quickly become politically contentious [31, 32]. The aim of the temporary intervention in such cases, then, is to demonstrate the feasibility of the change both to the public and decision-makers, creating a base for further development.

Often, radical aspects of projects are lost during the process of experimentation, or in the transition to a permanent incantation following evaluation of the temporary version. Ohlund et al. [33] describe alterations made to a temporary bike lane to better accommodate vehicle traffic following neighbourhood 'bikelash' in Zapopan, Mexico. Landgrave-Serrano & Stoker [34] find that efforts to make a Slow Streets programme more widely palatable in the transition to a permanent version led to a drop in use, as restrictions for automobile traffic were removed in favour of traffic-calming measures. A temporary bike lane in London reviewed by Nikitas et al. [17] experienced a similar fate following poor levels of acceptance. Several articles identify major reasons for public backlash against interventions which aim to support active modes, namely concerns about limitations on parking and perceived increases in traffic as a result of spatial reallocation of road space [18, 33–36].

According to proponents, more radical changes can be tested when done temporarily as there is room for failure if initial versions do not function as well as expected [37, 38]. However, under a transitionary lens, this requires willingness to adapt measures based on evaluation, a contingency which must be planned into timelines and budgets.

The notion of 'pop-up' infrastructures exemplifies this risk aversion type of temporary urbanisms. A planner interviewed by Stevens, Awepuga & Dovey [19] connects this with short-termism, a version used by policymakers unprepared for long-term change. This was a key point of contention for many authors writing under

COVID-19 [39]. While some pop-up infrastructures were explicitly used as a precursive measure in a long-term strategy towards permanent change, in others it performed the role of a stopgap, addressing time-sensitive demands [40, 41].

Radical character, then, is not a universally applicable category, instead dependent upon how developed active travel provision is in the local context and citizens' perceptions of and willingness to accept change. Rather, it necessitates a fundamental break from dominant practices [12]. For cities with no or very weak cycling provision, testing using tactical urbanism may be relatively limited, but should focus on providing routes where most valuable [6, 42]. On the other hand, in cities with existing networks, tactical urbanism is used radically to strengthen weak points, creating safe routes for longer journeys [6, 11, 38]. It was these cities which achieved the most promising results while exploiting pandemic conditions, adapting existing plans to the context with clear lines for future development.

4.2 Challenge Driven

Bertolini defines the characteristic of 'challenge driven' as answerable to the question 'Is the experiment a step toward a potential long-term change pathway to address a societal challenge?' [12: 744].

While pandemic-era mobility interventions centre around the short- to mid-term challenges to urban movement presented by virus transmission, for many case studies the issues presented a landscape opportunity to catalyse pre-existing plans for a sustainable mobility transition. Buck [5] notes that the pandemic drew attention to existing health-related arguments for supporting active travel as a means of increasing physical activity, alongside environmental changes which support safer journeys.

This characteristic is essential when considering public and political support for street alterations, linking with communication. Projects must be justifiable, with intentions for further development clearly articulated.

The challenge of improving safety functions as a strong justification for temporary alterations, particularly when the foci of improvements are oriented around children's needs in residential areas and around schools. Positive results for children's recreation have served as mandate for the continuation of temporary projects while challenging motor normativity as the dominant use for street space [4, 37, 43]. Programmes such as School Streets are then often accompanied by complimentary policies on surrounding streets such as lower speed limits [38, 44, 45], recognising that discrete street changes are not adequate to bring about change of the scale intended.

Sets of complimentary measures arranged around the same challenge may more effectively support spatial changes, including campaigns to support lasting competencies for trying new modes like cycling, alongside wider measures to make driving less attractive [45].

4.3 *Feasible*

Feasibility can come under two interpretations. The first, as put by Bertolini [12], deals with the feasibility of the temporary intervention itself—it must be feasible to take place. The other interpretation looks longer term, where a project must be feasible to upscale and continue a productive trajectory, designed to be reproducible.

Temporariness is the key factor in what allows such interventions to become feasible in comparison to their permanent counterparts, as they are easily removable without the loss of a great investment, making them popular for creating space for cycling under the 'pop-up' bike lane concept [37, 45]. Temporariness can be material, or even discursive, using permanent materials but assuring that the space can and will be returned to its earlier state if it's deemed a failure. The Sarphatistraat Zuid project in Amsterdam is an example of this, laying a new bicycle street in red asphalt, removing traffic lights and lowering the speed limit—but still 'vowed to change the street back to its original state if unsuccessful' [13: 6]. It's unclear whether this assertion enabled feasibility amongst the public, as there was no formal consultation; a choice which in turn, did improve feasibility.

Public consultation generally improves feasibility in the short term [12, 46], but risks alienating the public when the project is considered for subsequent stages [35]. Where approval is high, however, it can be used to justify continued expansion of the scheme [27] or to create a base level of trust between the community and decision-makers useful in further iterations [19]. Some projects begin with participation as a key element but it is lost over time as the plan develops and authorities seek to lower the risks of public scrutiny [47]. In sum, the connection between feasibility and communicative/mobilising in practice is complex and variable, with the nature of this relationship discussed in more detail later.

Aesthetic purpose and alternative uses for street space 'beyond mobility' come into consideration of materials for reorganising space [12]. Plant pots, flowers and street furniture are popular for both creating new pathways for active travel from road space, but also for blocking through traffic from accessing whole stretches in the case of low traffic neighbourhoods and slow/active/school streets [31, 48, 49]. Aesthetics play a role in overall environmental quality, which can influence public perception and future feasibility of projects which may otherwise be oriented towards a specific user base who already have interest in walking or cycling [18, 48, 50].

4.4 *Strategic*

Strategic links with feasibility as defined as enabling a more forward-looking approach. According to Bertolini [12], it must be present in urban experiments as that which generates lessons for future practice, indicating that an intervention is even temporary in physical lifespan and openness in eventual directionality towards goals.

The role of strategy is highlighted under the question of goal formulation and framing. As noted by Gregg et al. [39], cities with most long-term success such as Paris, Milan and Bogota framed their street space alterations as transportation projects, while those in North America were largely positioned as responses to the sudden requirement for social distancing in the public realm. The emergency justification is certainly not new, but the COVID-19 crisis was unique as an opportunity for utilising the drop in demand for mobility itself to create entirely new habits of moving.

Varying practices of governing and funding projects are visible across the reviewed case studies. In Liverpool, funding from the National active travel fund supported pop-up cycling measures which, alongside lower initial traffic levels, allowed for the safe development of new mobility habits for cycling [5]. However, supportive measures were not continuously developed to account for the return of traffic following the first lockdowns, and as such, ground made in behavioural adaptation was lost.

Similarly, momentum can be lost during the initial project when temporary interventions are neglected. Implementation of a Thessaloniki pop-up bike lane failed to include supporting measures like enforcement of parking, drainage maintenance and connectivity at junctions, leading to very low overall satisfaction [41, 51]. Maintenance of interventions with temporary materials is necessary to maintain usability.

Paris can be considered a success case for COVID-era mobility intervention because of its precursive strategy to expand its city-wide cycling network, using the pandemic conditions as mandate to fill in gaps and improve connectivity. A higher share of protected, bi-directional lanes was implemented, with 58% connecting with four other bike lanes, compared to 28% of those built between 2005 and 2020 [20]. Improvements are reflected in an increase in cycling levels: '60% greater in 2020 and 2021 than in 2019' [37: 20]. Continual investment and support of measures, including making temporary infrastructure permanent, form part of Paris' strategy for maintaining the trajectory of the trend once the risk of transmission has subsided.

Communication between actors arises as a key challenge in maintaining momentum and longevity. During the process, actor networks do not remain consistent, being necessary to continuously expand as new competencies become required for subsequent stages, particularly in the eventual transition to permanence [52].

4.5 Communicative/Mobilising

In the literature, attention to communication within planning of tactical urbanism interventions varies greatly. Strategic avoidance of participatory processes was enabled during the COVID-19 pandemic as a crisis reaction, permitting suspension of normal requirements [31, 53, 54].

Some evidence exists to support participation throughout the entire process, where citizens may accept subsequent stages of development and change, even when initial efforts are not entirely successful [10, 13]. Others find 'more positive outcomes' and acceptance of change when communities were involved from the beginning, again being more willing to work with failures when there is some sense of ownership [18]. In these cases, higher levels of communication with the public lower the vulnerability.

In the same vein, poor communication can be a death sentence for projects-in-progress, halting them from reaching any subsequent stage of development. Brovarone, Staricco and Verlinghieri [32] highlight a lack of public knowledge of projects' justification as a key factor in project failure. Kyriakidis [55] cites the lack of a clear message about the positive impacts that road reallocation would have on the image of Athens as reason for low approval of a pilot version. In essence, the proposed benefits of changing street space must be clearly justifiable.

Beyond public participation, communication within scales of governance and external interest groups are shown by several case studies to greatly impact the post-intervention viability of networked projects [10, 56, 57]. Municipalities without direct decision-making power over their streets must negotiate with higher-level governmental authorities—provincial or national—for permission or funding to initiate the change [57]. Where goal formulations are inconsistent across different levels of responsible parties, it may result in continuation of projects being dependent on conditions impossible to meet [56]. Rather, new connections and often funding sources must be sought to maintain established momentum [5]. Power for the continuation or renewal of temporary projects ultimately lies within networks which are constantly evolving, leaving experiments vulnerable even when broadly supported [12, 28].

An ideal sense of communication may then be dependent upon what is to be achieved and the context of implementation. For practitioners, keeping internal actors informed of progress and goals at each point in the process is necessary for further development of short-term projects into significant changes.

5 Discussion

The aims of this review are to gain an overview of whether city authorities have been able to utilise tactical urbanism practices to set into motion longer-term plans for transitioning to active travel-based mobility norms. In cases where that has not been achieved, the paper aims to identify key blockages for practice, leading to pathways for alleviating these issues with attention to success cases.

Good practice for tactical urbanism in many ways mirrors standards for mobility planning more generally. Projects which achieved the greatest impact on transforming mobility locally were those which acknowledged and accounted for the characteristics of mobility, considering needs for measures beyond the intervention and beyond the period of initial implementation. Paris effectively utilised

landscape opportunity of the breakdown in mobility habits to provide grounds for building new ones in line with municipal goals. The city government implemented a strategy from established plans and adapted to the pandemic period, creating viable networks for cycling where demand was highest [11, 20], rather than along paths of least resistance [14].

Consideration of strategy for implementation is, however, dependent upon existing institutional factors: the nature of funding schemes; local powers and political willingness to enact change; stage of local progression towards that change and existing public support. Communication is emphasised here as critical but variable in suitable application. Certain conflicts can be anticipated and managed during the intervention stage, recognising that they challenge fundamental power relationships in cities.

6 Conclusions

The main objective of this literature study is to provide a wide overview of mobility-oriented tactical urbanism practice by institutional authorities, evaluated against assessment criteria which weigh transitional capacity of experimental urban interventions. Temporary projects can benefit from borrowing processual characteristics from their permanent counterparts, better utilising a strategy suited to the complexities of planning for mobility, recognising long-term change and multiscalar impacts.

Future research could build upon the points raised in this chapter in the creation of guidelines for practice, testing whether these issues can be eased. Rather, it may be that in many contexts, structural issues associated with funding, decision-making and implementation power must be resolved before full potential can be reached.

The field could benefit from follow-up study of eventual outcomes of projects, with attention to the evaluation and decision-making of subsequent iterations.

1 Introduction

Transforming the existing building stock to enhance energy efficiency is a crucial strategy for climate change mitigation and adaptation. This transformation largely involves the reduction of operational emissions through energy-efficient building operations and the integration of on-site renewable energy generation, making

Emergy (short for embodied energy) is a concept that represents the total amount of energy that is consumed directly or indirectly to produce a product or service, expressed in terms of one type of energy, often solar energy. It was developed by systems ecologist Howard T. Odum in the 1980s as part of his work on ecological economics and systems theory.

Building Energy Retrofit (BER) strategies vital for substantial emission reductions across environmental, energy, and societal dimensions. Notably, the quantity of embodied carbon dioxide equivalent ($CO_{2\text{-eq}}$), which arises throughout the lifecycle of building materials and components, often surpasses operational emissions, accounting for 69% in residential, 76% in warehouses, and 67% in commercial buildings [1]. Global initiatives aiming for a net-zero carbon building stock by 2050 require a 50% reduction in direct building CO_2 emissions and a 60% reduction in indirect emissions from power generation by 2030, correlating to a consistent annual decrease of about 6% from 2020 to 2030 [2].

Despite the focus on new constructions, retrofitting existing buildings is essential to meet the 2050 energy reduction targets, especially since 90% of current buildings will remain by that year [3]. The potential of retrofit strategies is emphasized by their proven capability to significantly enhance environmental performance, with documented energy savings of 66%, 50%, and 75% in various studies [4–6]. However, current tools for building evaluation often fail to fully recognize the socio-economic and environmental impacts, collectively known as Non-Energy Benefits, which include improved Indoor Air Quality (IAQ), resilience, health, and productivity [7]. These aspects are increasingly relevant in the evolving climate change economy and require greater emphasis in adaptation scenarios and decision-making.

In Mexico, a significant energy consumer and CO_2 emitter, ranking 11th globally in greenhouse gas emissions and heavily reliant on fossil fuels—with oil and natural gas comprising 45% and 38% of its energy supply, respectively [8]—the importance of retrofit strategies is accentuated. These strategies are critical not just for reducing fossil fuel dependency and enhancing energy security but also for stimulating economic benefits, improving indoor comfort, realizing long-term cost savings, and fostering urban planning and renewal efforts. Retrofitting in Mexico could thus catalyze a transformative shift toward a sustainable and resilient built environment.

The overarching goal of this study is to contribute to the body of knowledge by formulating a framework and evaluation method system for retrofit models tailored to temperate climates akin to the conditions prevalent in Mexico City throughout the year. This research endeavors to bridge the existing gaps in understanding, ultimately guiding the formulation of cost-benefit efficient retrofit strategies that align with the city's unique environmental context (Fig. 1).

2 Research Statement and Objectives

The landscape of Building Retrofit Models, while robust in many respects, reveals significant potential for enhancing the way Energy Efficiency improvements and decarbonization are approached. Existing models have yet to fully integrate a cohesive framework that effectively balances Energy Efficiency, embodied carbon, and the broader architectural context, often resulting in fragmented retrofit strategies. This is compounded by the absence of established methodologies to perform the Emergy analysis concept at an urban scale, limiting the ability to thoroughly assess environmental impacts of retrofit interventions. Moreover, the challenges in

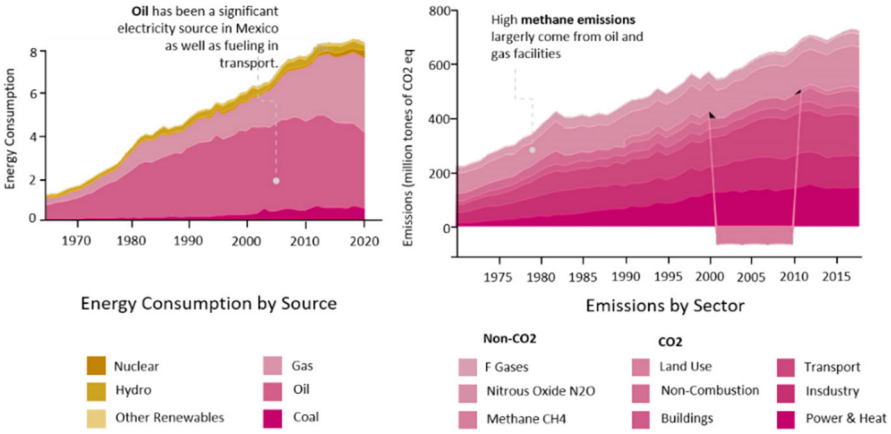

Fig. 1 Energy consumption by source and emissions by sector in Mexico (Carbon Brief Profile 2023)

establishing reliable baselines for evaluating retrofit impacts due to inconsistent and inaccessible data further exacerbate the difficulty in measuring true retrofit efficacy. Disparities in accuracy between urban-scale and individual-scale retrofit analysis undermine effective decision-making and hinder the adoption of impactful strategies. Additionally, current models do not sufficiently account for non-energy benefits—such as improved indoor air quality, occupant health, and resilience—which are critical for a holistic assessment of retrofit interventions. Addressing these aspects within a value-based framework designed to enhance retrofit strategies offers a significant opportunity to improve the efficacy and comprehensive nature of building retrofits, driving forward the agenda for sustainable urban development.

The research objectives of this study are designed to address the gaps and challenges identified within the realm of Building Retrofit Models, with a clear focus on enhancing energy efficiency and decarbonization strategies.

Developing a Robust Building Stock Model Framework One of the primary objectives of this research is to establish a comprehensive and robust Building Stock Model framework. This framework will be intricately tied to a Baseline Approach, enabling accurate comparisons and assessments of retrofit interventions. By creating a systematic and standardized model, this objective aims to provide a reliable foundation for evaluating and comparing building efficiency, from the baseline to its performance after the retrofit strategies

Emergy analysis of Retrofit Proposals This study recognizes the crucial significance of considering the entire lifecycle of buildings, including their embodied carbon and operational emissions. To address this, an essential research objective is to formulate a method for the Emergy calculation of the retrofit proposals. This involves conducting thorough assessments encompassing various stages of a building's lifecycle, providing a holistic perspective on its environmental impact.

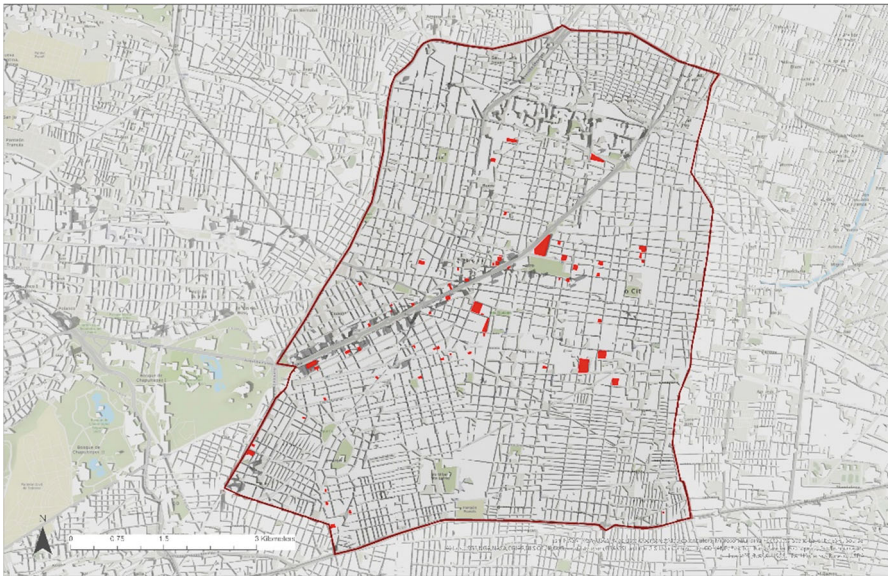

Fig. 2 Selected buildings mapping (Cuauhtemoc District, Mexico City)

Developing a Retrofit Model Framework as a Library of Solutions The development of an effective Retrofit Model framework is another core objective of this research. This framework will function as a dynamic "Library of Solutions," [1] offering a diverse range of retrofit strategies tailored to specific contexts. Through meticulous research and analysis, this objective aims to compile a comprehensive repository of technically sound and environmentally impactful retrofit options (Fig. 2).

3 State of the Art

The review of the current state of the art in the field of Building Retrofit Models reveals key concepts and research works that have significantly influenced and provided valuable insights in the development of this study:

Retrofit Strategies Implementation for Existing Buildings A noteworthy observation from the current body of literature is the prevalence of tools and methods designed to facilitate energy-efficient features primarily during the design and predesign phases of existing buildings. However, the literature considerable reduce when it is related to develop retrofit strategies for existing buildings, especially in an urban scale. In this context, the research of Claudio Nägeli et al. holds substantial importance, particularly, their works titled "Towards agent-based building stock modeling: Bottom-up modeling of long-term stock dynamics affecting the energy and climate impact of building stocks, Energy and Buildings" [1] and "Synthetic

building stocks as a way to assess the energy demand and greenhouse gas emissions of national building stocks. Energy and Buildings" [2] have offered critical insights into retrofit strategies through their case studies, such as the retrofit study conducted in Switzerland. Furthermore, Claudio Nägeli et al.'s article "Methodologies for Synthetic Spatial, Building Stock Modelling: Data-Availability-Adapted Approaches for the Spatial Analysis of Building Stock Energy Demand" forms the foundational basis for my forthcoming synthetic urban-scale analysis.

Data-Driven Analysis Tools for Building Retrofit Models The development of effective Building Retrofit Models is significantly influenced by the availability of instruments and tools. In shaping my own model as a Data-Driven Analysis Tool, the work of C. Szum et al. has provided valuable guidance. Their research, especially the texts "Data-Driven Analysis Tool Plays Critical Role in Climate Neutral Buildings. Advances in Applied Energy [9] and "Targeting Building Energy Efficiency Opportunities—An Open-source Analytical and Benchmarking Tool," [8] offers insights into open-source analytical tools that play a pivotal role in advancing climate-neutral building practices.

Building Stock Models and Retrofit Focus in Latin America While the research landscape is rich with studies focusing on retrofit strategies in the residential and non-residential sectors across European and North American countries, the perspective is notably limited in the context of Latin America, particularly Mexico. In this regard, the works of researchers such as Luis Eduardo Medrano-Gómez, Azucena Escobedo Izquierdo [10], Miguel Flores et al. [3], Itzell Torres et al. [4], and Rodrigo Mercado Fernández et al. [5] have emerged as pivotal resources. Their research, including non-domestic Passivhaus retrofit proposals, addresses the unique challenges and opportunities of retrofitting in the Latin American context.

4 Theoretical Framework

The theoretical foundations of this research are rooted in the dynamics and hierarchies of energy systems that are fundamental to achieving significant environmental impacts in architecture and urban planning. Recognizing buildings as open thermodynamic systems, this study leverages the concept of emergy—short for "energy memory" [6]—as a practical tool to assess the cumulative energy quality and historical energy use within these systems. Emergy provides a critical lens through which the magnitudes and hierarchies of energy systems can be comprehensively understood, highlighting their capacity to influence architectural and urban outcomes.

Central to this framework are the laws of thermodynamics, which are pivotal in the design of energy systems. The first law, emphasizing energy conservation, and the second law, which introduces the inevitability of increasing entropy in isolated systems, together guide the development of sustainable non-isolated energy systems in built environments. This research extends beyond traditional Life Cycle Assessment by focusing on how energy system analysis and design can transform the overall power and efficiency of urban architectural systems.

For existing buildings, the theoretical approach supports the visualization of retrofit strategies through two primary avenues to improve a building's Emergy Sustainability Index (ESI):

Maximizing Site Renewable Source This involves harnessing the renewable energy potential of the site to optimally reduce operational energy use.

Evaluating Carbon Impacts in Usage Stage and Maintenance Phase This focuses on assessing and mitigating the carbon footprint associated with potential retrofit strategies over the building's lifecycle.

5 Method

This section outlines the methodology employed to address the complexities inherent in assessing building energy demand and greenhouse gas emissions at an urban scale, particularly in the face of limited information availability. The method is structured into three primary steps, collectively aimed at creating an "Archetype Building Information" framework. These steps are conducted iteratively, guided by the pursuit of uncovering an accurate representation of the urban context.

Step 1—Synthetic Stock Generation The initial step entails the transition from the architectural to the urban scale, necessitating a paradigm shift to cope with information scarcity. Buildings are treated as fundamental model entities, forming the basis for further analysis. This step is directly related to the 1st research goal, "Developing a robust building stock model framework." It is made up of three parts:

Characterization of the Buildings. This involves defining the key attributes that distinguish one building unit from another. These attributes encompass physical features, usage patterns, and potential retrofit possibilities.

Building Agents: Incorporating the human element, building owners, and users into the model adds a layer of realism. Their behavior, preferences, and decisions play a pivotal role in shaping retrofit choices and energy-related strategies.

Archetype classification. This subset recognizes the need for practicality. It involves categorizing the urban building stock based on critical characteristics and finding archetype buildings.

Step 2—Building Stock Dynamics The second step is related to the second goal of the research, "Developing an emergy analysis of retrofit proposals." The intricacies of this step are informed by economic, environmental, and policy considerations. Three distinct facets constitute this step:

Identification of Retrofit Strategy. Each building unit is subjected to analysis to identify the most suitable retrofit strategy as a function of its typology.

Selection of Retrofit Strategy. The benefit-to-cost ratio guides the selection process, underlining the significance of economic feasibility.

Development of Retrofit Strategy. This aspect considers technological feasibility, policy restrictions, and the availability of market options.

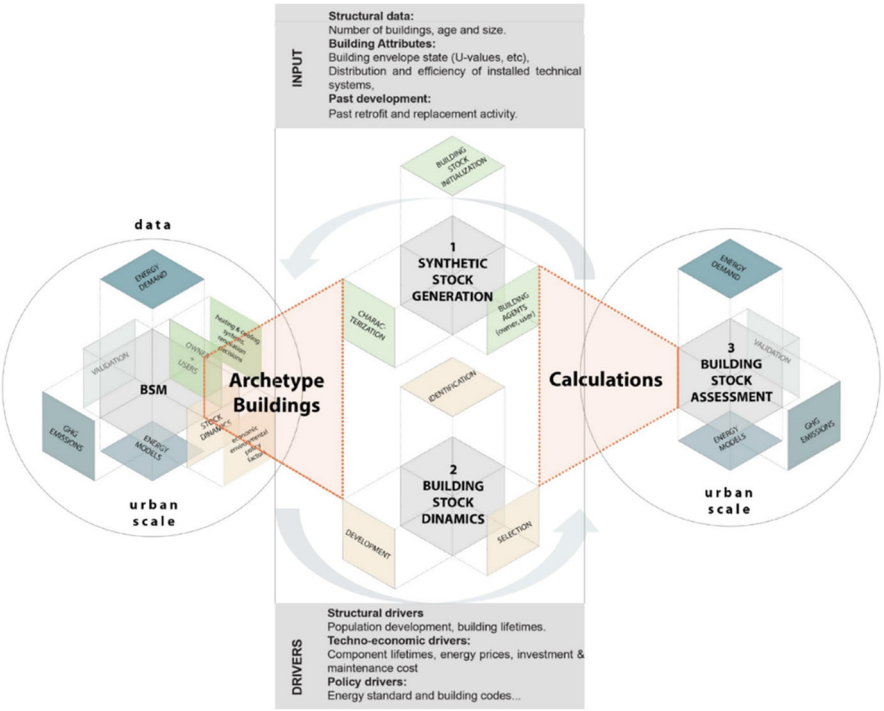

Fig. 3 Method overview

Step 3—Building Stock Assessment It involves validating the synthesized data and refining the Archetype Building Information framework. This step ensures the alignment of the framework with real-world data and its accuracy in reflecting urban building stock dynamics. The iterative nature of this research process is essential, as it embodies a continuous quest for the most accurate representation of the urban context (Fig. 3).

6 Hypothesis

Within the context of urban sustainability and building stock retrofitting, this study posits that by employing a value-based framework capable of amalgamating building stock performance data with the intricate interplay of Building Stock Dynamics (BSD), municipal decision-making processes can be significantly streamlined. Consequently, the urban environment will be empowered with an efficient approach to assess and compute retrofit scenarios on a citywide scale. The anticipated outcome of this approach is not solely limited to the enhancement of building performance, but also extends to encompass Non-Energy Benefits (NEBs) which will be quantitatively appraised, positioning them as indispensable as the evaluation of CO_2 emissions.

7 Preliminary Results

Regarding the lack of information from private and governmental buildings, the definition of Archetypes has a relevant importance in the development of the analysis, because they will represent the stock. As explained in the methodology, the retrofit strategies must be a function of each typology. Archetypes were defined under three main categories: Location, building characterization and renewable energy. Each of them will be measured by indicators, those related to the NEB (Non-Energy Benefits) concept and Emergy Sustainability Index (ESI) that includes cost/benefit analysis.

According to Mexico City's climatic data, the comfortable period of the year corresponds to 67%, 33% for hot days, and 0% for too cold days. This is an important fact, since too hot means temperatures from 25 to 35 °C, which exceeds the Environmental comfort temperature according to ASHRAE, from 20 to 25.5 °C. Mexico's temperature projection models show that the temperature will rise yearly, besides the correspondent increase use of Air Conditioning (Fig. 4). According to the CBE Thermal Comfort Tool Psychrometric chart, Air Conditioning mechanical system is the last source to reach comfort (Fig. 5). Sixty-seven percent of the building stock uses this mechanism, increasing the energy consumption, especially considering that HVAC systems and lighting, are the most energy consuming systems in Mexico City buildings, with 48 and 24% respectively.

Regarding the Building Characterization, four main periods were identified: Barroco Colonial (1521–1821), nineteenth century, early twentieth (1821–1920), Modernism and International Movement (1920–1985), and the present times after Mexico City 1985 Earthquake. The information regarding to constructive systems, materials and Thermal Resistance U-Values are described in Fig. 5. Each of the 65 buildings from the stock were classified according to its construction year. It is quite clear the relation between building's characterization and its year of construction since Architecture is an expression of its time.

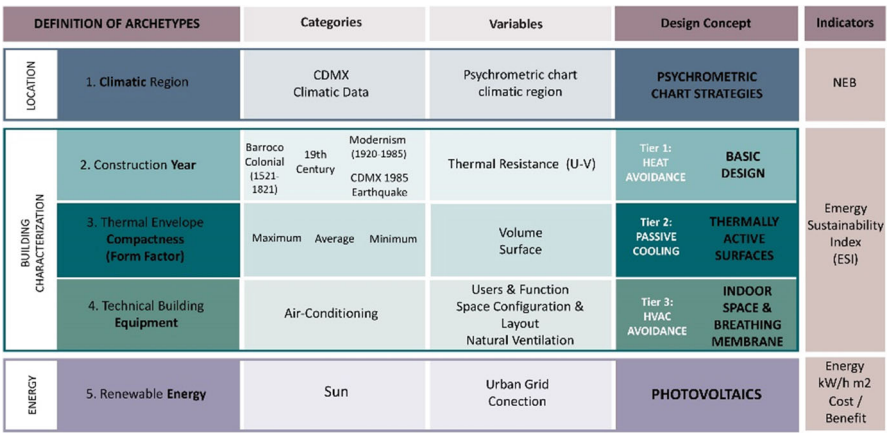

Fig. 4 Direct relation between the Archetypes definition and the design concepts for retrofit strategies

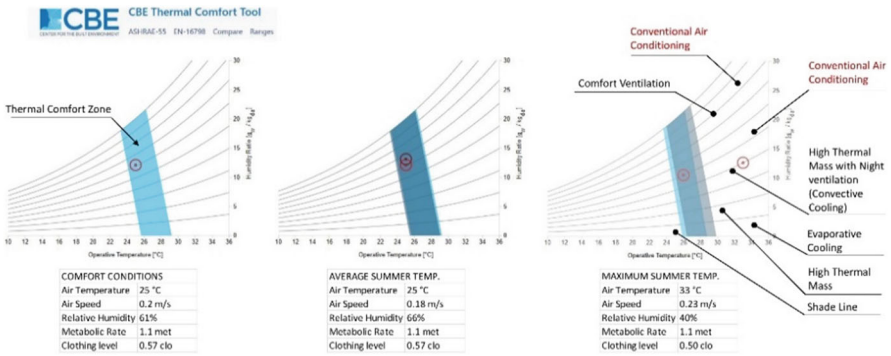

Fig. 5 Psychrometric chart strategies for Mexico City Summer Temperature. CBE Thermal Comfort Tool. CBE Thermal Comfort Tool for ASHRAE-55 (berkeley.edu)

As part of the building characterization, de degree of Compactness of building forms, must be considered as a function of their building shape, regardless their size. According to the square-cube lay, this means that compactness is a scale independent metric to measure the degree of building forms. Three classification of compactness were chosen: Maximum (1), average (1.18), and minimum (3.20).

The fact that a building uses or no Air conditioning will be taken into account in the global energy performance. The challenge is avoiding this system with low-tech strategies and bring buildings thermal comfort.

As a preliminary result of this stage in the research, were identified six archetype buildings, which will be analyzed in their baseline energy performance and in the development of retrofit strategies, according to the proposed design concepts:

Tier 1: Heat avoidance—Basic Design
Tier 2: Passive Cooling—Thermally Active Surfaces
Tier 3: HVAC Avoidance—Indoor Space and Breathing membrane.

The use of photovoltaics as a form to capture renewable energy will be explored since Mexico has a solar radiation of 5.5 kWh/m^2, five times the solar radiation of Germany; however, solar energy generated in the European country is 44.2 times higher.

8 Conclusions

Finding the correct and more representative Archetype buildings represents an inflection point in the research. The results will be proportionally assigned to the corresponding building among the stock. Not only the energy performance as a baseline but also their variations and feasibility after retrofit strategies.

The natural correspondence between the year or period of construction and its building characterization, as well as the proportional relation between the degree of compactness and optimality of building forms, makes possible the replicability of this model in any context. However, the renewable energy source must be reconsidered according to the location (Fig. 6).

ARCHITECTURAL STAGES IN CDMX & CHARACTERISTICS									
	PERIOD		CONSTRUCTIVE MATERIALS		CONSTRUCTIVE SYSTEMS & ELEMENTS		ELEMENT	U-VALUE	HIGHLIGHTS	EXAMPLES
1	Barroco Colonial (1521-1821)		Stone	Volcanic Tezontle Cantera	Vaulted Ceilings	vaults and groin vaults, these were common in churches and important	WALL	1.8-2.2 W/(m²K)	Made of thick stone and brick, the U-value would be relatively low, suggesting good insulation properties.	Mexico City Metropolitan Cathedral
			Brick	Used in fachades and structural elements	Dome Construction	Often constructed with a drum or on pendentives, decorated with	ROOF	2.5-3.5 W/(m²K)	Colonial buildings often used tile roofs over wood structures, which might have a higher U-value, depending on construction.	Church of Santo Domingo
			Wood	Often used for internal structures and decorative	Façade Treatments	Ornamental complexity, including carved stonework, statuary, and portal framing.				Palacio de Iturbide
			Stucco and Plaster	Commonly used for roofing frameworks, floors, and ornate doors and windows.						The Church of San Francisco
			Gold Leaf and Paint	Applied to walls for smooth finishes	Mural Painting	Murals depicting religious and historic themes in walls and ceilings in many	SLAB	1.8-2.2 W/(m²K)	Floor slabs made of stone or heavy brick would align with the wall values, also featuring good thermal mass and similar U-values.	
				Used for decorative purposes, especially in church interiors.						
2	19th Century, Beginnings of the 20th (1821-1920)	NEOCLASIC	Stone	Cantera	Masonry Walls	Thick walls constructed from	WALL	1.5-1.9 W/(m²K)	Given the thickness and dense materials used, such as stone and brick, the U-value would be relatively low.	Palacio de Minería
			Brick	Internal structures	Symmetrical Layouts	Central axis and symmetrical design				Palacio Nacional
			Plaster and Stuco	like cornices and capitals	Classical Columns and Pilasters	Often featuring Ionic, Doric, or Corinthian capitals.	ROOF	2.0-3.0 W/(m²K)	Roofs constructed with timber and covered with tiles or metal would have higher U-values, depending on the materials and construction quality.	Alameda Central and Surrounding Buildings
			Wood	Structural elements in floors and roofs	Pediments and Porticos	Grand and formal appearance.				
			Iron and Steel	Structural frameworks and ornamentation	Domes and Vaulted Ceilings	Less ornate than Baroque. More geometrically precise.	SLAB	1.5-1.9 W/(m²K)	Floor slabs made of heavy masonry would similarly have low U-values, comparable to the walls, due to their significant thermal mass.	Old Portal de Mercaderes
		ART NOUVEAU	Iron and Steel	frameworks and ornamentation	Steel Frameworks	Skeletal structures	WALL	1.5-2.0 W/(m²K)	Typically constructed from a combination of masonry, plaster, and decorative tiles, providing moderate insulation.	Edificio La Nacional
			Glass	Light-filled interiors and decorative stained glass features	Reinforced Concrete	Organic forms and shapes.				Museo Nacional de Arte (MUNAL)
			Stone	Structural and decorative elements	Masonry Walls Decorative Facades	Ceramics and glass	ROOF	2.5-3.5 W/(m²K)	Roofs in Art Nouveau buildings often featured decorative elements and used materials such as tiles or metal.	Casa de los Azulejos
			Ceramic Tiles	Interior and exterior decoration						Palacio de Bellas Artes
			Plaster	Ornamental interior details and smooth			SLAB	1.5-2.0 W/(m²K)	Floor slabs were usually of reinforced concrete or masonry, offering similar U-values to the walls, benefiting from good	
		ECLECTIC	Stone	Volcanic Cantera	Masonry Construction	Thick walls made of brick or stone	WALL	1.5-2.0 W/(m²K)	Constructed from thick masonry, reflecting good insulation properties due to the mass of the materials.	Postal Palace of Mexico City
			Brick	Structural support and façade elements	Decorative Facades	Elements from Gothic, Baroque,				Palacio de Bellas Artes
			Stucco	Applied over brick or stone for a smooth	Ironwork	Decorative iron	ROOF	2.5-3.5 W/(m²K)	Often featured tiles or metal, which can have higher U-values.	Gran Hotel Ciudad de Mexico
			Iron and Steel	Ornate balconies, railings, and other	Complex Roofs	Flat and pitched sections, with decorative elements such as cupolas and				
			Glass	Large windows, often stained or etched			SLAB	1.5-2.0 W/(m²K)	Floor slabs made of reinforced concrete or heavy masonry would likely have U-values similar to the walls, benefiting	Edificio La Nacional
3	Modernism & International Movement (1920-1985)		Glass	To create clean, light-filled spaces. Often employed in large panels and curtain walls	Frame Structures	Steel and reinforced concrete frames allowed for open floor plans, free of load-bearing walls.	WALL	2.5-5.5 W/(m²K)	Curtain walls primarily made of glass and steel have higher U-values, indicating poorer insulation compared to traditional materials.	Torre Latino
			Steel	Allowed for the creation of slim profiles and wide spans	Curtain Walls	Non-structural outer coverings of buildings which are hung from the structure.				Museo Nacional de Antropología
			Concrete		Flat Roofs	Enabled the creation of clean and horizontal roof lines, often used as	ROOF	0.5-1.0 W/(m²K)	Modernist flat roofs often constructed with reinforced concrete, covered with a waterproof membrane, depending on insulation.	Ciudad Universitaria (UNAM)
			Aluminum	Window frames						Centro Cultural Universitario
					Open Floor Plans	Lack of interior walls allowed adaptable interior spaces.	SLAB	1.0-2.0 W/(m²K)	Concrete slabs, often used in floors and ceilings, benefiting from the thermal mass of concrete.	Tlatelolco
4	After Mexico City 1985 Earthquake to the Present (1985-Present)		Reinforced Concrete		Seismic Isolation Systems	Base isolators and dampers that absorb seismic energy	WALL	0.3-1.0 W/(m²K)	Modern materials and technologies have lowered the U-value , depending on the material and insulation techniques used.	Torre Reforma (2016)
			Steel							Torre Mayor (2003)
			Glass		Moment-resisting Frames	Steel or reinforced concrete frames designed to resist bending during earthquakes	ROOF	0.2-0.5 W/(m²K)	Innovations in green roofing and insulation have brought U-values, significantly improving thermal performance.	BBVA Bancomer Tower (2015)
			Composite Materials	High-performance fibers and polymers used for their strength, lightweight, and corrosion resistance.	Shear Walls	Reinforced concrete walls that add rigidity and strength to structures				
					High-tech Facades	Double-skin facades				
							SLAB	0.2-0.5 W/(m²K)	Concrete slabs with modern insulation can achieve low U-values, which help in maintaining thermal comfort and reducing energy costs.	

Fig. 6 Architectural stages in Mexico City and buildings characterization

1 Introduction

The expansion of urban centers, such as Trondheim, Norway's third-largest city with a 2023 population of approximately 206,000 [2], underscores the pressing need for infrastructure modernization to address challenges such as traffic congestion and pollution driven by rising populations and mobility demands. Trondheim's growth—spurred by the presence of educational and research institutions like the Norwegian University of Science and Technology, SINTEF, and St. Olav's University Hospital—places pressure on its transportation infrastructure and mobility

system. This development has led to a shift toward sustainable mobility solutions, with initiatives like Miljøpakken and MobilitetsLab Stor-Trondheim (MoST) emphasizing public transit and active transportation over private car usage. Achieving such goals necessitates a data-driven approach toward understanding and improving the spatiotemporal dynamics of urban mobility systems for enhanced efficiency, sustainability, and human well-being.

One significant hurdle faced by such mobility initiatives is the difficulty in precisely evaluating the effectiveness and necessity of projects and interventions in alignment with their mobility goals. Such evaluation demands the collection of detailed mobility data across the entire transportation and mobility system. Yet, traditional data collection methods such as traffic surveys, sensor networks, and traffic cameras not only incur significant costs when deployed at scale but also often provide insufficient coverage. These methods typically yield either highly detailed temporal data for narrow segments (e.g., specific areas or intersections) or overly generalized, aggregated data for the whole system. To enable truly effective, data-driven decision-making, there is a critical need for cost-effective methods that can deliver detailed temporal insights spanning the full geographical extent of the mobility system.

2 Cellular Network Data

Network data—derived from the cellular network activity of millions of subscribers across extensive areas—can serve as a source of rich mobility information. This data captures the movements and behaviors of large groups, offering insights into the spatial and temporal aspects of population flows within and across regions. The cellular network data explored in this research was obtained from Telia's Crowd Insights platform.

2.1 Methodology

To transform cellular signals into mobility data, a network operator collects temporal data generated during routine mobility subscriber activities (such as calls, texts, and movements within network coverage), anonymizing and aggregating this data to respect privacy and meet GDPR standards. Spatial data from network cell coverage is used to estimate geospatial positions, facilitating movement pattern analysis without traditional triangulation. Such a dataset typically excludes sensitive, roaming, and inactive subscriptions, focusing on active mobile subscriptions and extrapolating this information to reflect the broader population in an area. Advanced algorithms distinguish between stationary and moving signals, classifying them as dwells and transits, thus providing a foundation for understanding wider mobility trends via reports such as [3]:

- *Activity Reports*, which shed light on the locations, times, and origins or destinations of groups
- *Trip Reports*, which offer an origin–destination matrix to understand movement volumes between pairs of locations
- *Routing Reports*, which provide insights into the most likely travel routes taken, encompassing various modes of transportation

2.2 Advantages and Challenges

As discussed, a serious challenge in analyzing mobility trends is the acquisition of high-resolution temporal data that also spans extensive geographical areas. Cellular network data, collected during routine telecom operations, provides a rich source of mobility information which offers valuable insights into both real-time and historical patterns of population movement. This information is invaluable for researchers, policymakers, and planners in understanding traffic flows, thus facilitating informed, data-driven decisions and policies in urban transportation and mobility planning.

However, leveraging cellular data for mobility analysis comes with some drawbacks and challenges, including variable spatial resolution from differing network coverages and the potential loss of granularity due to anonymization and aggregation. Data processing assumptions, such as stationary signals and proximity to the nearest cell, may not always reflect the complexities of urban mobility. Furthermore, policies excluding data from smaller groups to protect privacy can lead to an underrepresentation of certain areas or times. These limitations necessitate a careful evaluation of the data's utility against the backdrop of privacy considerations and the inherent characteristics of cellular networks.

3 Routing Reports for Trondheim Municipality

Routing Reports analyze *peopleFlow*—journey patterns of groups of people—inferring the most probable travel routes to gain insights into travel behaviors, highlighting preferences in routes and transportation modes over various regions and times. This analysis incorporates multiple transportation modes—such as road, rail, ferry, and pedestrian pathways—leveraging OpenStreetMap for mapping probable trip paths over 1 km. The routing reports employ an open trip planner to ascertain the quickest route between two points, considering the operator's network coverage and penalizing unnecessary mode switches.

3.1 Data Description

The routing report dataset used in this study spans from January 17, 2019, to November 30, 2023, covering 1744 dates, with 35 dates omitted due to data gaps or poor signal quality. The raw dataset is aggregated into hourly and daily intervals, resulting in 82,798,311 and 3,792,160 data points, respectively. As shown in Fig. 1, the dataset geographically covers the entire Trondheim municipality and extends into parts of the neighboring Malvik municipality, due to the location of Trondheim Airport just beyond the municipal boundary. The dataset contains six (or seven) attributes for the daily (or hourly) temporal aggregations, as follows:

- *Date and Hour*: These refer to the date and hour the mobility data was recorded. The *Hour* attribute is only present in the hourly temporal aggregation.
- *wayID*: This is a unique OpenStreetMap identifier assigned to each road segment. A stretch of road, rail, or ferry route is thus composed of several connected *ways* (segments) each encoded as a `LineString` object consisting of the longitude and latitude coordinates of its nodes. There are 2210 and 2212 unique *wayID* values in the hourly and daily aggregations, respectively.
- *tagKey*: This refers to the transportation mode, one of three options: road, rail, or ferry.
- *tagValue*: This is a breakdown of each *tagKey* into its subcategories as defined by OpenStreetMap, such as primary/trunk/secondary for roads and expressboat/cruise for ferry, among others.

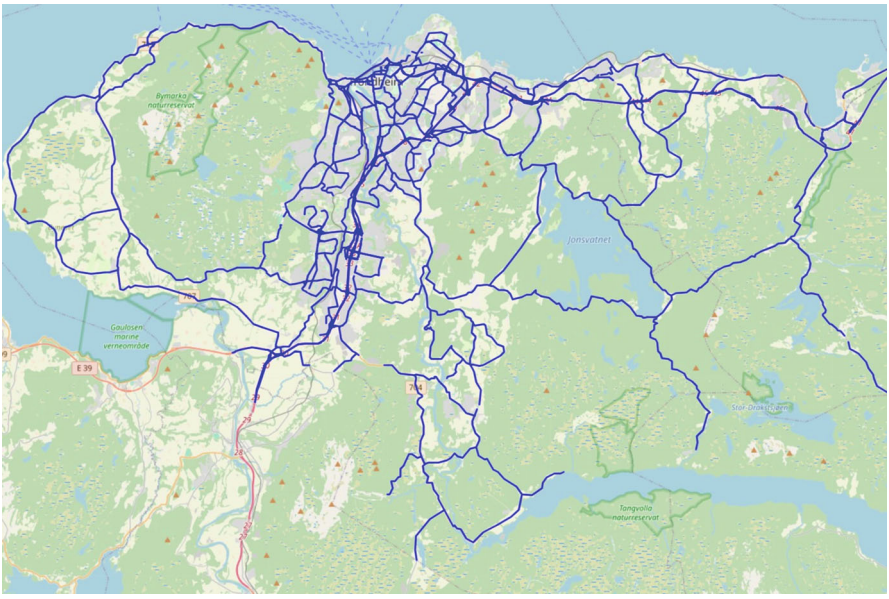

Fig. 1 Satellite map of ways covered by the routing reports

- *Municipality*: This refers to the municipality the *wayID* falls under based on the geographical coordinates of its nodes, either Trondheim or Malvik.
- *peopleFlow*: This is the estimated number of people passing through a specific *wayID* at the daily or hourly aggregation.

3.2 Data Preprocessing, Feature Engineering, and Graph Augmentation

The raw dataset was preprocessed to rectify missing *tagValue* entries in the hourly and daily aggregations, supplementing them with data from OpenStreetMap. To facilitate direct comparisons, the daily dataset was constrained to *wayIDs* consistent with those in the hourly data. The excluded *wayIDs* from the hourly dataset typically had such low *peopleFlow* volumes in the daily data that the hourly numbers would not meet the minimum threshold of five individuals. In addition, some discrepancies were identified in the daily data, which were corrected to align with the total hourly *peopleFlow* values for the respective days.

Subsequently, the dataset was enriched with temporal attributes by extracting metadata from the *Date* feature—including *Day*, *Month*, *WeekNumber*, *Year*, and *HolidayName*—for subsequent analysis. Historical weather data [4] was incorporated to assess the impact of weather conditions on mobility patterns. Additionally, population statistics for Trondheim and Malvik municipalities were sourced from Statistisk Sentralbryå [2] to examine the relationship between mobility patterns and demographic trends over time.

Routing reports enable the analysis of *peopleFlow* trends by selecting origin and destination coordinates and calculating routes within a mobility network represented as a `MultiDiGraph`—a graph that allows multiple directed edges between the same pair of nodes. However, the geospatial graph associated with the routing reports has discontinuities, preventing some nodes from being reachable. To address such gaps, a fully connected graph from OpenStreetMap, covering road, rail, and ferry modes was obtained and adapted to prioritize ways in the routing reports while ensuring all nodes are accessible. Subsequent trend analyses were then confined to ways (and *wayIDs*) documented in the routing reports and associated *peopleFlow* data.

4 Analyses and Discussion

This section details our investigation into the spatiotemporal dynamics of Trondheim's mobility system, utilizing historical *peopleFlow* volumes obtained from the routing reports. Our analysis encompasses geospatial trends, temporal patterns, and the impact of external factors. In addition, we explore the dynamics of specific routes and areas of interest in the city.

4.1 Geospatial Trends

Figure 2 presents the average (mean) *peopleFlow* volumes derived from routing reports between January 7, 2019, and November 30, 2023, juxtaposed with annual population data. This reveals a consistent increase in *peopleFlow* volumes, mirroring the average yearly population growth of approximately 3000 residents. The COVID-19 pandemic's effect is pronounced, showing a dip and subsequent recovery in *peopleFlow* volumes from March 2020 to March 2021. Excluding this period, seasonal declines in *peopleFlow* are evident during Easter, Summer, Christmas, and New Year holidays. The rationale for using mean *peopleFlow* rather than total sums is due to the overlapping volumes across different routes. For instance, a single individual traversing a road segmented into three ways would be counted in the *peopleFlow* for each segment, thereby overestimating the total mobility if sums were used.

Figure 3 breaks down the annual *peopleFlow* volumes by municipality, offering insight into the mobility patterns to and from Trondheim. Notably, much of the data from Malvik municipality pertains to road and rail traffic on the E6 trunk highway east of Trondheim which extends to Trondheim Airport. This analysis reveals that Malvik's traffic volumes generally remain lower than Trondheim's, except during significant holiday seasons when there is increased travel in and out of Trondheim. Furthermore, analyzing the yearly volumes by transportation mode (*tagKey*) in Fig. 4 highlights periods of increased volume in one mode compared to others. Such fluctuations may signal shifts in the transportation preferences of the city's inhabitants, prompting further investigations.

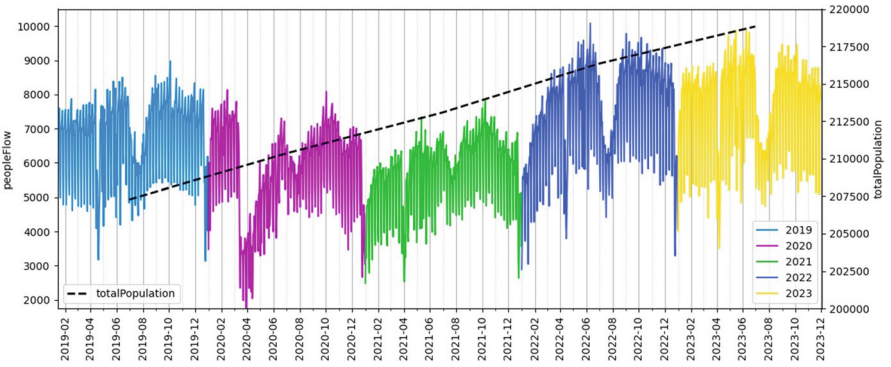

Fig. 2 Yearly breakdown of *peopleFlow* volumes from January 2019 to November 2023

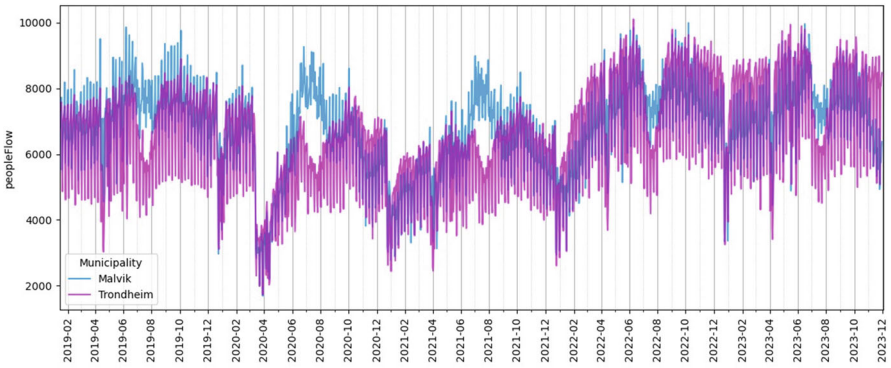

Fig. 3 Detailed overview of *peopleFlow* volumes across municipalities

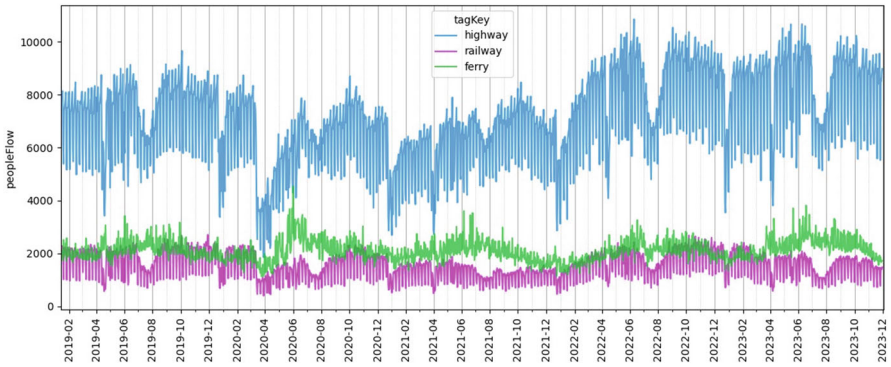

Fig. 4 Detailed overview of *peopleFlow* volumes across transportation modes

4.2 Temporal (Normalized) Patterns

The temporal analysis of the routing reports encompasses hourly, daily, and weekly levels across different transportation modes, focusing on data from March 1, 2022, to November 30, 2023, with the COVID-19 period analyzed separately in Sect. 4.3. Due to significant volume disparities among the transportation modes, normalization within the range `[0,1]` was applied to each mode's data for a fair comparison of flow trends. Figure 5 shows that the hourly patterns for rail and road traffic are similar, while ferry traffic tends to increase during road and rail's off-peak hours.

Similarly, Fig. 6 reveals that ferry traffic peaks on Sundays, contrasting with the weekend decline in road and rail flows. Meanwhile, Fig. 7 indicates a less pronounced correlation among the three modes, though road and rail still exhibit parallel trends. Notably, road and rail traffic decrease during the summer holidays, but ferry traffic remains consistent due to tourism around the city. The monthly trends, not shown here, offer a broader view which smoothens out the weekly fluctuations.

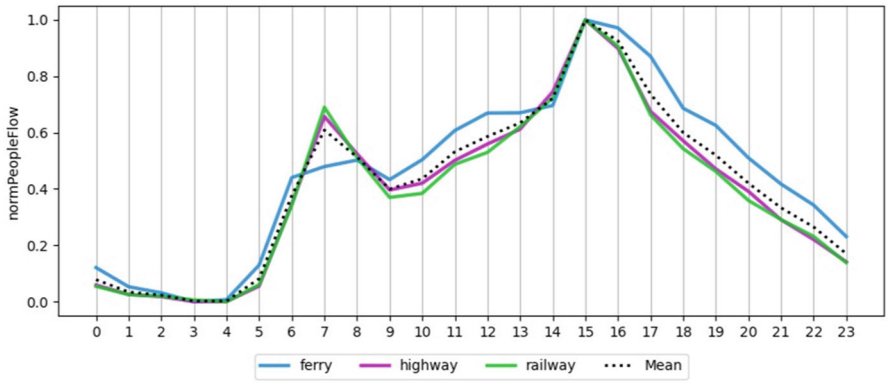

Fig. 5 Normalized hourly variation of *peopleFlow* volumes across transportation modes

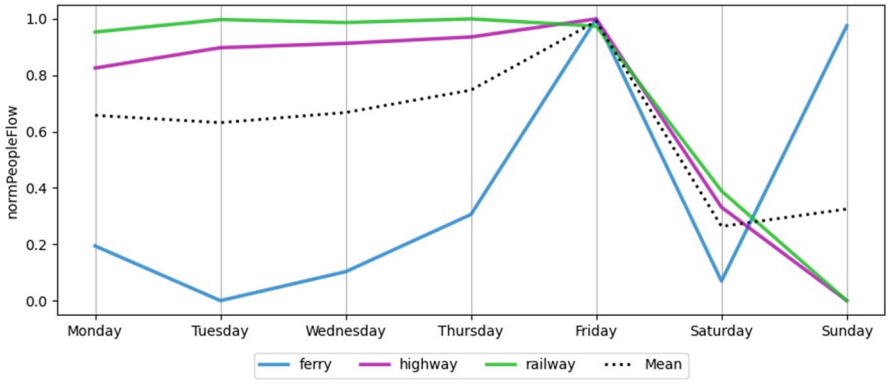

Fig. 6 Normalized daily variation of *peopleFlow* volumes across transportation modes

4.3 External Factors

This section delves into how external factors like the COVID-19 pandemic, weather conditions, and road attributes (speed limits and lane counts) affect *peopleFlow* volumes across Trondheim.

COVID-19 Pandemic The pandemic's impact on *peopleFlow* volumes is discernible across Figs. 2, 3, and 4. The correlation between the Norwegian government's COVID-19 measures (from March 13, 2020, to March 1, 2022) and *peopleFlow* variations is visible in Fig. 8, which presents a 7-day rolling average of the *peopleFlow* volumes. The clear correlation between policy changes and mobility patterns justifies the exclusion of this timeframe from earlier analyses.

Weather Conditions An analysis incorporating historical weather data shows a slight impact of weather on *peopleFlow* trends. For precipitation types, Fig. 9

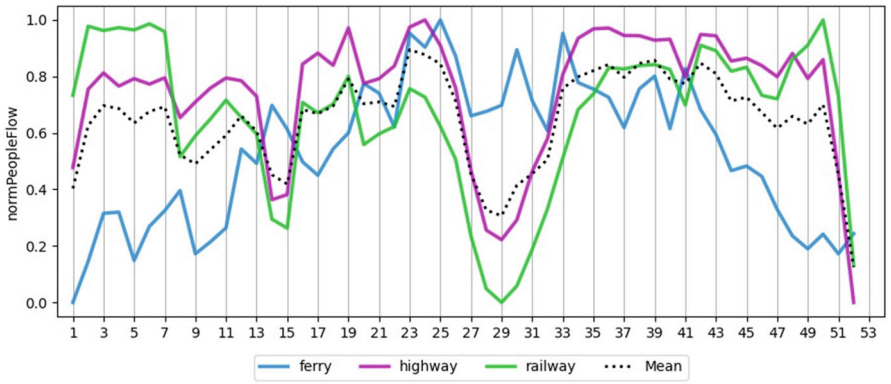

Fig. 7 Normalized weekly variation of *peopleFlow* volumes across transportation modes

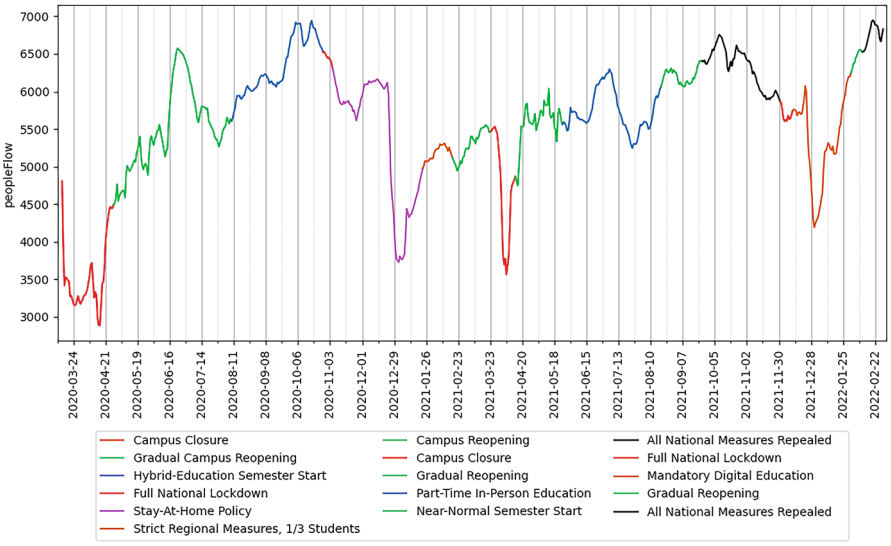

Fig. 8 Effect of COVID-19 measures on *peopleFlow* volumes

indicates that flow volumes are highest in clear weather, followed by rain, snow, and mixed rain/snow conditions. On the other hand, the lowest flows are associated with rainy, snowy, or cloudy weather conditions.

Speed Limits and Lane Counts OpenStreetMap data, linked via *wayIDs* from the routing reports, provided information on speed limits and lane counts for each way. The analysis, depicted in Fig. 10, reveals a positive correlation between *peopleFlow* volumes and both higher speed limits and greater lane counts. This trend might be influenced by the routing algorithm's preference for quicker routes. Notably, the effect of speed limits on *peopleFlow* plateaus beyond 80 km/h due to the reduced number of routes supporting such speeds.

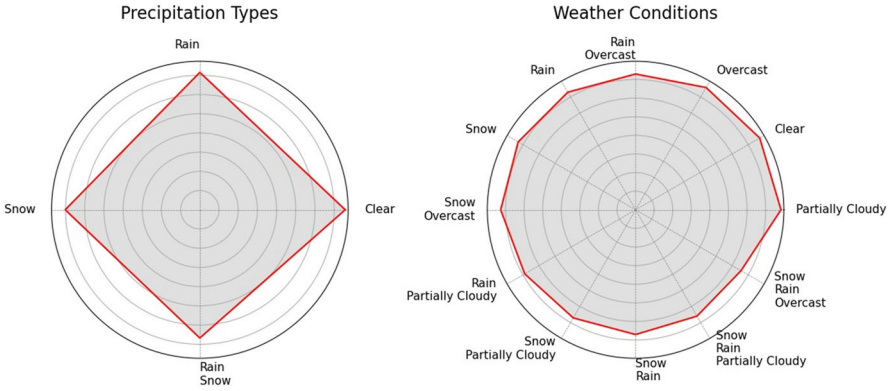

Fig. 9 Variation of *peopleFlow* volumes with weather conditions

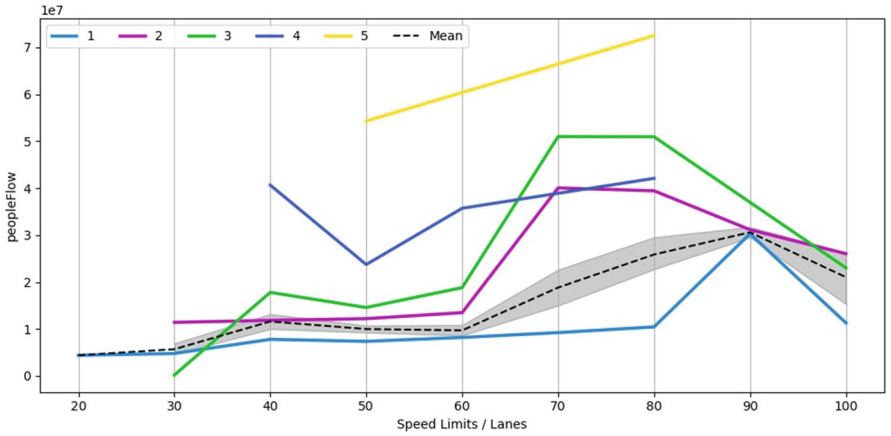

Fig. 10 Combined effect of speed limits and lane count on *peopleFlow* volumes

4.4 Specific Routes and Areas

This section provides a temporal analysis of *peopleFlow* trends along specific routes and areas identified as relevant to the Miljøpakken and MoST initiatives.

Comparison with Public Transit Leveraging Automated Passenger Counting (APC) data from AtB, Trondheim's public transport authority, enabled a comparison between public transit and overall *peopleFlow* volumes along identical routes.

The AtB APC data—covering the period from May 1, 2020, to November 30, 2023—included 1,112,221 unique bus trips over 1295 days, spanning 6 lines and 204 stops. For the analysis in Fig. 11, both AtB and routing report volumes were

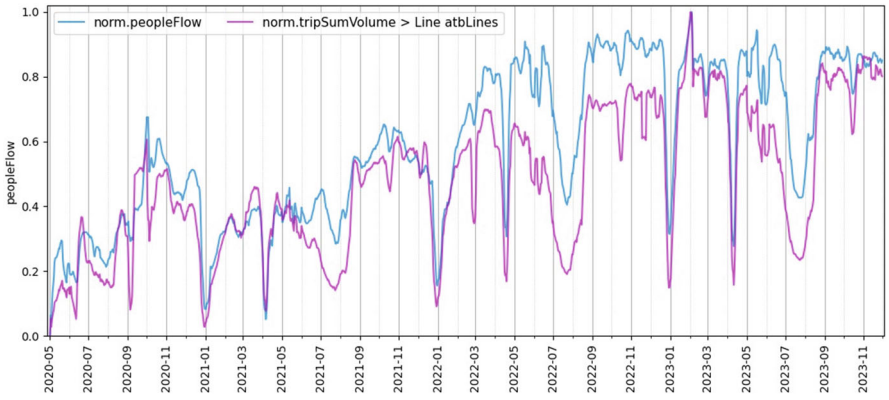

Fig. 11 Comparison of public transit and *peopleFlow* volumes along selected bus routes

smoothed using a 7-day rolling average to eliminate the weekday/weekend variations and subsequently normalized to address the considerable scale differences between them. While a strong correlation exists between AtB and Telia volumes, the instances where AtB volumes surpass Telia volumes stand out and require further investigation, suggesting public transit might be experiencing traffic increases not reflected in the broader mobility system. It is also instructive that the majority of these occurrences took place during the COVID-19 period, analyzed separately earlier.

Miljøpakken Bromstadruta Project Miljøpakken is developing a 3.2 km cycle path and sidewalk project in Trondheim named Bromstadruta [1], depicted in Fig. 12 (left) with the cycle path outlined in red and the corresponding routing report ways in blue.

Such infrastructure projects stand to benefit from a thorough analysis of mobility patterns along the proposed route early in the planning phase. For example, Fig. 13 shows normalized *peopleFlow* trends along Bromstadruta versus the city at large, uncovering unique dynamics that could be crucial for planning and achieving project goals.

Trondheim City Center A similar analysis for specific urban areas can be conducted, in this case focusing on the city center as shown in Fig. 12 (right) with the target area highlighted in gray. Figure 14 reveals the city center's pronounced daily (unnormalized) *peopleFlow* volumes compared to other areas. An in-depth examination of these central urban mobility patterns could provide valuable insights for optimizing traffic flow, managing congestion, and allocating public transit resources more effectively.

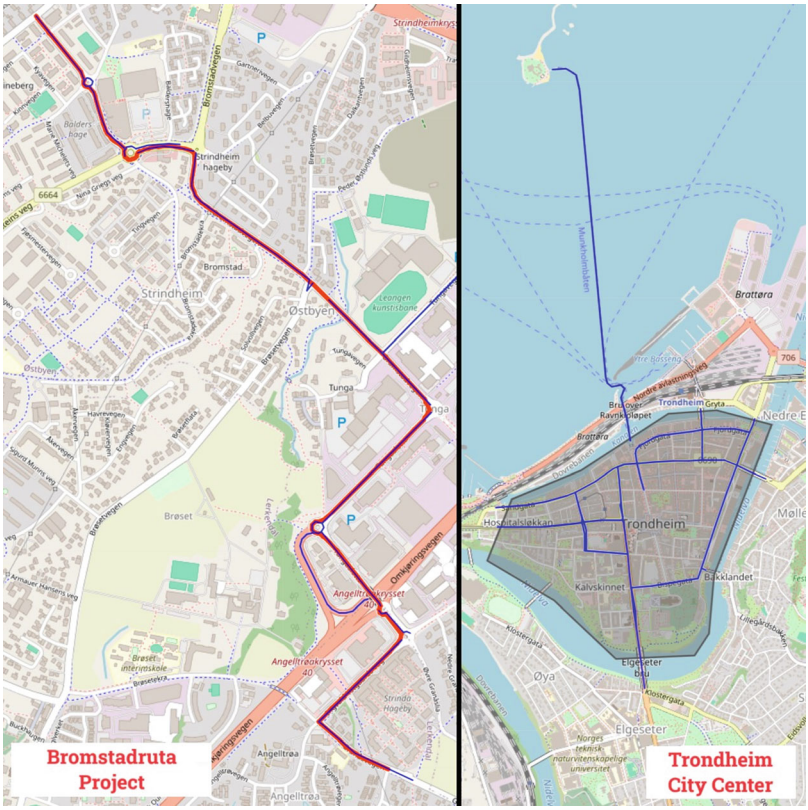

Fig. 12 Bromstadruta cycle path (left) and Trondheim city center (right)

5 Conclusion and Future Work

This chapter explores the utility of cellular network data to support efficient and sustainable mobility initiatives like Miljøpakken and MobilitetsLab StorTrondheim, offering a cost-effective, detailed, and wide-ranging source of mobility information. Through the analysis of Trondheim, Norway's routing reports, the potential of such data for gaining insights into mobility flows within and across regions becomes evident, highlighting:

1. Geospatial trends of the mobility dynamics of specific areas and routes within and across municipalities
2. Temporal patterns across different transportation modes from across hourly and daily scales
3. The impact of external factors like pandemics, weather, public transit, and transportation infrastructure on mobility volumes

These insights are crucial for data-driven decision-making in urban mobility planning and policy formulation. However, the inherent nature of cellular network signals and practical realities such as privacy concerns bake some assumptions into the mobility data which require careful consideration in its application. Furthermore, data preprocessing and other enhancements are required to fully capitalize on its potential.

This study is part of a larger initiative to develop a digital twin of Trondheim's transportation infrastructure and mobility system, enriched with comprehensive data-driven historical insights and predictive modelling capabilities. Future research will focus on a thorough spatiotemporal analysis of the mobility network—extending to other modes of transport such as cycling and walking—to pinpoint key ways critical to the *peopleFlow* dynamics across the network.

Acknowledgements This research received funding from the PERSEUS project, a European Union's Horizon 2020 research and innovation program under the Marie Skłodowska-Curie grant agreement No. 101034240. The authors also acknowledge MobilitetsLab Stor-Trondheim (MoST) for their financial contribution and AtB for providing mobility data, which has been instrumental in our research.

1 Introduction

Cities of the future are envisioned to be smart cities, where digital technology and data-driven societies are at the central role, and the sustainability of cities is attributed to their smartness [6]. This explains future cities to be sustainable through their intelligence fundamentally by using digital technologies and their interconnections to optimize infrastructure, services, and resident's quality of life [15]. Beyond technological advancement, the essence of smart cities lies in smarter citizen participation at the core [4]. Adopting a participatory planning approach becomes imperative to integrate the diverse needs, aspirations, and values of people within the city. The use of new and innovative digital technologies to include individuals in planning and decision-making related to their city is one of the fundamental requirements

of the future of smart cities [4]. This approach to building and shaping future smart cities with a data-driven participatory framework empowers communities to shape their cities and neighbourhoods through a collaborative, inclusive, and transparent process. As such, data-driven smart cities with participatory urban planning and development at the core are imperative to developing and envisioning the cities of tomorrow [4].

On the other hand, digital technologies have also evolved significantly, becoming smarter in recent years, presenting opportunities to involve more individuals and communities in the participatory process. This evolution has been particularly more pronounced in recent years, with advancements in technology enabling greater connectivity, accessibility, and functionality, leading to more diverse and inclusive data-driven planning and participation [16]. Acknowledging the fact that, the COVID-19 pandemic accelerated the adoption and utilization of digital technologies for individuals and cities; the participation in the urban planning process as the traditional mechanisms of participation like public events, workshops, and seminars were restricted due to social distancing and restrictions on physical gathering. Cities around the globe started using this digital shift, leveraging it to engage citizens in tasks and meetings that would otherwise be held in town halls and city centres [14]. As such, studies of participatory processes during the pandemic have highlighted that the use of digital technologies increased the number of individuals in such processes [14]. This increase was attributed to the implementation of different measures, such as effective communication using social media by governments [7] and the utilization of digital citizen participation tools like discussion forums, reporting tools for urban issues, satisfaction questionnaires, and more [18].

However, while there is a strong emphasis on leveraging digital tools and technologies to make cities smarter and more efficient, the major challenge lies in the risk of relying solely on data-driven insights without considering the nuanced needs, aspirations, and values of the individuals and community. The ultimate risk of solely relying on attaining more data-driven solutions has the potential for expert-driven decision-making, top-down processes that prioritize technocratic decision-making [17]. In such a scenario, data may be used to justify and defend the participatory processes and demonstrate accountability while nudging actual citizen participation [10, 17]. Additionally, this framework can lead to one-way communication, and decisions leading to disconnections of city development and aspirations of the individuals or losing the essence of citizen control which is the notion of participatory smart cities of the future while requirements are pushing the threshold higher at each step through learning from previous engagement [22].

The following question has guided the research presented in this paper:

How can digital citizen participation be evaluated and what lessons can be drawn from the participatory process?

This study addresses the research question by performing an interpretative case study of a development area called Torskeholmen in Grimstad, a coastal

municipality in the southern part of Norway. To translate "Torskeholmen" from Norwegian literally into English would be "cod-islet"; highlighting that the case area studied is essentially an urban redevelopment project of a historical and cultural fishing area and fishing market. The islet lies in the middle of the town of Grimstad and is owned by the municipality themselves. The municipal goal for developing the area is to revitalize the seaside area to make the area an appealing part of the city for future generations to live, work, and study in [8].

Primarily, the public participation process for the discussion of alternatives and designs was initially planned as a public meeting but due to the COVID-19 pandemic, the participation scheme was changed to a digital survey accompanied by a live digital meeting [2]. The survey was performed by a consultant company Asplan-Viak. The digital survey was able to generate a total of 3474 responses, nearly 15% of the total population (23544) of Grimstad in 2020 [11]. As stated in the survey results, one of the many positive effects of the digital survey was the inclusion of the younger generation, who were generally not present in the town hall and public meetings in a proportionate number [2] (Figs. 1 and 2).

As such, to perform the case study, firstly a theoretical background for evaluating digital citizen participation is presented in Sect. 2 of this study. The theoretical notions presented were used to evaluate the participation scheme of the case study area. The methodological approach to this study is further described in Sect. 3. Remaining within the theoretical framework, an analysis of the participatory scheme in the case area is done and presented in Sect. 4 of this paper. A brief discussion and conclusion are summarized in the final section with implications and recommendations for further studies.

2 Theoretical Background

This section highlights the overview of theoretical notions that guided this study. They are different frameworks extracted from the literature and presented, which was done remaining within the context of the relevance of the theoretical models in the setting of participation, use of digital technologies and the Norwegian context.

2.1 Degree of Citizen Participation

The perspective of the community about the digital participation process being able to represent nuanced needs, aspirations, and values of the individuals and community can be discussed through one of the most famous and relevant frameworks of the rungs of the ladder by Arnstein [1]. In participatory planning processes, citizen engagement is facilitated through various mechanisms like town hall meetings, digital tools, workshops, and so on. The different mechanisms used in such processes can be analysed through this perspective of eight levels of participation. The rungs or steps in the ladder here represent the extent of power citizens have in the decision-making process [1]. As described in the concept, participation extends from non-participation to tokenism, and up to the highest level of citizen control and citizen power.

Contextually, this framework was adopted in the Norwegian setting, and the ladder of citizen participation has been discussed as five rungs consisting of Information, Consultation, Dialogue, Agenda Setting, and Co-management [20]. Information dissemination advertises planning processes, informing, and engaging citizens from the start. The consultation makes plan proposals publicly available for feedback, ensuring inclusivity. Dialogue fosters communication between citizens and decision-makers, encouraging discussions on issues. Agenda setting allows citizens to influence planning strategies by suggesting themes. Co-management involves citizen initiatives in initiating or revising planning processes [20].

2.2 Evaluating Digital Participation

The evaluation perspective of digital participation for this study is to be able to understand the underlying notions beyond data and recognize engagement effectiveness to capture the cultural notion of participation. One of the very first well-recognized frameworks to evaluate participation highlights that before starting the evaluation procedure of any participatory scheme, it is essential to identify the goal of the evaluation process [19]. If the evaluation is being done for management, auditing, or learning objectives, it must be made clear. For this study, the main purpose of the evaluation was to draw lessons and learnings from the evaluation of digital participation.

As discussed, in data-driven planning, a more dominant approach to evaluating the success of the participatory process would be to look at the numbers or counting the heads of people involved in such processes. Although this is an important metric through which the impact of the use of digital technologies is evident and is quantitative and measurable, the overall quality of participation should also be assessed in terms of metrics like representativeness, inclusiveness, transparency, and facilitation in the process of participation itself [13].

From the quantitative side, the framework from Sæbø et al. [21], for the case of "e-Participation" can be used as a solid standpoint for this research. The amount of participation is determined by tallying the total number of users and contributions made online. In addition, participant demographics can be used to examine and compare offline involvement. Age, gender, educational level, and other demographic variables were deemed to be important for the analysis [21]. This has been represented similarly, through the standpoint of representativeness and inclusiveness in the planning process quality [13]. Representativeness entails ensuring that participants reflect the demographic diversity of the affected population, while inclusiveness involves providing equal opportunities for all participants to contribute, considering factors like gender, age, and education.

Additionally, the other aspect introduces the depth of participation to assess the manner and tone of online interactions, seeking out characteristics like openness, respect for differing viewpoints, and coherent reasoning [21]. As such, understanding and analysing these aspects enables the customization of participation initiatives, ultimately contributing to the enhancement of engagement in the digital age. Further parameters like clear and accessible information and objectives, facilitation to foster constructive exchanges and understanding among participants, digitally mediated settings, and promoting consensus-building or respectful disagreement can be discussed as criteria collectively aiming to ensure the legitimacy, effectiveness, and fairness of the digital participation process [13, 21]. The qualitative parameters of questions like knowledge, feeling, opinion and behaviour-question-based evaluation can also be used to frame the evaluation study [19].

3 Research Design and Methods

The methodological approach for this study consists of an interpretive case study. A single case design was selected, and a theoretical background based on literature was used to understand the participation using digital technology. A qualitative interpretation of the phenomenon is done to highlight the meaning embedded in the analysis of the case. This interpretation is based on the focus of strategy adopted during the information flow and interpretation guided by questionnaires and analysis of digital technology use. The study draws specific implications or lessons from the generalizable results of the participatory scheme in the case area based on digital participation.

The case was chosen as a success story due to its interesting approach to recording a huge number of responses as data from citizens and the utilization of interesting and innovative methodologies to gain more data-driven insights from the community [2]. As such, the process was also framed by the municipality as an approach to incorporate value-based planning for the redevelopment of the area [8]. This study interprets the participatory scheme of the redevelopment project using interpretation from document studies as a method.

For this study, documents from the digital survey were accessed through the municipal website [12] which were then analysed through the lens of the theoretical background presented in this study. The overall design of the survey is analysed, and lessons are drawn from this case for future recommendations. To sort out, data triangulation newspaper narratives were also drawn from the local newspaper Grimstad Adressetidende (www.gat.no). The keyword "Torskeholmen" was used with dates defined including September and October, the whole period of the digital survey undertaken. This study is also based on the 47 results obtained from the process.

4 Digital Participation in Torskeholmen Case

The theoretical frameworks developed were used to analyse the case study from the citizen participation process in the project. This is done in parts, Firstly, this study analyses how information flow or dissemination of information about the survey was done to reach individuals. Then the participatory tools used are analysed using the degree of participation framework, afterwards, the depth of the survey and analysis performed in the survey report are discussed in this section.

Firstly, the dissemination of information regarding the survey was done using live meetings, SMS, and social media handles of the municipality. A general strategy using low-priced advertisements on social media is used along with links to in-depth websites and detailed information [5]. This was exactly done in the Torskeholmen project where SMS was sent out to around 16,000 numbers registered in the address of Grimstad, with a link to the digital survey and municipal website. A huge response

from the individuals was seen with a drastic increase in the daily visits to the municipal website [2]. Strong messages like "What will Torskeholmen become in the future?" [3] as a leading question with incentives like a set of Air pods and 10 pizzas were the efforts used to generate more responses to the survey, which can be regarded as to encouragement factor for youths under the age of 34 to be represented quite well in this process. From the perspective of the theory of degree of citizen participation, although this may lie in the lower rungs of the ladder, good information flow in the early stages is the first step to a good participatory process [20].

Another part of the process was the survey itself, which consisted of 13 questions, 11 of which were quantitative, closed-ended questionnaires and the last two qualitative free-text questions were used [2]. These included questions from the demographics to choosing different alternatives or models of development for the city. Evaluating through the framework of OECD [19], behaviour-based questions like "Living situation" with close-ended answers "alone, with a partner and with children, student, single parent" were asked to know the individuals better from the perspective of what types of housing requirements would individuals have and what solutions would be required in the development. Likewise, "means of livelihood", visits to the centre of Grimstad were asked to understand the behaviour patterns of the individuals of the city. Feeling-based questions were used like "Relationship with the Grimstad centre", with closed options "I live here", "I do my job here", study, work and tourist were presented as options to know the respondents better. Although this may be argued to be opinion-based questions the evaluation can be done based on the feelings of the individuals. Opinion-based questions which were majorly important were "What do you like best about Grimstad city centre today?", "What has the greatest potential for improvement in the centre of Grimstad?" where individuals opined for "location by the sea" as the best thing about the city and opted for improvement requirements for shops and outdoor areas. These opinions help shape the city better through value-based interpretation of the individuals rooted in the culture of the community. The use of mixed questions like "What is most important for you in the development of Torskeholmen" can be argued to lie in a mix of opinion, knowledge and feeling-based questions.

Similarly, The questionnaires described were followed by an opinion-based digital survey questionnaire where respondents had to choose the development type they wanted from the city. This was done after different "development alternatives" as options for different development models were presented and alternatives from low-rise to high-rise developments had to be chosen by the individuals filling the survey. Visual cues were developed in 3D and 2D, and "Development alternatives", and interactive development design were presented in the survey. Following the development alternative question a deeper insight, feeling-based questionnaire had to be provided with an open-ended typology, in which individuals could comment on why they had chosen the particular development alternative and their thoughts and comments on the development alternative. The interactive maps and tools for visualization can make engagement interesting, but it is a one-way communication or a tool with asynchronous communication and lies in the consultation

in rungs of the ladder typology, although the presence of open-ended questions or narration element may be argued to be a dialogue to foster communication and encourage further discussions on the issues [20].

Hence, the depth and value of the project from the residents' perspectives were laid in the cultural dimensions of the planning area. The area had been a place for fishing for generations and was also an important part of the landscape of the town. Hence, citizen participation and their thoughts on the development of the project were an imperative part of the project planning.

The survey questions were also centred on this fact, and they revolved around these dimensions. Closed questions like "What do you like best about Grimstad city centre today?", "What is most important to you in the development of Torskeholmen?" was used to know the tangible things people expected from the development of Torskeholmen [2]. These questions were used as prompts to attach values, desires, and aspirations individuals and the community had from the development of the area, which is shown in Fig. 3.

The analysis of the survey results was presented concerning the demographics broken down by age and gender. The development alternatives chosen were discussed from the perspective of how and what forms of development people with ages below 50 and after 50 wanted and these were discussed from the narratives of the open-ended questions. This was done to understand better the underlying meanings associated with the area by different individuals [3].

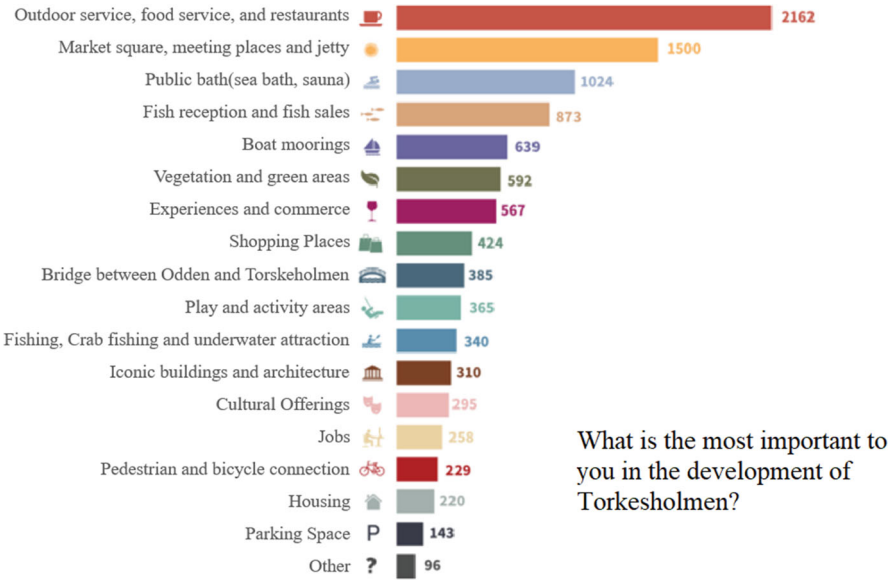

Fig. 3 Results from the questionnaire. (Source: [2])

5 Discussion and Conclusion

This study posed a question regarding the evaluation of digital participation, which was sorted through the theoretical framework presented and drawing lessons through the evaluation of the case area. This study highlights how digital technologies may effectively promote citizen participation with innovative methods that are not only able to represent a wide number of participants but also deeper lying notions through good practices. The evaluation of participation through the degree of participation framework has been to demonstrate meaningful participation oriented towards empowering citizens in the decision-making process. The analysis beyond mere numbers and parameters like representativeness, and inclusiveness is critical to ensuring legitimacy and effectiveness of the process. Hence, the study was able to develop a framework for a value-based approach to enhance participation. From the case, digital participation in the Torskeholmen project was in a similar line as described and overall, Grimstad had a successful participatory process with a good response rate and engagement. The framing of the questions was designed to include the cultural aspect of the fishing town and the findings were further used as a starting point for discursive urban planning and the use of digital tools was performed in a way that was able to represent the notion of need of involving citizens. The findings of the survey were used to enhance further public meetings and for the development of a planning proposal that incorporated the survey findings in line with the development alternative which was chosen by most people as their preferred choice [8]. This process was further worked together with fishermen through physical meetings in the area to locate fish reception and finally ended with two alternatives for consideration in the municipal council in the last quarter of 2022 [8].

Moreover, the major highlight can be seen as the use of digital tools, which can be used to engage young citizens as demonstrated in the case, which had a huge presence in this planning process, despite the presence in physical meetings being rather low for the group of young participants. The correlation of data from different demographics and their choices provided valuable insight into their aspirations from the project, presenting how different groups of people in the area had associated the values of their environment. The use of interactive maps and communications can be a major lesson for future projects in a similar manner. The questionnaires and message set up by the team of surveyors.

Nonetheless, it is important to acknowledge the fact that the Torskeholmen project is not distant from controversies surrounding participation in the project. The project has been criticized and several newspaper articles have been published with reports regarding the failure of the project to capture needs, aspirations, and values into the planning process.

Hence, the evolution towards smarter cities necessitates a careful balance between technological innovations and value-based urban planning principles, which are reliant on the cultural, needs, desires, and aspirations of the citizens. For the cities to become smarter as claimed and to be sustainable through the smartness. Digital participation can be used to encapsulate the visions of a large group of

citizens all at once at a fair and cheap price. But it must be highlighted that digital technologies are the future and citizen empowerment in future cities lies in this participation being able to present the needs, suggestions and demands of citizens. This study argues that the need for a participatory framework in planning requires tools and measures that truly create a genuine collaboration between citizens and cities. Relying on digital participation that is not designed properly runs the risk the participation becoming one way, there is a risk that it may be headed towards tokenism if not carefully implemented, using data from citizens as a form of consultation [17]. To truly empower citizens and achieve meaningful engagement, efforts should aim to foster genuine partnerships and enable citizen control through digital platforms. Simply generating more responses on digital platforms does not necessarily translate to genuine engagement, and although lean digital tools can generate a larger response, seemingly from a larger audience, this may not capture meaningful participation [14]. Furthermore, these findings may be used to analyse the nature of citizen participation and improve the participatory process in smart cities. Special attention must be provided to include citizens for meaningful participation, thus leading to smarter cities through the use of smarter technologies and a net zero sustainable future.

1 Introduction

Linear infrastructure construction projects, such as railways, roads, and tunnels, often encounter challenges such as budget overruns, delays, high environmental impact, and subsequent public resistance [1]. Conventionally, prefabricated elements are manufactured in a stationary factory and then transported to the construction site. However, in linear infrastructure projects, the construction site shifts as the project advances. This dynamic characteristic can result in extensive shipping distances, leading to negative impacts on the economic and environmental aspects of the project [2]. Mobile factories are well suitable for situations in the construction

industry with long distances and high logistics costs [3]. However, factory relocation introduces significant variability in the distances for transporting materials to the factory and for delivering the prefabricated elements from the factory to the project site. This distance variability further introduces variability of transportation-associated carbon emissions.

In this paper, we present a two-stage integer linear programming (ILP) model to optimize the overall transportation carbon emissions. We aim to estimate the potential reduction in the carbon emissions related to the potential implementation of mobile prefabrication factories to supply large-scale linear infrastructure projects. Additionally, we compare the carbon emissions reductions associated with various relocation frequencies to identify feasible mobile factory relocation strategies.

2 Methodology

Figure 1 presents the conceptual framework used in this paper. The first step involves gathering project information data including details on the bill of quantities of the prefabricated elements, the locations of material suppliers, the potential factory sites, and the construction site locations for the prefabricated elements. In the second step, we calculate the distances of materials transportation and the prefabricated elements supply transportation using geographic information system (GIS) tools. We estimate the carbon emissions associated with the reconfiguration processes using life cycle assessment (LCA) following the methodology described in the ISO14040 [4]. Subsequently, this data is fed into the two-stage ILP model to determine the optimal relocation strategy of the mobile factory for different relocation numbers, which was developed in Pyomo [5] and solved using the COIN-OR

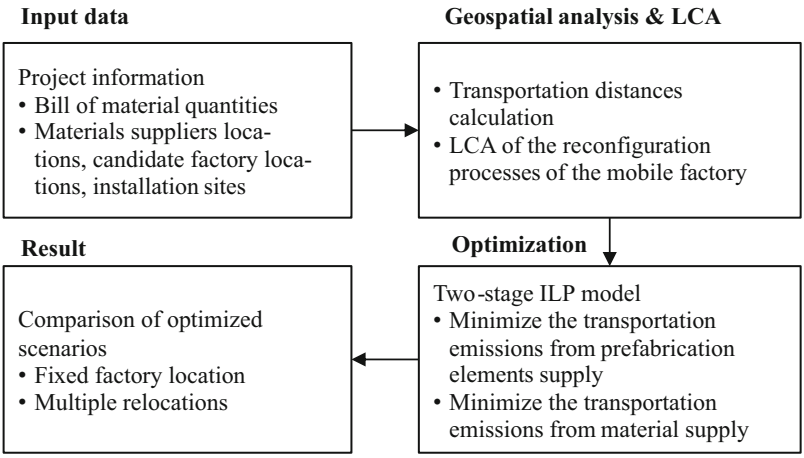

Fig. 1 Conceptual framework

Branch-and-Cut (CBC) [6] solver. In the final stage, we compare the relocation strategies to find the transportation scheme with the lowest carbon footprint. This process accounts for multiple suppliers for various materials at each potential factory deployment location.

2.1 Mathematical Model

The relocation of the mobile factory impacts both the material supply distance and the distance for supplying prefabricated elements, subsequently resulting in variability in the carbon emissions from the transportation of materials and prefabricated elements. Simultaneously, the reconfiguration processes of the mobile factory, along with the transportation of the factory, could also contribute to the overall carbon emissions. To address this computational complexity, we split this optimization problem into two stages. In the first stage, we construct an ILP model to determine the deployment locations for the mobile factory aiming at minimizing the carbon emissions from the transportation of the prefabricated elements, as well as the transportation and the reconfiguration processes of the mobile factory. In the second stage of the ILP model, material suppliers for the factory deployment locations are selected to minimize the carbon emissions from the transportation of materials.

First Stage Model To determine the deployment locations for the mobile factory, we need to find the supply pattern of the prefabricated elements with the lowest carbon emissions. This pattern involves three types of activities: transporting prefabricated elements from the mobile factory to the construction sites, the reconfiguration processes of the mobile factory, and transporting the mobile factory itself. We introduce three decision variables, X_{fi}, Y_f, and Z_{fk}, to quantify the carbon emissions from these three activities, respectively. X_{fi} is a binary variable that equals one if only the prefabricated elements required at the construction site i is supplied by the factory location f. Y_f is a binary variable that equals one if only the factory is deployed at the location f. Z_{fk} is a binary variable that equals one if only the mobile factory moves from the factory location f to the factory location k. With these three decision variables, we can formulate this optimization problem as follows:

$$\text{Min} \sum\nolimits_{f\in F}\sum\nolimits_{i\in I} et_{fi} m_i D_{fi} X_{fi} + \sum\nolimits_{f\in F} e_f Y_f + \sum\nolimits_{f\in F}\sum\nolimits_{k\in F} et_{fk} m_f D_{fk} Z_{fk} \quad (1)$$

subject to:

$$\sum\nolimits_{f\in F} X_{fi} = 1, \forall i \in I \quad (2)$$

$$Y_f \le \sum\nolimits_{i\in I} X_{fi}, \forall f \in F \quad (3)$$

$$Y_f \ge X_{fi}, \quad \forall f \in F, \forall i \in I \quad (4)$$

$$\sum\nolimits_{f\in F} Y_f = f_{\text{se}} \tag{5}$$

$$Z_{fk} \le Y_f, \forall f, k \in F \tag{6}$$

$$Z_{fk} \le Y_k, \quad \forall f, k \in F \tag{7}$$

$$Z_{fk} = 0, \quad \forall f \ge k, \forall f, k \in F \tag{8}$$

$$\sum\nolimits_{f<k} Z_{fk} = Y_f, \quad f = 1, \ldots, n-1, k = 2, \ldots, n \tag{9}$$

$$\sum\nolimits_{f<k} Z_{fk} = Y_k, \quad f = 1, \ldots, n-1, k = 2, \ldots, n \tag{10}$$

The first term in Formula (1) calculates the total carbon emissions from the transportation of prefabricated elements from the mobile factory to all the construction sites. Here, D_{fi} denotes the transportation distance from the factory location f to the construction site i, et_{fi} represents the carbon emissions indicator corresponding to the transportation mode for D_{fi}, and m_i denotes the mass of required prefabricated elements at the construction site i. F and I are the sets of the candidate factory locations and the set of the construction sites, respectively. Both sets are indexed in an ascending order along the linear infrastructure. The second term quantifies the total carbon emissions associated with reconfiguring the mobile factory for mobilization, including site preparation, factory assembly and disassembly, and site restoration. Here, e_f represents the carbon emissions from the factory reconfiguration processes at the location f. The third term calculates carbon emissions from transporting the factory throughout the construction project. Similar to the first term, D_{fk} denotes the transportation distance from factory locations f to k, et_{fk} corresponds to the carbon emissions indicator for D_{fk}, and m_f denotes the mass of the mobile factory.

Constraint (2) ensures that every construction site is supplied by exactly one factory location. Constraints (3) and (4) state that the factory should only be deployed to the locations that supply at least one construction site. Constraint (5) controls the relocation times of the factory, where f_{se} is the desired number of deployment locations for the factory. Constraints (6)–(10) regulate the factory moves through all the selected deployment locations in ascending order of the factory location indexes, where n is the number of candidate factory locations.

Second Stage Model The second stage optimization model locates the nearest materials suppliers for the selected factory deployment locations determined in the first stage. Similar to the first term in Formula (1), we can formulate this optimization problem as follows:

$$\text{Min} \sum\nolimits_{j\in J} \sum\nolimits_{f'\in F'} \sum\nolimits_{s_j\in S_j} et_{s_jf'} m_{jf'} D_{s_jf'} X_{s_jf'} \tag{11}$$

subject to:

$$\sum\nolimits_{s_j\in S_j} X_{s_jf'} = 1, \forall f' \in F', \forall j \in J \tag{12}$$

In Formula (11), $X_{s_jf'}$ is a binary decision variable that equals one only if the factory deployment location f' receives material j from supplier s_j, $D_{s_jf'}$ denotes the corresponding transportation distance, and $et_{s_jf'}$ represents the carbon emissions indicator for $D_{s_jf'}$, $m_{jf'}$ denotes the mass of the material j required at the deployment location f'. Here, $F' = \{f : X_{fi} = 1\}$ represents the set of the selected factory deployment locations. J denotes the set of materials required for manufacturing the prefabricated elements and S_j represents the set of suppliers for material j. We assume that, at each selected factory deployment location, the mobile factory receives each material from only one supplier. Therefore, we can use Constraint (12) to guarantee that the factory receives sufficient materials at each selected deployment location.

3 Case Study

In this paper, we developed the case study from applying the mobile factory to supply a hyperloop infrastructure project. The hyperloop concept consists of a passenger pod traveling through a tube under a light vacuum while being propelled and levitated by a combination of permanent and electro-magnets [7]. EuroTube Foundation (ETF) [8], a Swiss non-profit research organization, is dedicated to the development of hyperloop technology. Their hyperloop infrastructure solution utilizes concrete pipes to enable lower production costs and facilitate easier maintenance and management throughout the infrastructure's life cycle [1]. In this case study, the prefabricated elements are the concrete pipes produced in the mobile factory. The candidate factory locations were selected using Multi-Criteria Decision Making (MCDM) in collaboration with the factory design team from the Free University of Bozen-Bolzano (unibz) and ETF [8]. The main criteria include proximity to the infrastructure line, sufficient space for the deployment of the mobile factory, and good accessibility to main road networks.

Figure 2 depicts the geographic information near the candidate factory locations 17–19 in this case study. The numbers below the red cycles are the indexes of the candidate factory locations. The studied infrastructure line (dashed line) from Geneva to Zurich was defined in collaboration with ETF [8], with a total length of 248 km. Considering that each concrete pipe has a length of 0.02 km, the model would require 12,400 construction sites, posing a heavy computation burden. To address this, we divided the infrastructure into 248 segments, each with a length of 1 km. We assume that for each segment, the construction site for every concrete pipe is represented by the segment's midpoint (grey square). The locations of materials suppliers were obtained from Google Maps [9]. The red line demonstrates the transportation routes for concrete pipes from the candidate factory locations to the construction sites. The transportation distance in this case study is the direct distance between two locations. The distance calculation was performed using the GeoPandas package [10], with the projected coordinate system for distance calculation being EPSG 3035 [11].

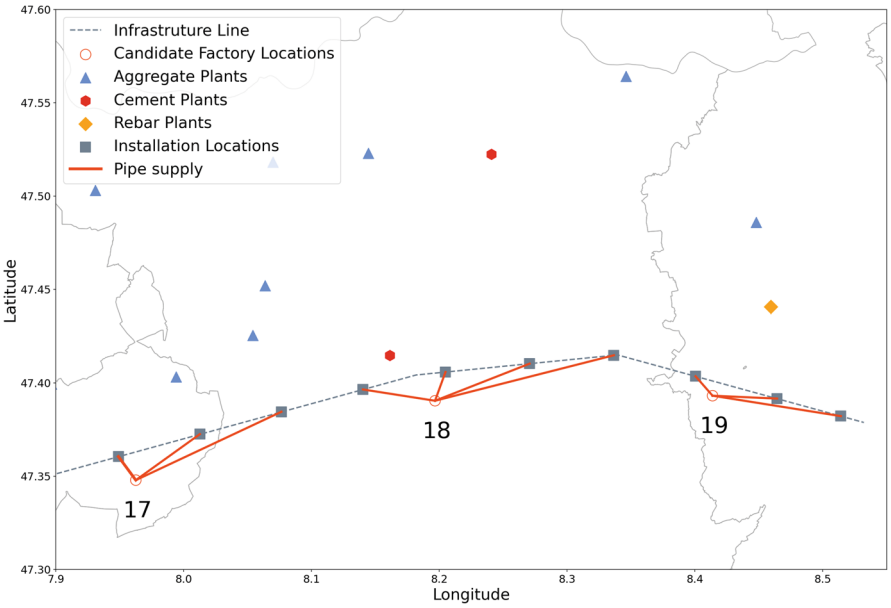

Fig. 2 Case study of hyperloop construction near candidate factory locations 17–19

The bill of quantities for the concrete pipes was provided by ETF [8]. ρ_p, ρ_a, ρ_c, and ρ_r are the required mass for constructing 1 km of the infrastructure for concrete pipes, aggregate, cement, and rebar, respectively. The concrete pipes mass m_i required by the infrastructure segment i with a length of l_i can be calculated with $m_i = \rho_p l_i$, and the mass of the material j required by the factory at the deployment location f' can be calculated with Eq. (13):

$$m_{jf'} = \rho_j \sum\nolimits_{i \in I} l_i X_{f'i} \tag{13}$$

Here, ρ_j represents the required mass of material j for constructing 1 km of the infrastructure, $X_{f'i}$ is the decision variable resulting from the first stage model at the selected factory deployment location f'.

The transportation carbon emissions indicators were obtained from the ecoinvent 3.9.1 database [12]. Due to the lack of detailed information, we assume the transportation modes for both materials and concrete pipes remain unchanged throughout the whole project. The transportation modes for material supply and factory transportation are set to use "lorries of all sizes" with a carbon emission indicator (et_a, et_c, et_r, and et_f) of 0.1478 kg CO_2-eq/tkm. Given that the mass of one piece of concrete pipe is approximately 125 tons, the transportation mode for pipes is set to be "lorries larger than 32 tons" with a carbon emission indicator et_p of 0.1002 kg CO_2-eq/tkm. Details of the mobile factory were provided by the factory design team from unibz, with further information available in [1, 13]. The mass of the mobile factory m_f is

Table 1 Key input parameters

et_a, et_c, et_r	et_f	et_p	e_f	ρ_a	ρ_c	ρ_r	ρ_p	m_f
0.1478	0.1478	0.1002	3822	4741.4	1208	219.9	6269.3	575

575 tons. The carbon emissions from the factory reconfiguration processes e_f were estimated to be 3822 kg CO_2-eq per relocation for the mobile factory that uses a pneumatic tent solution. e_f is assumed to remain the same for all the candidate factory locations. The LCA calculation was conducted using the IPCC 2021 GWP100 method [14] based on the ecoinvent database 3.9.1 [12] with the Brightway version bw25 package [15]. Table 1 summarizes the key input parameters for the two-stage ILP model. The model was built with Pyomo package 6.7.1 [5] and solved by the COIN-OR Branch-and-Cut (CBC) [6] solver 2.10.10.

4 Result and Discussion

Figure 3 illustrates the optimal total carbon emissions with respect to different factory relocation numbers. The overall carbon emissions demonstrate a significant decrease of 58% as the factory relocation number increases from zero to six. However, beyond six factory relocations, the reduction of the overall carbon emissions becomes insignificant. Specifically, as the number of relocations increases from zero to six, the carbon emissions from the transportation for the concrete pipes decrease by 84%, while the carbon emissions of the transportation for the materials fluctuate around 4000 tons CO_2-eq. These fluctuations are insignificant compared to the reduction of carbon emissions from pipe transportation. This is due to the relatively uniform geographic distribution of material suppliers around the candidate factory locations. Except for zero relocation, the carbon emissions from the transportation of the mobile factory remain around 20 tons CO_2-eq for all relocation numbers. This consistency arises because the factory is consistently deployed at the first and the last candidate factory locations, resulting in only slight changes in the total transportation distance of the mobile factory. Considering the relocation of the mobile factory can be time consuming, four to six relocations are efficient for reducing the overall carbon emissions from transportation in this case study.

Figure 4 shows the contributions of the six carbon emissions categories to the overall carbon emissions with respect to different relocation numbers. The carbon emissions from pipe transportation are the predominant contributor until four relocations at which point the carbon emissions from aggregate transportation become the largest contributor. The contribution of the carbon emissions from factory transportation is insignificant for all the relocation numbers.

Figure 5 illustrates the transportation distances for materials from suppliers to the factory, as well as the total transportation distance for concrete pipes from the factory to the construction sites in four, six, and eight relocations. The total transportation distance for concrete pipes is calculated as the sum of the distances from each

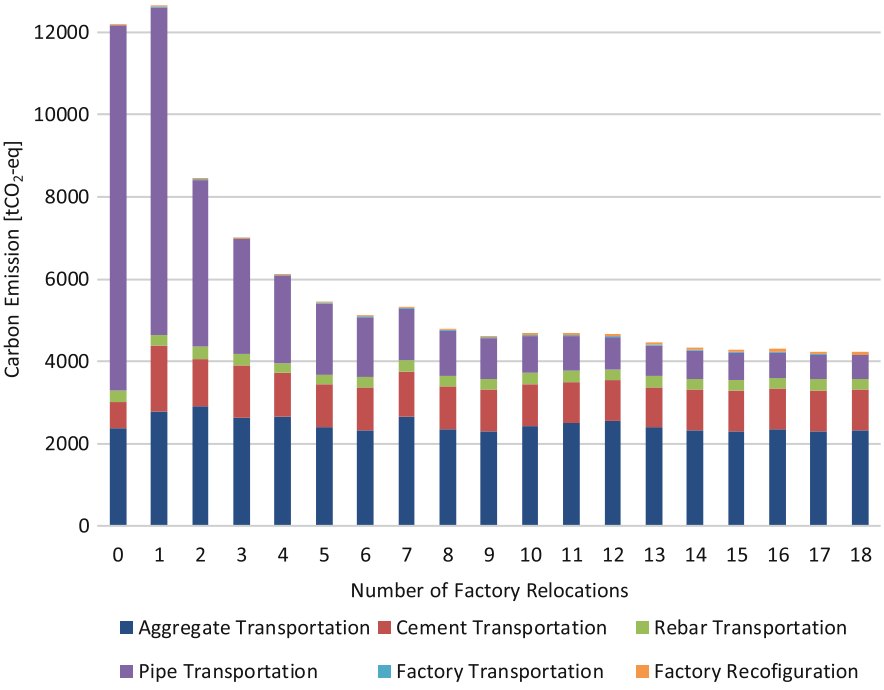

Fig. 3 Optimized total carbon emissions for different factory relocation numbers

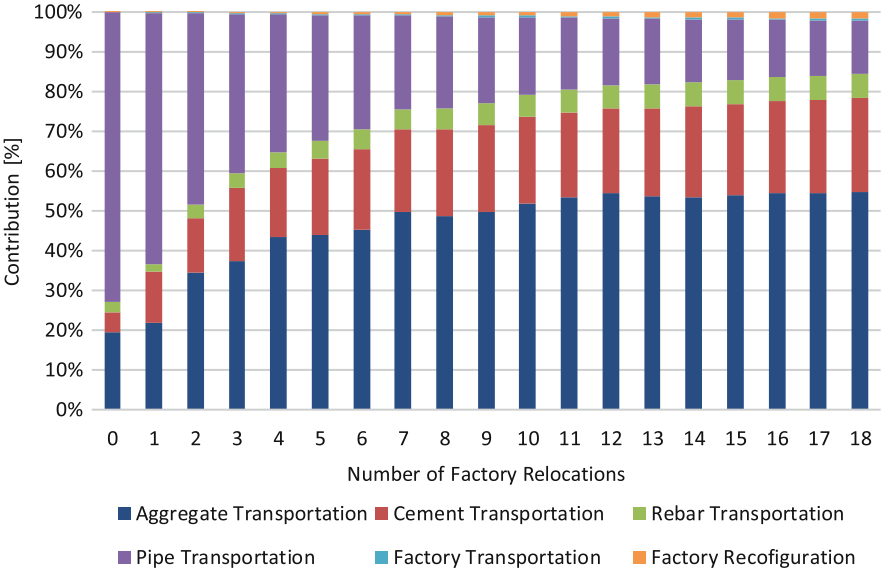

Fig. 4 Contribution analysis for various factory relocation numbers

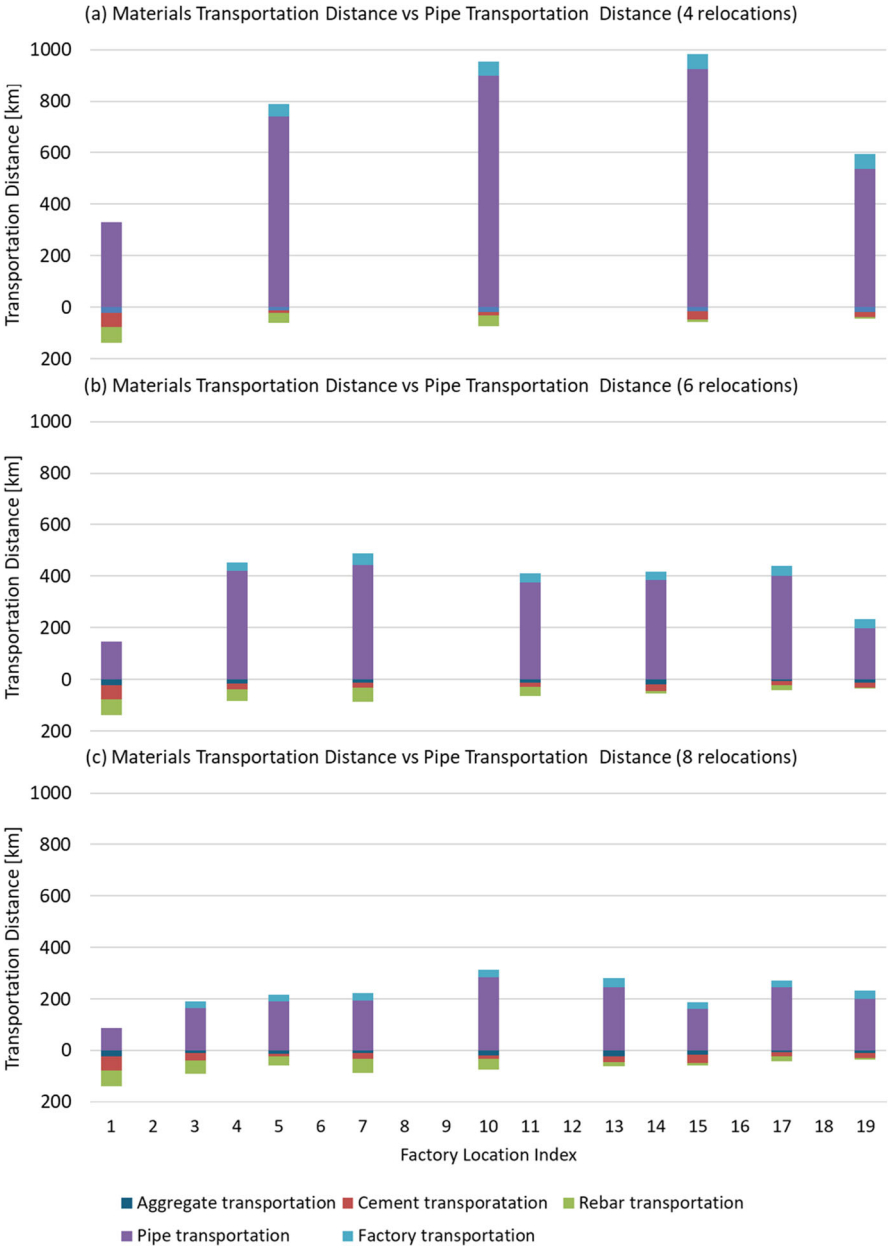

Fig. 5 Transportation distances for selected factory locations in (**a**) four-relocation scenario, in (**b**) six-relocation scenario, and in (**c**) eight-relocation scenario

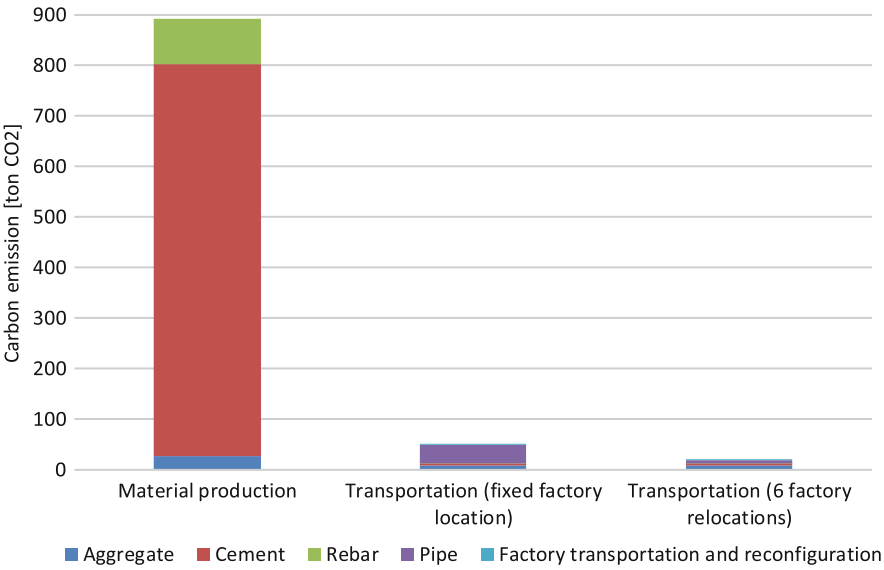

Fig. 6 Carbon emissions from materials production and transportation (averaged on 1 km construction of the infrastructure)

construction site to its corresponding factory location. Notably, the total transportation distance for pipes is significantly greater than that for materials at each selected factory deployment location. As the number of relocations increases, there is a significant decrease in the total transportation distance for pipes at each selected factory deployment location. However, the transportation distances for materials at each factory deployment location only show slight variations. Together with Fig. 3, it is evident that the reduction of carbon emissions by increasing the relocation number is primarily due to the reduction of the transportation distance for pipes from the factory to the construction sites.

Figure 6 illustrates the carbon emissions from both material production and transportation. Notably, carbon emissions from transportation, including material transportation, pipe transportation, factory transportation, and factory reconfigurations, are significantly lower compared to emissions from materials production. This suggests that while the use of a mobile factory for constructing the hyperloop infrastructure can reduce its carbon footprint, most emissions are still associated with materials production.

The main research limitation of this study is that the two-stage ILP model cannot guarantee a globally optimal solution for minimizing the total transportation carbon emissions, as the minimization of carbon emissions from materials supply relies on the predetermined factory locations from the first-stage model. Integrating the selection of materials suppliers into the decision variables could address this limitation in future studies. Additionally, the assumption that, at each selected factory location, the mobile factory receives each material from only one supplier may

underestimate carbon emissions if the selected supplier cannot provide sufficient material. However, this underestimation would not affect the recommended relocation strategy significantly, as the primary carbon reduction comes from reducing transportation distance for delivering prefabricated elements. Another limitation is the use of segment midpoints to represent construction sites, which simplifies computation but may underestimate pipe transportation distance. Despite this, this impact is minor given the small carbon emissions indicator for pipe transportation. To improve accuracy, future studies can run the model with exact construction site locations for each pipe. Finally, assuming unchanged transportation modes for materials and pipes in the case study may not accurately reflect reality, particularly in instances where roads are not well constructed. In the future study, we will conduct a sensitivity analysis to estimate its impact on the mobile factory relocation strategy.

5 Conclusion

In this paper, we developed a methodology that combines GIS and an optimization model to analyze the potential reduction in transportation carbon emissions achievable using the mobile prefabrication factory in large-scale linear infrastructure construction projects. A two-stage ILP model was established to identify the optimal relocation strategy for minimizing transportation carbon emissions. A case study of constructing a hyperloop from Geneva to Zurich was utilized to evaluate this model. The results indicate that, in this case study, the implementation of a four-relocation strategy can potentially reduce the total transportation carbon emissions by 50%. This reduction in carbon emissions is primarily due to the optimized transportation distance of the concrete pipes from the mobile factory to the construction sites.

Acknowledgments The research presented in this article was carried out within the research project “Smart Mobile Factory for Infrastructure Projects (SMF4INFRA),” which has received funding from the Swiss National Science Foundation under grant agreement no.204852 and Autonomous Province of Bolzano/Bozen—South Tyrol. The authors are grateful to EuroTube Foundation for the support and insights on this project.

1 Introduction

1.1 Background

Kenya is a developing country located to the east of the African continent, along the Indian Ocean coastline. It is home to the four major cities Nairobi, Mombasa, Kisumu, and the latest conceptualized Nakuru city. In the East Africa block, Nairobi

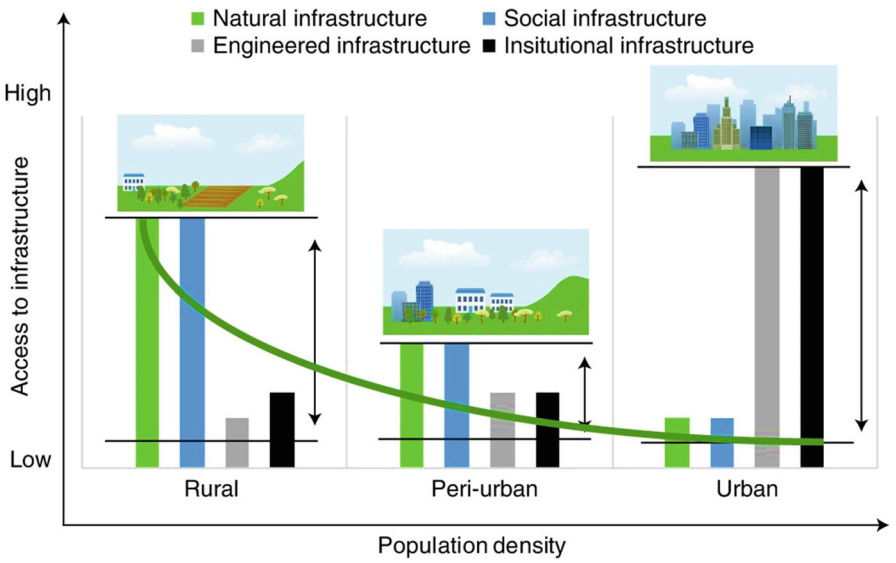

Fig. 1 Access to services varies across individuals within each area (arrows), and nature may act as a safety net in many areas across the Global South (green line) [4]

is the second most populated after Dar-es-salaam. The four cities are relatively straining from an increase in demand for infrastructure and decent housing [1] due to massive urbanization. According to Hope (2012), urbanization is due to social pressures for better and improved living standards (as illustrated in Fig. 1) but many people end up in undesirable living conditions [2, 3]. Urbanization comes along with many construction activities that cannot compare with global conditions such as in developed continents, i.e., Europe and North America. For example, in Kenya, cement manufacturers are located in the cities, with Nairobi accounting for 6 out of 14 registered plants as per the global cement report in 2023 as shown in Fig. 2.

The mushrooming construction activities around cities and towns within Kenya use Portland cement as the main binder. Cement production in Kenya is done according to the KS EAS-18-1-2017 [5] standard adopted from European Norm EN 197 for cement standards. The construction industry in Kenya uses Ordinary Portland Cement (OPC) CEM I, Portland Pozzolana Cement (PPC) CEM II/B-P of 21–35% pozzolana, CEM IV/A containing 11–35% pozzolana and Portland Limestone Cement (PLC) CEM II/A-LL having 6–20% limestone [6]. Different companies introduce pozzolans into cement blends to reduce the amount of clinker to save on marginal production costs. There is limited production of OPC (CEM I) unless on special orders and use [6].

However, the cement factories are trying to go green by introducing more pozzolana and finer grinding while keen not to compromise strength, consistency, and durability. Some of the pozzolana introduced include lime, volcanic ash, limestone, and clays. It is because Portland cement contributes 80–90% of the

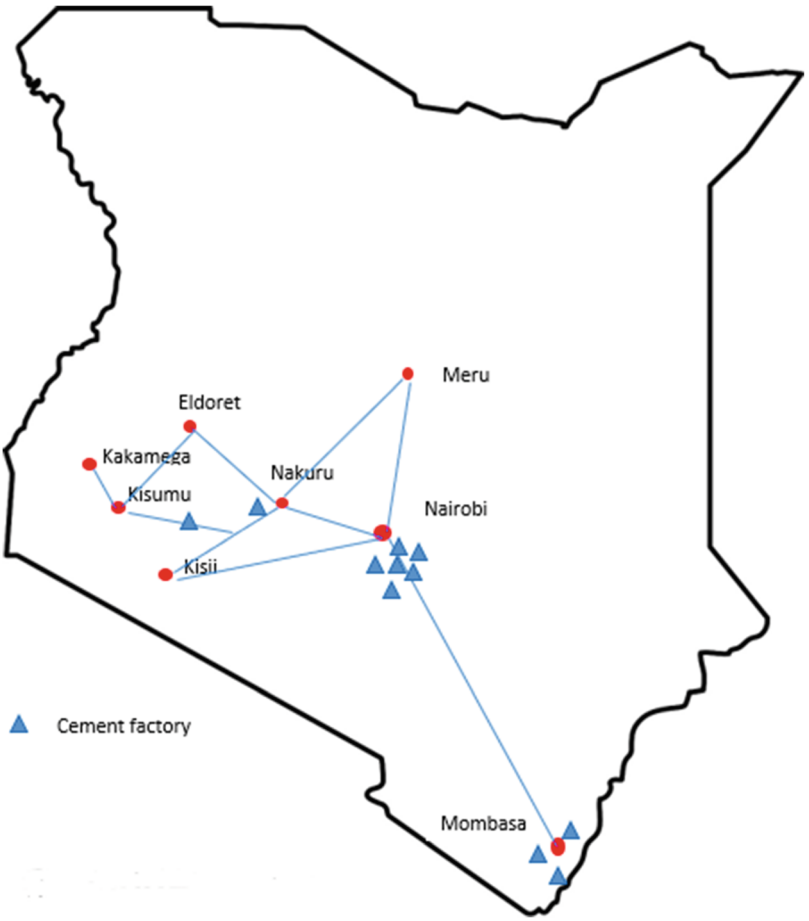

Fig. 2 A map of Kenya showing the distribution of cement factories

estimated 10% of anthropogenic gas emissions responsible for climate change [7]. There is an urgent need to decarbonize cement production despite increased demand by the government agenda to address the housing shortage. In addition, decarbonizing cement is difficult as 77% of the CO_2 emissions occur during chemical reactions in production. The other percentage of emissions are tied to operating equipment and transportation of aggregates [8]. Transportation of concrete elements such as aggregates and equipment has been linked to contribute about 7% of the 8–9% anthropogenic gas emissions [8]. Workable solutions must deploy low-carbon clinker, alternative SCMs, circular technology and AI. The cement industry has introduced targets to realize net-zero CO_2 emissions by 2050.

The distribution of cement plants in cities reflects on two major considerations that include materials and supply chain. The situation draws large construction activities to concentrate in major cities [9] including the precast products industries.

The status quo is not going to hold long enough as the population growth is increasing sharing the demand for both housing and infrastructure in the devolved government units such as counties and small towns like Eldoret, Meru, Nyeri, Kisii, and Kakamega shown in Fig. 2. Increasing demand for concrete from rural regions implies an increase in carbon emissions from the transport and storage of cement during distribution. The demand for materials such as limestone and clinker influence the locating of cement plants in the city. The transportation of raw materials to the factory and cement to customers is a reason for high cement prices as the cost of production is cascaded to the consumers. The location of a few plants outside the cities is linked to the main transport corridor between the cities due to the ease of the distribution matrix. Therefore, using supplementary cementitious materials (SCMs) would ease the pressure of having to set up plants in cities within proximity of major supply streams of raw materials. Innovatively introducing biomass from agricultural waste and natural resources such as abundant clay deposits are milestones toward affordable and ecological cement as traditional SCMs such as fly ash and slag are deemed unavailable and unaffordable. Clay has been proven to naturally occur in many parts of Kenya for manufacturing limestone calcined clay cement (LC3) [10]. Elsewhere, rice farmers are potential suppliers of rice husk that has proven to be rich in silica from the ash as a pozzolana [11]. Cassava peels are also converted to ash and can be substituted for about 75% due to the high contents of silicates and aluminates [12]. All the above solutions are presented but the country is stuck in the status quo from a poor supply chain due to a lack of infrastructure, low technology and lack of diverse national codes and standards in support.

In developed continents such as Europe, solutions are even traditionally feasible as the cement manufacturing plants are evenly distributed enhancing a good supply chain for industry waste such as blast furnace slag (GBBS) and fly ash (FA). They have developed codes of practice and standards for adopting the use of low-carbon types of cement with the potential of reducing the use of clinker by up to 50% as per EN 197-5 like LC3 [13]. The precast concrete (PC) technology involves designing structural components, manufacturing in a factory, transporting, delivering, and erecting on site [14].

Precast technology has been classified to be among the top ten innovations in the construction sector as it follows a modular approach [15]. The precast industry (PI) has been in practice for over a century with numerous advantages. Some of the benefits are due to its versatility in many applications such as road bridges, channels, towers, and buildings. The precast technology is efficient in terms of quality finishes as elements and connections are determined in a controlled environment. Also, the cost of construction of the overall structure is saved from reduced onsite labor, and saving on disarray scheduling. The expenses expected on formwork and smooth detailed finishes such as plastering is eliminated. The other secondary benefits include low repair and maintenance costs as the quality of components is guaranteed. Safety and health concerns are addressed through minimal onsite interactions with unskilled labor, thus reducing construction-related accidents. PI also is environmentally friendly due to flexibility in allowing the recycling and reuse of aggregates [16]

and demolished components. In some aspects, the damping of aggregate waste from demolitions is also minimized. In general, the PI sector is more beneficial and can save on the time and cost of completing a construction project and impart sustainability.

1.2 The Precast Industry in Kenya

Concrete has long been identified as the most used construction material [17, 18] across the globe due to its versatility in shape and form. The flexibility in the construction industry allowed the inception of precast products which means no more onsite ready mixes. Structural elements of defined shape, form, and size are manufactured in the plant, transported to the field, and fixed. The precast industry has gained prominence in Kenya for the past few decades. However, it is not well documented. The available sources imply that precast products have been largely on fixtures and fitting and not major structural elements. However, some companies are developing precast panels for walls, beams, and slabs. The sustainability of the precast industry is attributed to reduced construction time, low labor costs and overall benefits to the clean environment due to a controlled mix by avoiding heavy onsite construction machinery [7].

The global view of precast technology is well documented but lowly used in developing regions. PI needs to align its activities with the societal needs to improve uptake. Developing economies perceive concrete works as high-risk, labor-intensive, and technology-intensive [19]. The slow integration of technology in business advancement affects the uptake of precast technology—skilled labor in designing and managing PI components. The main objective of this study was to identify the potential of using AI in increasing the uptake of precast technology and sustainability in Kenya.

2 Methodology

The study focuses on identifying and analyzing the challenges and/or opportunities available for the adoption of precast products through available literature and artificial intelligence (AI). However, a qualitative research approach was used in obtaining data through questionnaires, observations, and cost comparison on a case study. In the case of questionnaires, four key research questions were posed and twelve corresponding companies' samples for their work on precast. One case study was picked for precise size and available quantitative information for a cost comparison. The research framework was adopted as in Fig. 3. The objectives of the study included the following:

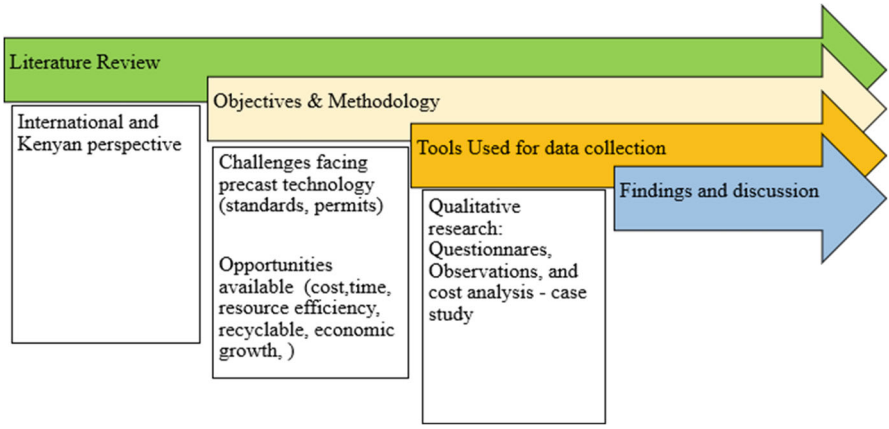

Fig. 3 Research framework

- To analyze the size and coverage of precast technology in Kenya
- To determine the challenges faced by the precast industry in applying the technology in Kenya
- To establish the potential application of AI in increasing the adoption of the precast technology

The study questionnaire involved four fundamental questions directed to the precast components manufacturing companies registered in Kenya.

1. What types of precast products does your company manufacture?
2. What are primary factors influencing your decision to adopt precast technology?
3. What are main challenges hindering the wider adoption of precast technology?
4. How would you rate the government's support for the precast industry in Kenya?

The cost comparison between the conventional concrete building methods and precast structure was done on the same area structure. The cost of the precast sampled building was as per the precast manufacturing company and the Kenyan government cost handbook for constructing the same structure. A 64 square meters 2-bedroom house was opted for cost analysis. The pictorial representation for conventional concrete walls and precast walls is shown in Fig. 4.

3 Discussion of Findings

3.1 Precast Components, Primary Factors, Main Challenges, and Government Support

While only 50 questionnaires were emailed to registered companies and contractors that advertised themselves to be handing precast products on the active websites, 24 responses were received. The responses were received through direct dialed calls

Fig. 4 Tuff stone conventional house vs. precast wall house

Table 1 Types of components prepared by different companies

Precast components	Wall panels	Beams and columns	Slab	Hollow blocks	Channels	Others
Number of companies	4	4	5	24	12	21

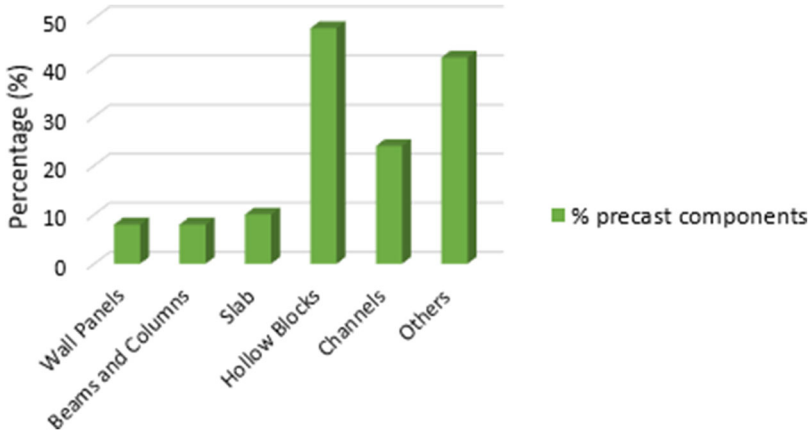

Fig. 5 Precast components

as many follow-ups preferred instant responses. The results of the data collected are in Table 1 and Fig. 5, respectively.

As per Fig. 5, 8% of the companies sampled were found to make wall panels, 8% of beams, 10% slab (suspended and foundation), 48% hollow blocks, 24% channels and 42% others. The results imply that only five companies can construct houses. At least all companies that responded are producing precast elements on a small scale. Many companies seem to concentrate on replacing tuff stones preferred in wall construction. The structural uptake can account for 8% on a large scale.

The respondents to the questionnaires agreed to have a unanimous choice to adopt precast to save on construction cost, period, and durability. The 8% of major players expressed optimism about saving on material waste, environmental degradation and

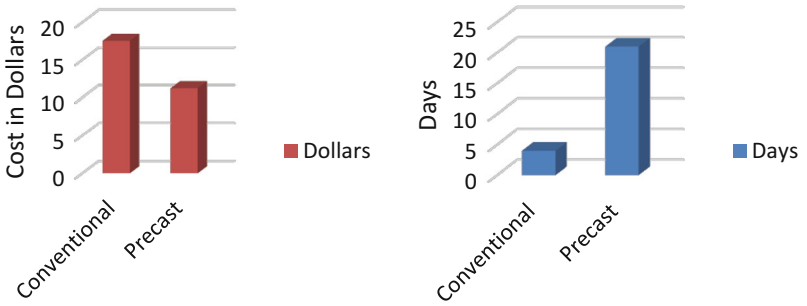

Fig. 6 Cost and time comparison for conventional and precast wall panel

reducing repair and rehabilitation costs. The cost component comparison was conducted on wall panels for a 64-meter square house. The comparison involved a wall panel component. The wall panel was selected as it involved a comparison of the time of construction and cost per square meter of a conventional wall as shown in Fig. 6.

The two projects of the same plinth area were compared against cost per square area and construction time according to Kenya's building code. It was noted that conventional concrete construction is 34% more expensive than precast concrete. The duration of erecting a precast wall was found to be 17 days slower for the same plinth area. The results are in line with Nyanam et al. (2017) findings on precast over conventional construction methods on overall projects [7]. The opportunities, challenges, pros and cons, and potential use of AI on PI in Kenya are further discussed in the next section.

4 The Opportunities Available for the PI in Kenya

PI products have been identified by many manufacturers, researchers, and consumers to offer versatility in applications. There are many opportunities present for Kenya PI in building products and construction elements. The opportunities include the following:

- Precast technology is versatile and flexible in recycling and reusing aggregates hence minimizing demolition and onsite mix waste. Precast components can be reused in case of demolition saving up to 50% embodied energy [20].
- The precast plant requires low initial capital investment compared to starting a cement plant as it accommodates the low supply streams of SCMs for the quality of precast components. Kenya is rich in natural pozzolana such as clay and limestone that enhance concrete durability.
- The precast industry offers opportunities for recycling and reuse of agricultural waste such as concrete fibers, admixtures, and SCMs. Hence PI can be built in any part of the country by utilizing local materials such as sisal fibre reeds from Kilifi, Kenya.

- The PC is a resource-efficient venture through saving on time of construction, minimizing material waste, and being less laborious for low-income earning households. The materials are easy to transport and install fast and safely at the site.
- The PI is a revenue stream for the local communities through selling aggregates and collecting agricultural and regenerative waste such as rice husks, cassava peels and water hyacinths from Lake Victoria, Kenya respectively. This supports the circular economy. The growth in precast components can be imported and enhance the growth of the country's gross domestic production (GDP).
- An opportunity exists for government support through creating national annex codes, standards, and consumer incentives, especially in the ongoing Boma Yangu Affordable housing projects, that are devolved to counties.

5 Pros and Cons of Precast Concrete

In both ways, blending cement as a binder from factory and precast production has both pros and cons. The precast industry (PI) will provide more advantages to the small towns as are reliable and durable, enhancing the quality and timely smooth finishes. Secondly, the precast concrete will enhance a clean built environment by minimizing waste and recyclable structural elements. Incorporating SCMs into OPC enhances reliability in building strong structures with reduced embedded CO2 footprint from conventional concrete.

Blending types of cement onsite bear a risk of unwanted reactions that can retard [13] or enhance flash settings that lead to early concrete cracks resulting in many active phases. Therefore, blends produced during concrete production and molding elements enhance a homogeneous and ideal mixture. This is possible by controlling OPC and SCM quantities in the concrete production process. The main constraint in concrete production is the low supply streams of SCMs in manufacturing cement processes. This is the reap for precast concrete as locally available materials can substitute large amounts of cement for structural components.

6 Challenges Facing the Precast Industry in Kenya

The precast industry is on the verge of penetrating small towns in Kenya as time goes on. Like any business model and technology, the PI faces several challenges hindering its fast growth. Despite having a good percentage of Kenyans connected to the internet, 26% don't have access or even use it [21]. A few have embraced the internet and integrated AI to improve businesses like precast technology. Some of the challenges facing PI in Kenya include the following:

- Limited knowledge of contractors and vast unskilled labor in adopting precast technology.

- The engineers and technicians show technical fears from the lack of codes and standards in supporting PI components.
- Setting up a precast plant is expensive among many low-income households as access to credit is difficult due to lack of collateral.
- Access to grants is limited to an informed population such as research institutions that lack a clear framework and government initiatives on enhancing business startups.
- There are no outlined government initiatives and incentives for the precast industry in place for either producers or consumers in Kenya.

7 The Future and Outlook of the Precast Industry in Kenya

The construction industry in Kenya contributes significantly to the gross domestic product (GDP). The PI as a sector in construction has witnessed notable growth over the past few decades. The country is driven by increasing population and demand for decent and affordable housing. The demand is increasing for overall improved infrastructure that requires fast, affordable, and durable construction methods. The current precast concrete in Kenya focuses on structural elements such as road furniture, beams, slabs, wall and slab panels, and columns. Opportunities for growing PI arise mainly from government projects. The projects that have contributed to the growth so far are roads and affordable houses under the government's bottom-up transformative agenda (BETA). It is a result of quality control, speed construction and durability on government projects that require longevity in performance. The rise of computer-aided design and AI-enhancing graphic representation will eventually enhance the two-fold growth of PI in Kenya.

8 Application Potential of Artificial Intelligence to Precast Concrete

Artificial intelligence (AI) is the ability to make machines mimic and perform human tasks. Engineering playing a major role in design and construction is inseparable from technology like the use of AI. Technological applications are multifaceted from mechanical applications in cars, computers, 3D printing and medicine. Technology has been integrated well into building information management (BIM) for the construction industry in applications for design, schedule, and management construction [22]. All these emerging technologies include the current rapid growth of the internet with an integrated algorithm of improving many operation ways faster than human brains.

Artificial intelligence (AI) has been made available by the high access to the internet. Kenya has already rolled out 5G internet connection which has boosted the connection and expanded the bandwidth for faster upload and download speed

[21]. AI aims at picking human traits and applies to tasks way faster than humans. It implies that AI can learn, plan, and perceive environmental language to execute a task. AI is getting into the construction industry to improve productivity, quality, and safety. Currently, AI can use cloud-based applications that are accessed remotely through the internet to capture key aspects like progress and resource allocation and management. The precast industry would not be different as machine learning (ML) models can be fitted into mixing and casting machines. The machines will be able to maintain quality by intelligently integrating algorithms that would execute leveraged mix designs and achieve prismatic shapes and sizes.

With logistics as key to implementing precast technology, AI can alter business models. Customer response and uptake of technology combinations will only be possible through automation systems. The overall implications will improve quality, minimize waste, reduce injuries, increase efficiency and reduce environmental impact to enhance sustainability. Generally, large projects will be realized within the timeframe.

Eventually, PI is the futuristic approach to the construction industry in Kenya. Been around for over a decade. Many companies have ventured into fabricating road drainage channels, road kerbs, fencing poles, slab waffles, fencing panels, bridge beams, and wall panels. PI in Kenya is about 8% successive as companies can form most elements and construct. Despite many challenges, PI has the potential to grow with an increase in skills, machinery, and alternative materials. The documentation of PI in market share is not well documented in terms of numbers. However, the market is growing gradually as many players are trying to modernize and localize materials used for specific uses. In addition, the precast components are cost-saving, eco-friendly, and time-saving for prefabricated ways of construction.

1 Introduction

In the current era of infrastructure development, the construction of geotechnical engineering systems (roads and railway embankments) is growing rapidly over the lands comprising soft soils that act as a week foundation medium. Such saturated soft cohesive deposits have poor geotechnical characteristics (such as low bearing capacity, high compressibility, and low permeability) and are generally found near the marine coast and in marshy lowlands around lakes and river beds. Hence, reclamation of lands is carried out by implementing suitable ground improvement techniques by the practicing community [1]. Application of prefabricated vertical drains (PVDs) with surcharge preloading is one of the efficient ways to enhance the ground conditions of saturated soft cohesive deposits [2, 3]. Introduction of PVDs into the low permeable soft soils creates an artificial drainage path that facilitates

quicker dissipation of pore water and excess pore pressure due to a shortened drainage length, thereby resulting in accelerated consolidation settlement [4]. Application of PVDs in managing the settlement of railway embankments passing through soft soils has gained profound popularity [5].

In most of the conventional studies involving PVD treatment, subsurface stratification is considered horizontal, barring very few literatures that consider the realistic undulations in the substratum [6, 7]. In this chapter, a case study of the Udaipur railway embankment in Tripura, India, raised over a marshy lowland, is presented. A finite element (FE) analysis is conducted to predict the consolidation of PVD-improved layered subsoils under the embankment. As per the data obtained from multiple borehole conducted at the site, the subsurface was found to comprise undulated stratification. The Mohr–Coulomb (MC) constitutive model is used to represent the cohesionless deposit and the embankment fill, while the Soft Soil (SS) material model is used to represent the soft cohesive subsoil layers. Assessment of PVD-improved subsoils is carried out to reflect upon the influence of realistic undulated soil profile over the conventional consideration of horizontally layered subsoil layers toward the estimation of consolidation settlement and excess pore-water pressure (EPWP). Furthermore, it is observed that an approach of implementing PVDs to varying depths, depending on site-specific scenario, should be adopted to attain a more sustainable solution in improving the consolidation behavior of the soft compressible soils.

2 Rehabilitation of Railway Embankment: Udaipur, India

2.1 History of the Problem and Proposed Ground Improvement

A new broad gauge (BG) line was proposed to be built as a part of the project for connecting Agartala and Sabroom (110 km) in the state of Tripura, India by Northeast Frontier Railways (NFR), Government of India (Fig. 1) [8]. At the chainage of 41.85–42.8 km from Agartala, Udaipur railway station yard and station building were to be constructed. The site for construction was proposed over a low-lying marshy land, referred to as Sukhsagar lake. The earthwork for constructing the railway embankment commenced without any pretreatment to the existing ground. While the embankment was being raised up to 5–6 m, a massive settlement exceeding 2 m was triggered at the site [9]. As a result, the embankment exhibited an unsustainable subsidence. Finally, after thorough site reconnaissance and based on geotechnical investigation, ground improvement through PVD was suggested to improve the properties of the underlying subsoil for reconstruction of the embankment [9].

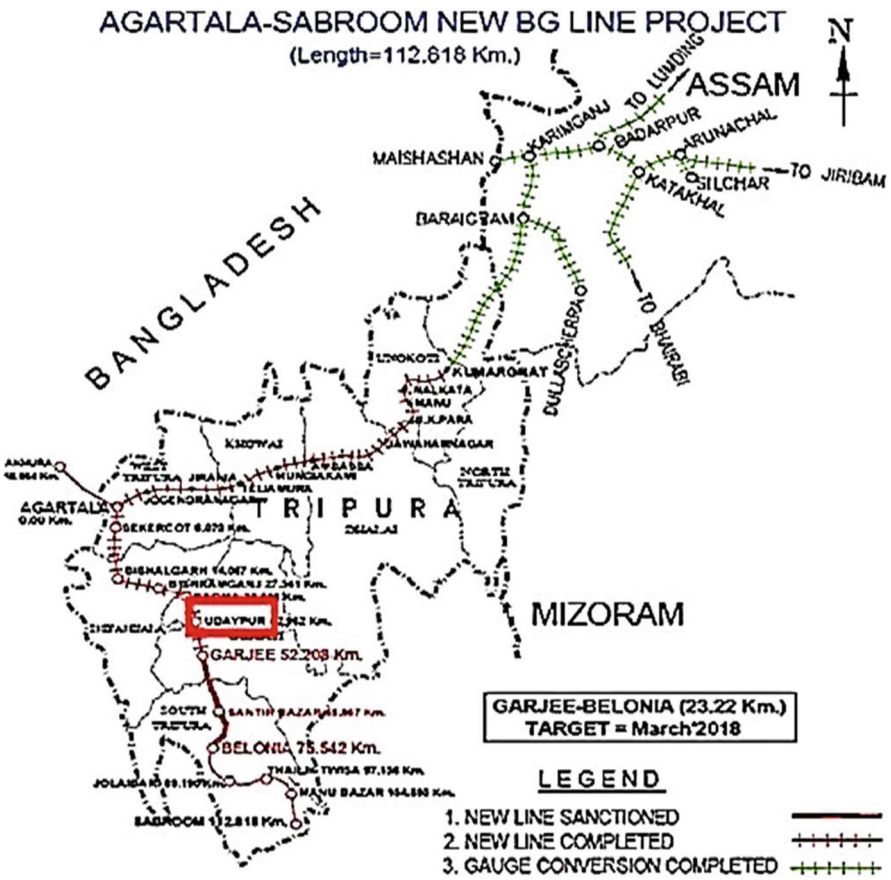

Fig. 1 Map of Agartala–Sabroom new BG line project [8]

2.2 Subsoil Conditions

The typical cross-section of the borehole soil profiles reflects the presence of embankment fill material over the soft cohesive deposits. Due to settlements of the underlying soft compressible layered medium below the embankment prior to the ground improvement, the embankment material has subsided and deposited over the existing subsoil strata [9]. As can be observed from the borehole data below the embankment centerline, the underlying subsoil consists of moderately to highly compressible clayey silt layers with traces of decomposed wood and organic matter overlain by sandy silt fill layer. The average SPT-*N* values range from 2 to 6 until 19 m below the existing ground level (EGL) [10]. Multiple boreholes along the embankment cross-section show that the soil profile is undulating with varying thickness of each soil layer. Figure 2 shows the soil profile at chainage location of 42.2 km. Table 1 shows the subsoil properties [10].

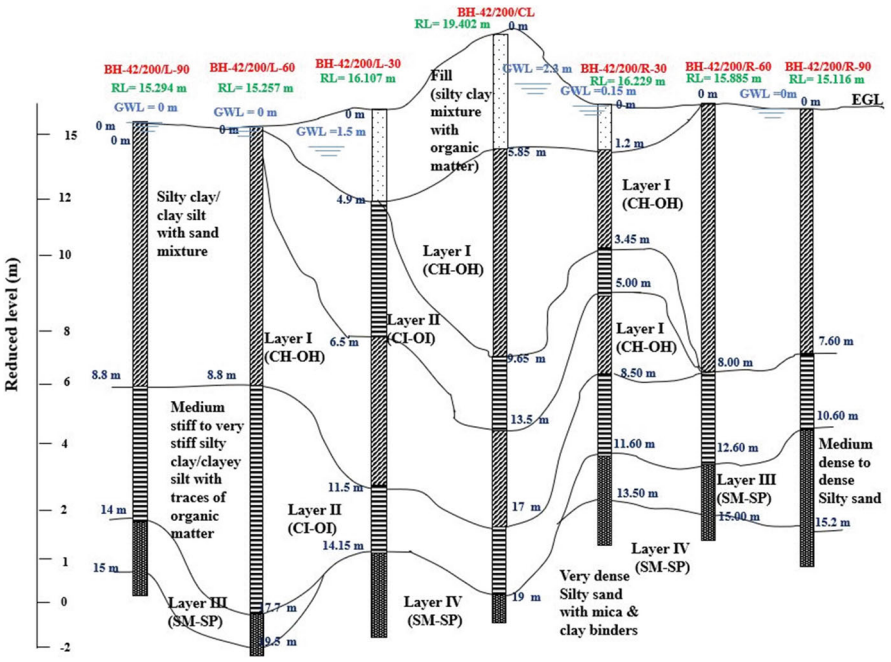

Fig. 2 Borehole stratigraphy showing actual soil profile at 42.2 km chainage of the Udaipur embankment site [10]

2.3 *PVD Installation Beneath the Embankment Constructed by Staged Loading*

PVDs were proposed to be installed up to a depth of 13 m from the EGL, owing to the presence of underlying compressible soft cohesive layers [11]. The PVDs are typically rectangular in shape with cross-section of 100 × 4 mm in size installed to the desired depth at a spacing of 1 m c/c in a triangular pattern. A 300 mm compacted sand mat, acting as a horizontal drainage, is constructed at the ground surface over the PVDs for draining out the pore water collected and transported by the PVDs from underlying layers [11].

Table 2 Stage wise embankment construction plan and assessed degree of consolidation [11]

Stage	Height of embankment (m)	Time for staged construction (days)	Cumulative time (days)	Degree of consolidation (%)
1	0.5	20	20	45
2	1	20	40	70
3	1.5	20	60	84
4	2	20	80	91
5	2.5	20	100	95

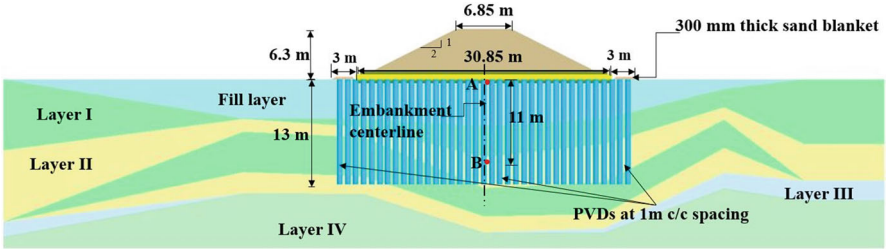

Fig. 3 2D FE model of Udaipur railway embankment supported over PVD-improved subsoil

The embankment was proposed to be built in stages, considering 20 days of time interval during execution of each stage of 0.5 m height. The degree of consolidation during the staged construction is computed through conventional analytical assessments, considering the coefficient of vertical consolidation for the compressible soft soil layer as $C_v = 3.8 \times 10^{-3}$ m^2/day [11]. Table 2 shows the stage-wise embankment construction plan with degree of consolidation achieved after completion of each stage.

3 Finite Element Analysis of Udaipur Railway Embankment Supported upon PVD-Improved Layered Subsoil with Realistic Undulated Stratification

Two-dimensional plane strain finite element (FE) analysis of the Udaipur railway embankment (located at 42.2 km from Agartala) is carried out using PLAXIS 2D v.2018.Typical FE-based model of the PVD-improved subsoil layers and embankment load is presented in Fig. 3. In the present analysis, a medium coarse mesh is selected with an average element size of 0.06 m. For modeling the soil, 15-noded triangular elements are employed, while PVDs are modeled with 1D drain elements inbuilt in PLAXIS 2D. The drain elements act as ideal drains, allowing infinite discharge of the pore water generated in its influence zone of the surrounding soil. The PVDs are assumed to be arranged in triangular pattern with 1 m c/c spacing, implying an equivalent diameter of the influencing surrounding soil around each PVD to be $D_e = 1.05S$ (S = c/c spacing between the PVDs) [4]. The soil layers are

allowed to deform freely at the top of the ground surface when subjected to compressive load from the embankment, while the vertical boundaries are allowed to deform vertically and the bottom boundary is fully restrained from any deformation. During radial consolidation of the subsoil layers takes, the pore-water dissipation from the subsoil takes place through the PVDs and is directed to the top horizontal drainage layer under the embankment (i.e., through the sand blanket).

As mentioned earlier, a suitable constitutive model for soil layers is adopted in the FE analysis; the corresponding model parameters are obtained from bore log reports (Fig. 2) and the corresponding laboratory tests conducted on the collected undisturbed soil samples [10]. Due to unavailability of relevant laboratory/field permeability test data, the vertical permeability coefficients have been adopted based on the type of soil and particle size distribution of the soil layers [12]. Table 3 shows the material models and parameters for the embankment material and each of the subsoil layers considered for the present study. The material properties are obtained from an exhaustive laboratory tests including the index property determination and assessment of shear strength, stiffness, and hydraulic characteristics [10]. The horizontal coefficient of permeability of the soil, subjected to radial consolidation through PVDs, is computed based on Hird's equivalent plane strain permeability compatibility approach [13], as given by the following expression (i.e., Eq. 1):

$$\frac{k_{hp}}{k_h} = \frac{2}{3\left[\ln(n) - \frac{3}{4}\right]} \tag{1}$$

where k_{hp} is the equivalent plane strain permeability neglecting the smear effect, k_h is the axisymmetric horizontal permeability coefficient of the soil surrounding each PVD at the given cross-section neglecting smear effect, and n is the drain spacing ratio (i.e., the ratio of equivalent circular diameter of the influencing surrounding soil to the equivalent circular diameter of band-shaped PVD, i.e., $n = D_e/d_w$).

The installation of PVDs results in smearing of the soft cohesive soil around the PVDs. In the smeared zone, the permeability reduces to magnitudes lesser than the surrounding undisturbed soil. For computing the permeability coefficient in the smear zone (neglecting the well resistance), an equivalent plane strain smear permeability coefficient (k_{sp}) is evaluated from Eq. 2 proposed by Indraratna and Redana [14] The smear zone permeability is considered to be 1/3rd of the horizontal coefficient of permeability of surrounding undisturbed soil (i.e., $k_s = k_h/3$), and the diameter of the smeared zone (d_s) is assumed twice that of the equivalent drain diameter (d_w) (i.e., $s = d_s/d_w = 2$) [4].

$$k_{sp} = \frac{\beta \times k_{hp}}{\frac{k_{hp}}{k_h}\left[\ln(n) + \frac{k_h}{k_s}\ln(s) - 0.75\right] - \alpha} \tag{2}$$

where $\beta = \frac{2(s-1)}{n^2(n-1)}\left[n(n-s-1) + \frac{1}{3}(s^2+s+1)\right]$ and $\alpha = \frac{2}{3}\frac{(n-s)^3}{n^2(n-1)}$.

4 Results and Discussion

4.1 *Effect of Installing Uniform Length PVD in Layered Subsoil Comprising Undulated Stratification*

In line with the conventional practice of FE analysis of embankment resting on PVD-treated soft soil, the underlying subsurface is assumed comprising horizontally stratified layers. Such stratification is either generally based on the information from a single borehole data or based on an equivalent horizontally layered soil profile from multiple borehole data. Consequently, in the process, the influence of the realistic soil profile, which is mostly undulated, is lost, and the accuracy of consolidation prediction is often compromised by ignoring the spatial variability of the soil layers and their properties. In this regard, a benchmark analysis is carried out in PLAXIS 2D considering horizontal subsurface stratification conforming only to the borehole data pertaining to the centerline of the embankment (Borehole 42/200/CL as in Fig. 2). As in the case in Fig. 3, the FE analysis for horizontally stratified substrata is carried out by considering the PVDs installed up to 13 m depth below EGL (Fig. 4). For symmetricity, one-half of the PVD-treated subsoil from the centerline of the embankment is considered in the present analysis.

Through the present FE-based study, a comparative assessment is carried out between the vertical settlement and EPWP evolution during the consolidation of the underlying stratified soil deposits with and without PVDs. As indicated in Figs. 3 and 4, the settlement and EPWP magnitudes for the underlying subsurface soil layers are considered at point A (just below the embankment, at its centerline) and point B

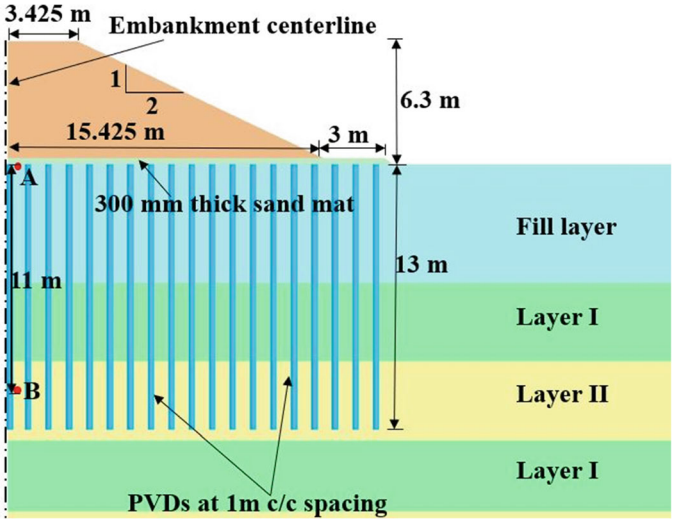

Fig. 4 2D FE model of the Udaipur railway embankment supported over PVD-treated horizontally stratified soil layers

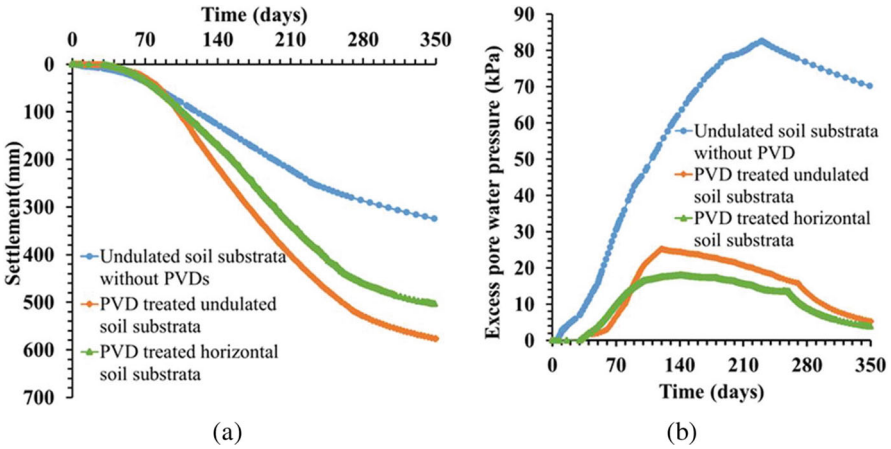

Fig. 5 Effect of PVD installation on consolidation characteristics of soft soil layers with and without considering the presence of undulations in the subsoil profile

(at 11 m depth from the EGL along the embankment centerline), respectively. The rate of settlement is noticeably rapid in case of embankment with PVDs due to creation of an artificial drainage path, leading to the faster dissipation of generated EPWP in the relatively low permeable soil layer (Fig. 5). It can be further noticed that for the case with actual undulating soil profile, a settlement of 577 mm is attained at the end of 350 days (i.e., 250 days after the completion of embankment construction), as compared to 300 mm for the case of unimproved soil (without PVDs). Similarly, for the case with actual undulating soil profile, the developed EPWP for the low permeable soil layers without the PVDs is much higher (peak EPWP of 83 kPa) as compared to that in case with PVD treatment (peak EPWP of 25 kPa). Moreover, the time for attaining peak EPWP is much quicker (i.e., 28% faster) in case of subsoil layers with PVDs compared to the unimproved subsoil case. On the other hand, the vertical settlement and EPWP attained at the end of 350 days is underestimated approximately by 25% when simplified horizontal subsurface layering is considered in contrary to the undulated subsurface profile.

4.2 Sustainable Practice of Ground Improvement Using Nonuniform Length of PVDs for Consolidating Soft Soil Under Udaipur Railway Embankment

The most conventional practice of PVD-treated ground improvement is carried out by installing PVDs of uniform length within the base width of the embankment at a given cross-section. However, the efficacy of PVD-based ground improvement also lies with optimized usage of PVD installation below the embankment (i.e., extending the intermediate PVDs to underlying deeper low permeable strata), governed by the

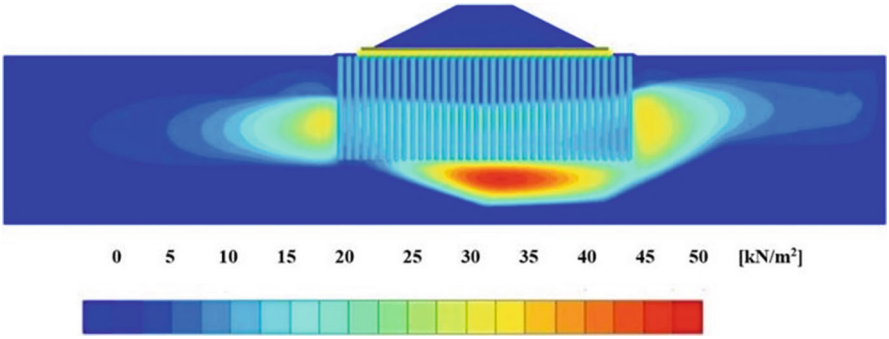

Fig. 6 EPWP accumulation below 13 m depth of PVDs with actual undulated stratified subsoil at the completion of embankment construction in Udaipur railway embankment site

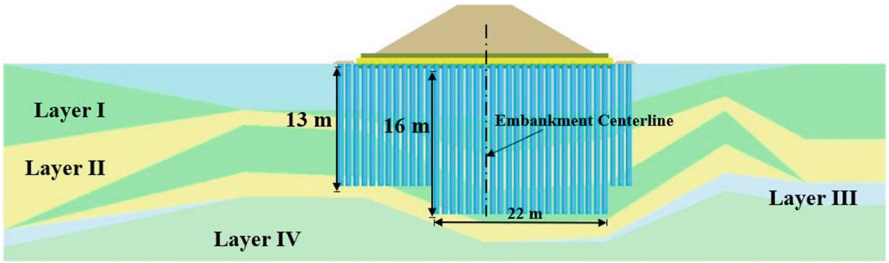

Fig. 7 FE-based model of Udaipur railway embankment considering nonuniform length of PVDs (i.e., a combination of 13 m and 16 m) below the EGL

spatial distribution of the soil layers and nature of subsurface stratification. Figure 6 shows the EPWP distribution at the end of embankment construction. It is evident that substantial magnitude of EPWP (approximately 50 kPa) is accumulated beyond the depth of installation of PVDs (i.e., below 13 m from EGL) This observation is attributed to the basin effect developed due to the undulating Stratum-I below the PVD-treated substrata (as shown in Fig. 3) that acts as an underground reservoir to store the pore water. In this case, it would not dissipate easily as it remains beyond the reach of the PVDs. As a matter of fact, it is noticed from FE analysis that even after allowing a consolidation time up to 350 days, the decrement in EPWP is merely 32%.

Therefore, in order to arrive at a more sustainable solution of ground improvement through PVD treatment, it would be prudent to extend the length of the PVDs deeper into the undulating Layer-I below the embankment. Accordingly, an FE analysis is conducted similar to earlier scenario but extending the PVDs up to 16 m depth within the zone of accumulated EPWP (for a width of 22 m, around the centerline of embankment), as shown in Fig. 7. The length of PVDs in the remaining locations is maintained to 13 m as earlier. Figure 8 shows the comparison of time rate of settlement and evolution of EPWP for the underlying consolidating

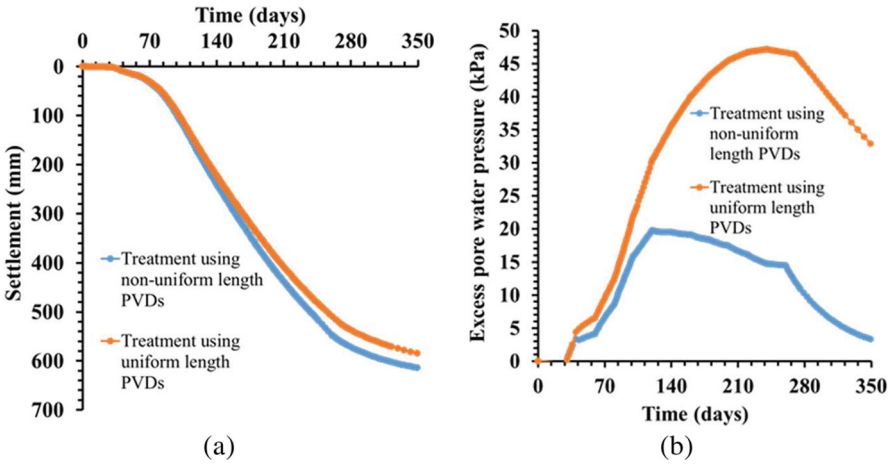

Fig. 8 (**a**) Time rate of settlement and (**b**) EPWP evolution for PVD implemented up to 16 m depth below the embankment near the embankment centerline with that at 13 m depth of PVD

soil deposits (pertaining to the locations A and B, respectively, as indicated in Fig. 3) when nonuniform length of PVDs is used (a combination of 13 m and 16 m lengths) with respect to the uniform length PVDs. It can be observed that although the difference in settlement magnitudes at the end of 350 days is less than 0.05% (Fig. 8a), a substantial difference in peak EPWP generated in both the cases is noted (Fig. 8b). The maximum EPWP generated for the case of treatment with nonuniform PVD lengths is approximately 60% lesser than that observed from uniform length PVDs. It can be observed that much lower EPWP is attained in much quicker time, which is substantiated by a higher time rate of consolidation for the case with nonuniform length PVDs, as reflected in Fig. 9. In comparison to the uniform length PVDs, the rate of consolidation at each stage of embankment construction is observed to be faster, in the range of 34–49%. Figure 10 shows the EPWP distribution for the case with nonuniform length of PVDs considering the undulated soil profile at the end of embankment construction. As can be noticed that, the EPWP dissipation takes place at the designated depth of PVD insertion, with remaining EPWP magnitude within the soil surrounding the PVDs to be lesser than 20 kPa.

5 Conclusion

The present study aims toward a more sustainable solution of ground improvement through PVDs by considering the consolidation behavior of fully saturated and low permeable deposits by incorporating the actual undulated substrata profile and nonuniform length of installed PVDs. Based on the present study, the following inferences can be drawn out of present study:

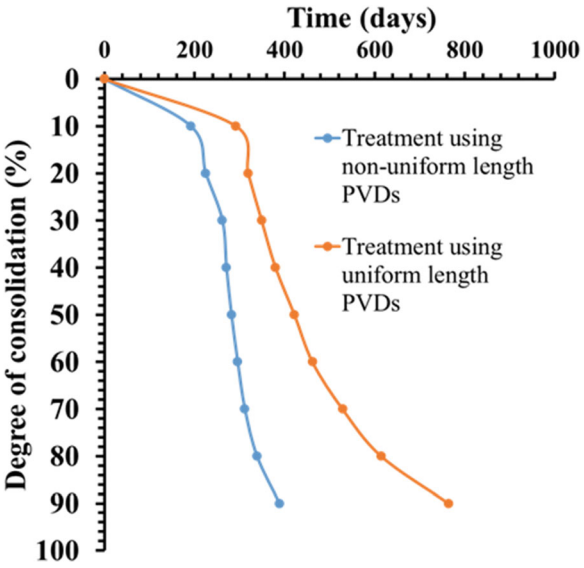

Fig. 9 Time rate of consolidation for PVDs of uniform length (extending to 13 m depth) and nonuniform length (a combination of 13 m and 16 m depth) below the embankment

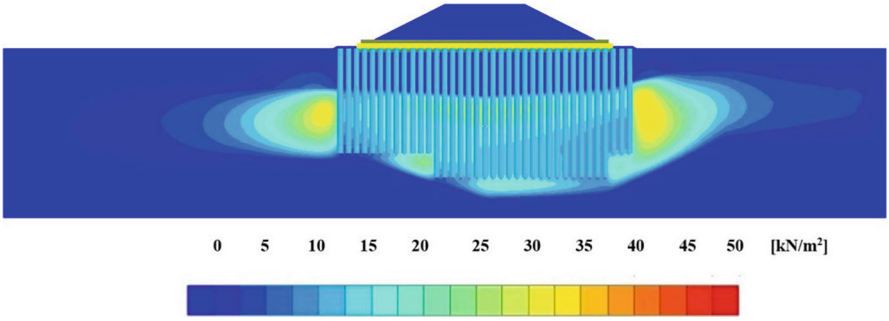

Fig. 10 EPWP distribution at the completion of embankment construction for undulated soil profile treated with nonuniform length PVDs (up to 13 m and 16 m depth below EGL)

1. The rate of settlement of the underlying fill layer below the embankment center is much quicker for PVD-treated soft subsoil layers as compared without PVD treatment. In this study, with PVD treatment, the settlement at the end of 350 days is observed to be 48% higher in comparison to untreated substratum.
2. Application of PVD leads to significant and quick dissipation of pore-water pressure from the deep-seated low-permeable substrata. For the present study, reduction in peak magnitude of EPWP is observed to be more than 50% for the PVD-treated subsoil. Besides, the time of evolution of the peak EPWP is 28% quicker than subsoil without PVDs.

3. It is very important to develop detailed knowledge about the spatially varying soft substrata beneath the embankment as it significantly affects the time rate of consolidation and EPWP evolution. In the present case, the settlement and EPWP is observed to be underestimated by 25% for conventionally adopted horizontally layered subsoil profile in comparison to the undulated substrata profile.
4. Uniform length PVDs might not always be sufficient to reduce the EPWP from deeper strata due to the basin effect of specifically undulated layers as was evident from the present study in which significant EPWP is noticed below PVDs of 13 m depth.
5. In comparison to uniform length, PVDs with nonuniform length (with a hybridization of 13 and 16 m long PVDs) below the embankment leads to a substantial improvement in the time rate of consolidation, nearly 34–49% for the present study.
6. Consideration of the actual and realistic undulating subsurface profile comprising soft soils is immensely important in developing sustainable solutions to long-term ground improvement measures. Conventional practice of considering uniform length PVDs for accelerated consolidation of thick soft undulating deposits might not be effective in specific scenarios. In such cases, extending the PVDs to larger depths would be required, thereby leading to providing nonuniform length of PVDs along the cross-section of the embankment. Such provision can yield more efficient and sustainable practice in improving the consolidation behavior of the soft cohesive soils.

1 Introduction

Co-creation and stakeholder engagement are crucial for shaping corporate competitive strategies and for sustainable transitions. Unlike the market-based view (MBV), the resource-based view (RBV) research reinforces the relevance of co-creation for corporate success [1–3]. Originally, industrial co-creation processes evolved from co-production, where consumer participation was integrated in the supply chain with the aim of cost minimization (e.g., IKEA) [4] in the 1990s. This evolution marked a significant milestone as IKEA launched "Co-Create IKEA" in 2018, establishing a digital platform for customer-driven product development. This initiative was further expanded with the opening of the first Co-create Hub at the IKEA Home of Tomorrow in Szczecin, Poland, in 2020, giving everyone a space to co-create better living futures with IKEA [5]. The effectiveness of co-creation in creating customer-friendly solutions is well supported by empirical evidence, especially within corporate environments. Therefore, empirical evidence of successful co-creation activities

within various EU-funded projects focuses on applied co-creation, i.e., the different steps in a co-creation process [4].

Before delving deeper into co-creation, it is important to highlight that the success of these initiatives lies not only in the mechanisms of collaboration but also in who is involved. The focus shifts from the broad perspective of stakeholder engagement to an important subset, the citizens. In this context, citizen engagement emerged as a separate study in the late 1990s and early 2000s and is in line with the RBV interpretation of the source of competitive advantage. It is considered as a long-term sustainability strategy. Engagement strategies have progressively shifted towards more interactive methodologies, ranging from two-way dialogues to active stakeholder participation, encompassing strategic, normative, moral, or pragmatic approaches [6, 7].

Among these, the moral approach emphasizes the empowerment of less visible stakeholders, advocating for the democratization of science and projects to ensure inclusive participation. Methods for engaging citizens in this manner include representation by public officials, direct involvement of individuals and community members, and advocacy by NGOs, all aimed at fostering a deeper understanding of citizen motivations and values for sustained participation [8]. The significance of citizen engagement becomes more pronounced in the energy transition context, where legitimacy and social acceptance are essential. This narrative is supported by the energy democracy movement and the concept of "energy citizenship," advocating for a more participatory role for citizens beyond mere consumption. Emphasizing the social dimensions of energy systems encourages citizens to become producers, investors, and activists, thereby enriching the dialogue on energy transition and sustainability [9].

1.1 Definitions of Co-creation

Co-creation can refer to diverse practices with the shared goal of engaging the stakeholders from the design or creation stage. Therefore, it involves stakeholder engagement for the creation of a product or value. Co-creation is often defined through two primary lenses: The business literature refers to "value co-creation" as creating a shared value between the business and the customers leading to mutual benefits and the "co-creation in design" as a research and innovation tool involving multiple stakeholders [10]. Similar definitions have been proposed in various contexts and applications. In urban planning and public services, co-creation enhances democratic processes and addresses societal complexities. Successful initiatives stress the need for a clear mission, emphasizing genuine collaboration over treating co-creation as a rhetorical tool to achieve meaningful outcomes [10].

At its core, co-creation involves high levels of citizen participation, in which citizens play a major role in identifying problems, generating solutions, and/or determining policies [11, 12], aligning with the concepts of stakeholders' empowerment. Co-creation may take various forms of participation: "Co-initiation" when

citizens take the initiative, "Co-design" when they participate in the design phase, and "Co-implementation" when they are involved in the implementation phase [13]. J. Eckhardt et al. [14] model this stakeholder involvement in co-creation as an ecosystem of transdisciplinary cooperation that can have organizational and cultural effects across various sectors.

The authors define co-creation, in the context of this chapter, as an approach that tailors the design of products or service concepts to the needs and expectations of customers. By actively involving future users and key stakeholders in interactive workshops, focus group meetings, or other events, co-creation aims to unleash creativity, share ideas, and enhance product development and concepts in an organized process. In summary, regardless of the co-creation application across various disciplines and domains, active citizen engagement emerges as a common thread. Whether in business, urban planning, or public services, the process is dependent upon involving diverse participants from various sectors.

1.2 Research Questions (RQ) and Objectives

To achieve the overarching objectives of speeding up the green transition in a net-zero built environment, the two key research questions will be addressed.

- *RQ1*. What are the experiences and practices in the co-creation and citizen engagement activities, challenges, enablers, and tools applied in selected EU-funded projects and how do they support green transitions?
- *RQ2*. How can identified effective co-creation and engagement processes be structured and organized to expand/replicate from electricity to a sustainable and net-zero built environment?

2 Methodology (Case Studies and Review)

In this research, a qualitative approach is used by combining case studies and a scoping review. In this regard, the chapter employed Intrinsic and Extrinsic Case Studies complemented by a topical literature review focusing on the co-creation, stakeholders, and citizen engagement in the transition towards a Net-Zero Built Environment. In this connection, a tailored EU-funded project (SENDER) is considered for the intrinsic case analysis to understand deeply the evolvement of the co-creation and citizen engagement concepts. The rationale for selecting SENDER is that it focuses on sustainable consumer engagement and demand response.

For extrinsic cases, the chapter considers relevant projects in the green neighbourhood sharing common net-zero objectives. Moreover, co-creation-focused literature review articles on the electricity and net-zero built environment area are considered and discussed to incorporate a broader perspective of the topic and

understand various contexts before generalization and reaching a conclusion. In this regard, the chapter used Google Scholar with a publish or perish database and search review articles published between 2003 and 2023 using keywords: Co-creation, Citizen Engagement, Demand Response, Net-Zero Transition, and Net-Zero Built Environment. Based on the authors' content analysis from 121 articles found in the database, selected papers are used for the result and discussion and to drive a conclusion.

2.1 Overview from the EU-Funded SENDER Project

The project is considered for the intrinsic analysis of co-creation and citizen engagement strategies. SENDER (Sustainable Consumer Engagement and Demand Response) [15] aims to develop and test novel solutions and tools that engage consumers and prosumers in demand–response mechanisms and energy services. SENDER puts household consumers at the heart of the energy market, using behaviour change measures, addressing specific loads, maximizing the use of next-generation energy services, creating a digital "twin" of the consumer, and developing new business models.

SENDER Social Innovation Meta-Level Approach
The SENDER project, along with several previous projects coordinated by Smart Innovation Norway, follows a meta-level multiple helix approach. This represents a way of broadening and opening former relatively closed policy-making processes and innovation systems, thereby making them more democratic. Early innovation systems, such as the "triple helix" based on collaboration between universities, government, and industry [16], have evolved. Later development to this model added a "fourth helix"—civil society—to form a quadruple helix model [17]. Further expansions of the quadruple helix model point out that definitions of democracy must also include sustainable development, not only energy but also other broader perspectives [18]. This has led to the creation of a quintuple helix, including also environmental settings of a specific region. In the context of the SENDER project, the quintuple helix acts as the meta-model for the selection of stakeholders (e.g., Academia, Civil Society, Government, etc.) that provide relevant contributions to the project as shown in Fig. 1.

SENDER's engagement strategy, focusing on consumers, technology providers, and electricity market actors, employs a three-phased approach (see Fig. 2). The initial phase centres on recruitment, disseminating materials, hosting events and workshops, and conducting individual energy counselling and surveys. The second phase focuses on social pressure and gamification to underscore participation benefits and engage citizens in rollout and installation. The third phase targets persistence, establishing an online forum, enrolling beta users, arranging exhibitions and seminars, and showcasing the real impact of the demand response (DR) actions of the citizens [19].

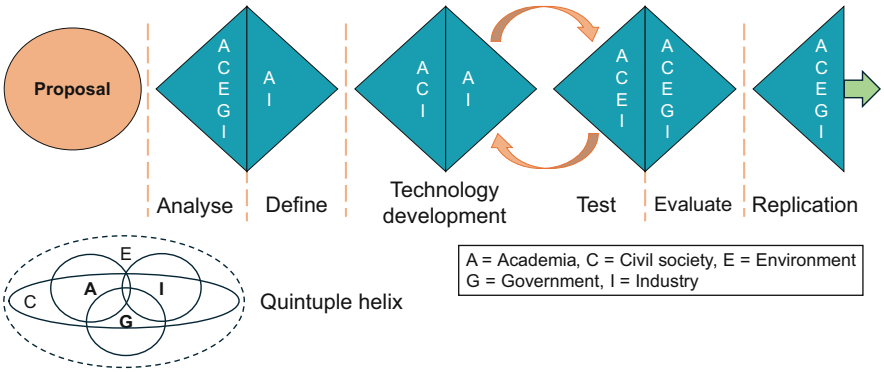

Fig. 1 The quintuple helix innovation model used in the SENDER project

Fig. 2 SENDER consumer engagement phases

2.2 Overview from the EU-Funded HESTIA Project

HESTIA [20] has created an inclusive and participatory strategy for engaging households in the design and development of the HESTIA platform and the proposed DR solutions. Co-creation, as the ongoing involvement of all relevant stakeholders, not just users/householders in the development of the platform, has proven to be a fundamental and challenging task, e.g., to create DR projects with a bottom-up approach. Challenges, like the pandemic restrictions that took place during the first months of the project, brought about the need to rethink the engagement approach (e.g., face-to-face interactions were partly replaced with virtual home tours and online interviews to keep a continuous line of communication with users).

The key lesson learnt is related to the need for keeping project participants in continuous communication with the project partners and engaging them—making them aware of the process and the requirements of their involvement at each stage. Community and collective engagement have proven to be particularly important to participants, rather than just individual engagement of single households. Some of the pilot sites were already established energy communities, such as a Dutch pilot, whereas others, such as an Italian pilot, were in the process of being established.

The HESTIA platform interface, which is co-designed with the users, therefore expresses the input of the community, as households can monitor not only their own energy but also watch the contribution or consumption of their neighbours. Furthermore, the co-creation activities have helped the project partners uncover issues such as the gendering of energy technologies and the unequal distribution of household labour at home between operators of energy technologies and those performing household tasks. Such challenges relating to socio-cultural background, gender, and digital literacy have informed recommendations for the design of DR solutions and community engagement for different household typologies. Examples of these recommendations include the flexibility potential for different households, through the empirical insights of the HESTIA pilots, according to the time householders spend at home, and the recommendations for the coordination of everyday housekeeping with digital housekeeping, which involves the interactions with the energy systems.

2.3 Overview from the EU-Funded ReDREAM Project

ReDREAM's [21] engagement strategy is based on three pillars: first, to provide benefits over time to maintain user engagement throughout the project; second, to offer added value so that benefits obtained are greater than the costs involved; and third, to build a trustful ecosystem. In addition to these pillars, a complementary set of principles guides the design of engagement strategies and the ecosystem: personalization, feasibility, transparency, simplicity, discoverability, and automatization.

Regarding recruitment strategy, ReDREAM defined a threefold approach based on target, messages, and channels. Two strategic recruitment approaches were applied. Initially, a "motivation-to-eligibility" strategy targets users with allegedly mid-to-high levels of motivation and then screens eligible users with electrical assets that can be interrupted for short periods. To recruit these motivated users, messages emphasized the main benefits unearthed in the initial research: potential monetary savings, reduced environmental emissions, community self-sufficiency and resilience, or the anticipated pride in being an early adopter of these services. This approach eventually evolved into an "eligibility-to-motivation strategy," targeting users with the necessary equipment and using messages to demonstrate the value they will glean from participating in the project. To identify these eligible households, ReDREAM proposed five strategies that could be used by demo managers to identify and locate households with the appropriate equipment.

2.4 Overview from the EU-Funded ACCEPT Project

The ACCEPT project [22] is focusing its engagement strategy on awareness-raising campaigns, recruitment—primarily via pilot partners acting as "gatekeepers" to their communities—and planning for engagement activities including workshops, one-to-

one meetings, and presentations. Furthermore, the elaboration of communication material plays a crucial role in ACCEPT's engagement strategy, as it enables the process of building trust between the pilot leaders and the local communities. The recruitment strategy is still being implemented.

2.5 Overview from the EU-Funded iFLEX Project

iFLEX's [23] engagement strategy focuses on the recruitment of end users (residential energy consumers and prosumers) from the three pilot sites that are being deployed in Finland, Slovenia, and Greece, by using personal and direct communications and concise surveys during registration to gather information on devices, energy-awareness, and incentives; offering free equipment installation, prizes, and chances to join iFLEX's environmental and innovation; and creating communication campaigns on the pilot websites and social media.

2.6 Overview from the EU-Funded PROBONO Project

The EU-Funded Horizon 2020 PROBONO project [24] caters to the integration of green buildings in a delimited area or district level to develop energy-positive and zero-carbon Green Building Neighbourhoods (GBNs). The concept of GBNs focuses on several domains related to stakeholder engagement, investments in green energy, green mobility, sustainable built environment, etc. The project also demonstrates co-creation benefits through its living labs serving as pilot sites and first users of the PROBONO's project results. The project focuses on introducing innovations to address technological challenges, enhance energy savings, reduce emissions, and develop sustainable infrastructure meanwhile including citizens as active participants and crucial stakeholders in the co-creation of the sustainable GBNs. The PROBONO project aims to deliver five GBN Transition Acceleration Enablers of which Enabler 2: Social Engagement and Innovation Clusters [24] facilitates the engagement of citizens and stakeholders in the GBN initiatives utilizing different tools like workshops, interviews, and site visits.

2.7 Lessons Learned from EU-Funded Projects

In conclusion and answering RQ1, the engagement strategies of the European projects reflect a commitment to inclusivity and participatory methods in end user recruitment. External challenges, such as the pandemic, prompted innovative adaptations, showcasing the projects' resilience. The emphasis on community engagement, as seen in HESTIA, underscores the importance of a bottom-up approach.

SENDER's phased strategy, ReDREAM's pillars, and ACCEPT's focus on awareness and trust-building highlight the multifaceted nature of engagement. iFLEX's personalized communication and incentives demonstrate a tailored approach to end user recruitment. Collectively, these projects offer valuable insights into effective approaches for engaging end users, emphasizing adaptability, personalization, and community collaboration as key components of successful recruitment strategies that support a bottom-up approach towards a green transition.

Drawing from the lessons learned and to provide valuable insights to projects currently implementing or considering engagement strategies, the following recommendations [19] are derived:

1. *Diverse engagement strategies*: Employ a range of strategies for tailored and impactful user engagement.
2. *Phased implementation*: Organize engagement strategies into distinct phases for enhanced efficacy and adaptability, aligning with the timeline of engagement.
3. *Keyword utilization*: Incorporate targeted keywords and focus on specific daily life aspects to facilitate personalization and adaptability
4. *Adaptability in crisis*: Be prepared to adapt strategies during challenges, maintaining flexibility for continued effectiveness, particularly in the face of unforeseen circumstances like the COVID-19 pandemic.
5. *Motivation and eligibility*: Craft engaging recruitment materials recognizing the vital role of motivation and eligibility criteria.
6. *Continuous assessment*: Navigate diverse contexts through continuous assessment, ensuring alignment with community needs and infrastructural support.
7. *Sustained collaboration*: Foster collaboration and knowledge sharing among project partners, leveraging shared on-field experiences for enhanced effectiveness.
8. *Overcoming barriers*: Proactively address encountered barriers and provide strategies for effective user involvement in DR initiatives.

These recommendations serve as a guide for project developers and decision-makers, offering valuable insights to enhance citizen engagement in the evolving landscape of energy transition projects. The following discussion serves to analyse the transferability of the recommendations from the energy domain to the net-zero built environment.

3 Discussion of Co-creation in Net-Zero Built Environment

While the idea of co-creation has been explored in various fields, its systematic consideration within the built environment is still in its infancy [25]. The limited number of publications on co-creation projects in this domain outlines applications with a small number of involved stakeholder groups. Co-creation is presented as a tool for collaboration between researchers and industry players during the innovation

development process [26], as an approach to creating built environment knowledge for sustainable development [27], and as an approach to service concept design and architectural practice [28].

The noted underrepresentation of co-creation in the construction and buildings industry, as well as the limited number of involved stakeholder groups discovered in research publications, indicates a potential area for further exploration and implementation. Therefore, the following paragraphs serve to outline how the transfer of experiences from various EU-funded, energy-related projects can serve to develop a more holistic co-creation approach for projects in the building industry.

Net-zero buildings are structures that offset their consumed energy, creating a self-sustaining system. They embody a holistic approach to sustainability, integrating high-efficiency appliances, HVAC systems, and building insulation, along with renewable energy systems [29]. These initiatives aim to minimize the carbon footprint of the building, both during use and the embodied emissions of building materials.

To achieve a net-zero built environment, strategies can be categorized into efficiency (optimizing energy demand and using highly efficient appliances), consistency (utilizing renewable energy and sustainable materials), and sufficiency (reducing living space and heating/cooling needs) [30]. This categorization reveals an overlap in the objectives and methods of energy-related projects and net-zero efforts.

Both energy-related projects and net-zero efforts rely on stakeholder engagement, particularly with citizens as the main end users. Many net-zero initiatives in Europe focus on retrofitting existing buildings. Like DR projects, these initiatives aim to incentivize citizens to optimize their consumption, use smart and efficient appliances, and indirectly enhance the grid's capacity to accommodate more renewable energy.

3.1 Proposed Framework for Replicable Co-creation

With respect to RQ2, it is relevant to outline how identified effective co-creation and engagement processes from selected EU-funded projects can be structured and organized to expand/replicate from electricity to sustainable and net-zero built environments. From an overarching point of view, the proposed phased implementation of co-creation activities serves also in net-zero environments to structure engagement strategies and to enhance their efficacy and adaptability.

Recruitment Phase Due to the very high stakeholder variety in net-zero initiatives, the number of involved stakeholders is much higher compared to EU-funded DR projects. The utilization of a City Portrait Canvas is proposed to foster big-picture thinking on how a particular city strategy may impact the world—both socially and ecologically, locally and globally, and how to shape approaches to reducing both sector-based and consumption-based emissions, as well as to climate change

adaptation [31]. Therefore, the requirement to diverse engagement strategies applies to a much higher degree in net-zero initiatives. The employment of a range of strategies for tailored and impactful user engagement requires the crafting of engaging recruitment materials, recognizing the central role of motivation and eligibility criteria, which must be based on a highly detailed stakeholder analysis.

Consumer Response Phase In line with the definition of stakeholder-specific motivation and eligibility criteria, targeted keywords that focus on specific daily life aspects must also be used in net-zero ecosystems to facilitate personalization and adaptability. Furthermore, a sustained collaboration and knowledge-sharing culture among project partners will serve to leverage on-field experiences for enhanced effectiveness. This counts especially for realized barriers during the consumer response phase in net-zero implementations. The project duration of EU-funded electricity projects is usually limited to 3–4 years and an exploitation phase of up to 5 years. The impact of net-zero building implementations will last for generations and, therefore, it is of utmost importance to identify barriers and challenges experienced by consumers during the response phase and to immediately apply corrective actions. This is also fostered by the fact that in contrast to EU DR projects, where implementations strive for a technological readiness level (TRL) of 7–8 out of a scale of 10, net-zero building implementations rely on market-ready technology solutions. Therefore, it will be difficult to re-assess and adapt technologies once they are implemented.

Persistence Phase Finally, also co-creation activities in net-zero built environment approaches must provide fall-back solutions to provide adaptability in crisis, maintaining flexibility for continued effectiveness, particularly in the face of unforeseen circumstances like the COVID-19 pandemic, supply shortages for tech components and appliances and primary energy resources [32]. Especially, the latter aspect is of utmost importance as regulatory and political impacts on net-zero built environments must not be under-evaluated. Due to the long-term characteristics of net-zero building implementations, it is inevitable to model and forecast mid- and long-term regulatory and political objectives, e.g., in terms of national or European energy supply strategies. This serves to create future proof solutions that do not require major adjustments over time. Also, in the context of the SENDER and other EU DR projects, this should be based on continuous assessments during the persistence phase to simulate and navigate diverse contexts, ensuring net-zero approaches alignment with community needs and infrastructural support.

A co-creation framework that includes the three identified phases, quintuple helix, and guiding recommendations towards the net-zero built environment transition is presented in Fig. 3.

Based on the guiding recommendations, the co-creation steering committee manages a co-creation space that consists of various co-creation clusters. These clusters' work is supported by social science and ecological and environmental analysis, partly provided by external partners. The processing of internal and external knowledge is organized according to the three-phased co-creation approach

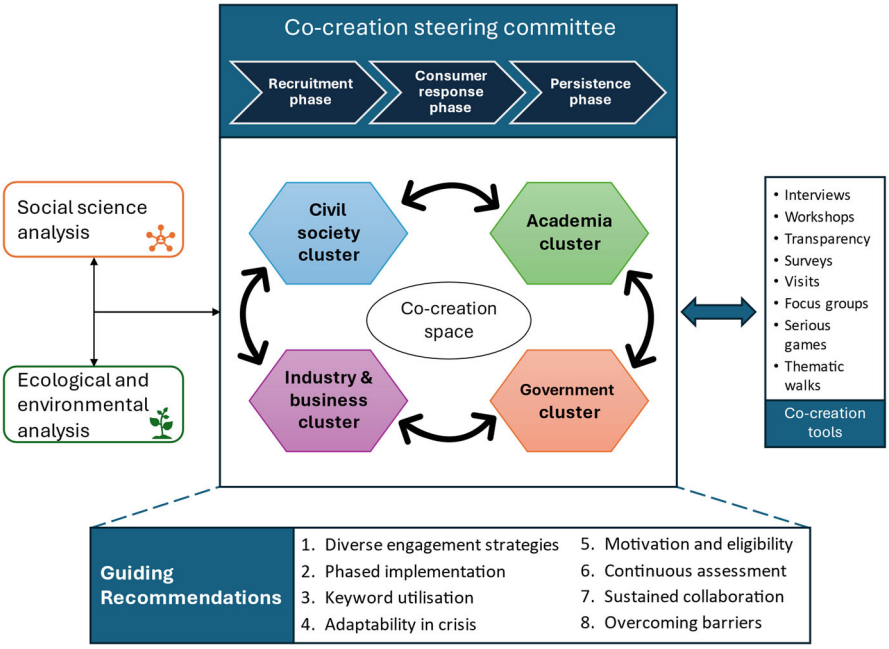

Fig. 3 Proposed framework for co-creation in net-zero built environment initiatives

and will provide jointly agreed solutions, reflecting the democracy aspect of co-creation.

The limitation of the study is the lack of concrete indicators and metrices as most of the social and behavioural science studies involve people and are based on human factors. There are efforts in some of the projects, such as PROBONO, on identifying some measurable indicators. However, they need to be validated and tested in more similar cases, especially within the net-zero built environment.

4 Conclusion

In conclusion, this chapter outlined, according to RQ1, experiences and practices in co-creation and citizen engagement activities, challenges, enablers, and tools applied in selected EU-funded projects. Green transition is supported by active citizen participation and motivation for green transitions.

In addition, referring to RQ2, the co-creation guidelines developed within EU DR projects can be expanded to and replicated in a net-zero building environment in a three-phased approach. Nevertheless, compared to EU DR projects, net-zero building implementations are characterized by a much longer impact period, an overly

complex stakeholder variety, and the risk of political and regulatory changes over time.

Therefore, the authors propose to adjust the structured three-phase approach for consumer engagement and co-creation to the net-zero building ecosystems. Their complexity requires the integration of highly detailed expertise from different knowledge domains. An approach defining required knowledge clusters and applying appropriate co-creation techniques is suggested. Co-created recommendations of the various clusters should then be bundled and provided to a co-creation steering committee comprising strategic net-zero building initiative decision-makers. This approach will serve to facilitate democratic decisions based on integrating expertise from all relevant knowledge domains of the net-zero building ecosystem.

Future research should implement, document, and analyse co-creation approaches in the net-zero build environment. This field research approach might create insights for a building industry-specific adjustment of the proposed, three-phased approach.

1 Introduction

The International Energy Agency (IEA) Net Zero Emissions by 2030, which is a normative scenario showing a pathway for the world's energy industry to achieve net-zero CO_2 emissions by the year of 2050, meets the United Nation's Sustainable Development Goals (SDGs) [1]. According to the IEA, by 2021, of the total 830 GW wind capacity installed in the world, only 7% were offshore wind farms, while 93% were located onshore [2]. While onshore wind is a developed technology with a location in 115 countries, offshore wind is at a relatively early expansion stage with 19 countries currently having such systems. Offshore presence is however expected to increase in the upcoming years as more and more countries are in the developing stages of their first offshore wind farms. Windmills, used for grinding grain and pumping water, have a long history dating back to seventh-century Persia (Iran) [3]. However, generating electricity with wind is a much newer development. Large-scale wind turbines for electricity generation only emerged in the 1930s, primarily in

Europe and the USA. There are several benefits of offshore wind power compared to onshore wind power. Firstly, offshore wind turbines can generate more electricity due to higher wind speeds and less turbulence over water. Secondly, offshore wind farms can be located closer to population centers, reducing transmission costs, and improving energy security. Thirdly, offshore wind turbines have less visual impact on the landscape and can be placed in deeper waters where they are less likely to interfere with shipping lanes or fishing grounds. The FOWT farms can create jobs in coastal communities and act as a reliable source of clean energy while minimizing environmental impacts.

Life Cycle Assessment (LCA) is a quintessential tool to assess the environmental impacts associated with all stages of a product's life cycle and helps to improve sustainability (see Curran [4]). Yildiz et al. [5] performed LCA of a Barge-Type Floating Wind Turbine and Comparison with Other Types of Wind Turbines. The authors made an environmental comparison of three scenarios of a 2 MW wind energy system—onshore, offshore floating, and jacket offshore wind (OW) turbines. The study revealed that the greatest environmental impact corresponds to the manufacturing stage of the system components steel and concrete emissions, and total GHG emissions stated in GWP for the offshore floating concept was 18.6 g CO_2-eq./kWh, the onshore concept had 7.09 g CO_2-eq./kWh, and the jacket offshore concept had 9.49 g CO_2-eq./kWh. Authors from the leading French OW development firm Ideol SA (now BW Ideol, Japanese) studied an offshore unit involving square ring floater. They have recommended that the construction could either be a steel-concrete combination or could be made purely of steel [6]. Calculated results were 3376 and 1468 tons (tot/8250 T = 0.409 t CO_2/T and 0.177 t CO_2/T) of CO_2 emissions for the concrete concept, and 7018 and 2420 tons (3.19 T and 1.1 T CO_2/T) of CO_2 emission for the steel concept—with new and recycled materials, respectively. The study found that concrete hulls are heavier but offer better stability, while steel hulls are lighter but require more maintenance, and that a steel hull's carbon content is twice as large as a concrete hull. The comparative study of concrete and steel substructures for FOWT was reported in DNV's project study [7] to investigate the possibility of establishing an industrial plant to produce concrete structures for the offshore wind industry. The objective of the study was the comparison of two offshore floating concepts made in steel or concrete, and results indicate the concrete concept has both lower financial costs and carbon emissions compared to steel. The study concludes that Norwegian firms are capable to deliver concrete concepts target of 67 units per year, while the steel industry is not capable of the same. Calculated results show that the carbon emission of concrete is 2.5–3 times lower than those of steel; even with even a 70% recycled steel used in the Chinese plants, concrete remains the more favorable. For the Norwegian National Framework for Wind power, the NVE performed a study on wind power emissions [8]. Their report provides an insight into LCA of wind turbines mounted on Norwegian land and compared wind power to other sources of energy. The report concluded with the fact that the leading environmental impact of these turbine systems came from the production of concrete for the foundation and transport of wind farm components. GWP values stated in the framework were that wind power has a GWP of 3–46 g

CO_2/kWh compared to gas- and coal energy sources with 500 and 1000 g CO_2/kWh, respectively. The life-cycle energy and environmental emissions of a typical offshore wind farm in China is reported by Yang et al. [9] where the authors have presented the emission from China's first offshore wind power farm. They performed an LCA study in which Life Cycle Inventory (LCI) assessment is reported to list the system components based on GHG emissions and reported a GWP emissions of 25.5 g CO_2-eq/kWh over the lifetime.

On March 29th, 2023, the Office of the Prime Minister, and OED—the Ministry of Petroleum, announced the first public tender for offshore wind projects in two areas of the North Sea—Utsira Nord and Sørlige Nordsjø II. The aim is to increase renewable energy production and reduce GHG emissions, a big step toward Norway's aim of 30 GW offshore wind by 2040. The government will propose a proposition to Parliament with a proposal for a cost framework and commitment authorization. The projects that receive support are awarded support for 500 MW each but can build up to 750 MW, while the project that does not receive state funding retains the right to the area and may use the public support system and participate in future competitions.

In the OW industry, both steel and concrete are critical, and while the sector has a low environmental impact compared to traditional fossil fuel energy sources [10], there are still carbon emissions to consider. The manufacturing process of the OW turbine structure requires significant amounts of energy and resources, including steel, concrete, surface treatment chemicals and the transportation to site. The extraction and processing of building materials and chemicals can result in GHG emissions. Transportation of the structures to the installation site also requires large vessels with emissions. The objective of this work is therefore to assess the carbon emission effects on the environment, comparing a hull made of steel vs. concrete, with the aim of filling the knowledge gap in LCA studies and raising carbon footprint awareness.

An industrial case scenario was used to conduct an LCA study, project layout projected (see Fig. 1), of the following: Case study scenario 1: steel hull, installed in Singapore, then shipped to Hanøytangen, Norway—Chinese steel origin (see Fig. 2a, b). Partial goal: determine EN-15804- and NORSOK-compliant surface coating system. Case study scenario 2: concrete hull, produced, installed, in periphery of Hanøytangen, Norway—Norwegian concrete origin (see Fig. 2c). Before gaining interest in this research study, a relevancy analysis was performed to use an industry specific case scenario applicable to the LCA study (see Fig. 1). An approach was made to map engineering consultancy firms in the offshore structural field, and a finalized reach out was done to SEVAN SSP—with whom a correspondence resulted in the study task, and the following project data and system description (see Table 1).

The article is organized as follows. A brief methodology is described in Sect. 2, with the subsection of steel surface coating, followed by Sect. 3 of results and discussions, with the subsection of a result sensitivity analysis. Finally, conclusions are drawn in Sect. 4.

Fig. 1 SEVAN SSP SWACH™ wind

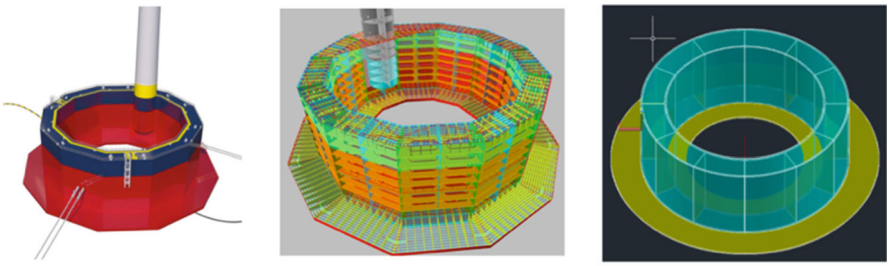

Fig. 2 SEVAN SSP-engineered FOWT concepts - a, b are steel, and c is concrete

Table 1 Project system description

Functional unit	Value	Description
Lifetime	50 years	The average technical lifetime of whole wind farm
No. of platform units	30	Study consists of 30 in steel versus 30 in concrete
Freight distance, SIN-OSL	10,000 nm	10,000 nautical miles equals 18,520 km
Freight distance, HAN-UTS	50 nm	50 nautical miles from Hanøytangen to Utsira

2 Methodology

In this section, we present the methodology for calculating CO_{2e}/T for steel vs. concrete FOWT units. It outlines the LCA analysis using chosen software and breaks down the steps of the study to find CO_{2e}/T, a material data assessment for

Fig. 3 Study-specific process flow chart

30 units steel vs. concrete, and GWP calculation in CO_{2e}/T. A flow chart (see Fig. 3) outlines the process. Iterations ensured compatibility with the SEVAN SSP case study.

As sustainability, climate change, and circular economy practices become more prevalent in the Engineering, Procurement, Construction and Installation (EPCI) industry, the demand for a time and cost-efficient method continues to grow. LCAs can be complex calculations, but there are digital tools and databases available to make the process easier. Ecoinvent is an online database that provides comprehensive information on the environmental impact of various products and services and contains data on the entire life cycle of a product, from raw material extraction to disposal. For this study the database search tool used was Ecoinvent's section for EN15804-compatible allocation and cut-off—since the system gives LCI describing waste and resource categories, excluding excessive by-products.

With so many LCA-software options on the market, it is important to determine a suitable one for our assessment. Tools considered were Ecochain Mobius, Ecochain Helix, GaBI, OneClickLCA, openLCA, and SimaPro, based on a selection criterion of having free trials, BIM compatibility, being web-based, while having a user-friendly Interface (UI). The appropriate software for this study was OneClickLCA, justified by the fact it has free online courses, help center with common FAQ, open-source learning material (YouTube, Vimeo), BIM-compatibility (IFC-file readability), and discounted academic and trial licenses.

OneClickLCA sources its data from a selection of sources, and they can be generic or product-specific if a producer has uploaded an Environmental Product Declaration (EPD) available for each country's EPD Program Operator and publisher. To shortly describe the software tool use process, a Life Cycle Inventory Assessment (LCIA) was done based on case study project specifications. Concrete concept hull design weighs 20,500 tons, of which 2000 tons are steel reinforcement bars—rebar/concrete ratio subject to confidential research. The 18,500 tons of concrete (high-strength C60/C70-grade NORSOK-compliant with 10900PSI compressive strength) was given A2 mode transport distance from producer to storage of 70 kilometers onboard a 40-ton trucks with EURO-6 engine with 100% capacity. Subsequently, A4 shows 26 kilometers transport distance from storage to project site.

2.1 Coating System

A partial objective is to determine an EN15804- and NORSOK M-501-system1-compliant surface treatment system for the steel hull. Method is to manually

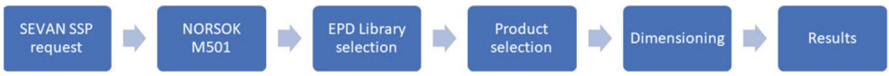

Fig. 4 Coating system selection process chart

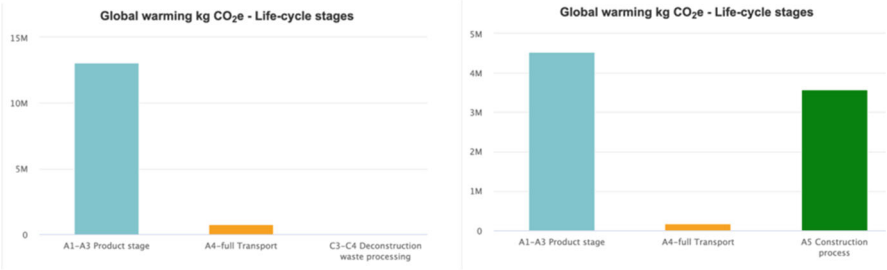
determine the case study needs (see Fig. 4), of a specific product and its feasible availability, GWP given in CO_{2e} per Ton, and total GWP for the 30-unit steel case scenario.

The NORSOK M-501 system 1 [11] is the requirement for the selection of a compliant coating system given by communication with engineers from SEVAN SSP—selected from the range of choice spanning from system no. 1 to system no. 9.

Selection criteria determined coating system no. 1, and to continue the determination of a product-specific EPD compliant with the PCR rules of EN15804, GWP stated in CO_{2e}, and a factory proximity to East-Asian Sea ports, a survey of available coating systems on the EPD Norway library was done. This resulted in the elimination of brands and factory locations from Norway, Germany, India and resulted in Jotun Jotamastic 70, Zhangjiagang, China, with EPD number: 1599-624-EN. The basis of the choice of the given factory location roots in the fact that there is a seaport proximity, for the easiness of shipping to the Singapore installation site.



Results found in the EPD [11] with a EN15804-product stage system boundary A1-A3, *cradle-to-gate*, consist of A1: raw materials extraction, production, packaging, then A2: transport of raw materials and packaging, and finally A3: product stage: preassembly, pigments mixing dispersion, quality control, filling, and labeling. The calculations necessary to find GWP is based on; the EPD data of 3.19 kg CO_{2e} per kg paint, film thickness range 7.7–3.1 m^2/l, density (ρ) of 1.6 kg/l, with a project specific steel hull surface Area = 30,430 m^2, resulting in total masses of 6323.12 kg and 15705.81 kg paint, simply using $m = \rho/V$ for both film thicknesses.

3 Results and Discussions

Steel concept LCA study resulted in having the environmental impact parameter GWP of 13,821.257 T CO_{2e}/T, for the 5000-ton steel concept which is equivalent to the study selected unit of 2.76 T CO_{2e}/T (see Fig. 5a).

As for the NORSOK-compliant Jotun Jotamastic 70, the results are calculated to: Total GWP for spread rate 1 with 7.7 m^2/l = 30 × 6323.12 kg × 3.19 kg CO_{2e}/kg = 6051 T CO_{2e} Total GWP for spread rate 2 with 3.1 m^2/l = 30 × 15,705.81 kg × 3.19 kg CO_{2e}/kg = 1503.1 T CO_{2e}. The steel concept surface coating system necessary for 30 units has GWP ranging from 605.1 T to 1503.1 T CO_{2e}/T.

The concrete concept gives a GWP of 8298.743 T CO_{2e}, for the 20,500-ton concrete structure of which 2000 tons are reinforcement bars which is equivalent to the study selected unit of 0.404 T CO_{2e}/T (see Fig. 5b).

(a) LCA Results Steel units. (b) LCA Results Concrete units.

Fig. 5 (**a**, **b**) LCA results

Note that this is per system boundary of A1-A3. Installation, operation, maintenance stage is not defined in this case. The steel concept GWP per ton is 6–7 times higher, but that is only per weight. The project concept states 30 units, of which each concrete hull has 20,500 T while the steel concept only has 5000 T—equaling a 1/4 steel vs. concrete hull weight ratio which makes the steel concept only 1.77-times higher than concrete—equaling 70% worse than the concrete in total project mass.

Few LCA studies are performed on FOWT structures involving steel or concrete—results from this study are therefore relevant as supplementary scientific material. In relation to the aforementioned literature studies, the GWP calculation of this study with 0.404 T CO_{2e}/T for concrete and 2.76 T CO_{2e}/T for the steel concept falls within Choisnet et al.'s published article where the impacts amounted in 1.1–3.19 T CO_{2e}/T for steel and 0.177–0.41 for concrete. Simultaneously the NVE National Framework concluded with the fact that concrete production has a significant environmental impact, which confirms the graph from this study's result section where stage A1-A3 is shown in the results (see Fig. 5a, b).

Regarding the selection of the 10,900-PSI C60/C70 grade high-density concrete selected in OneClickLCA for the study, an estimated 10% recycled additive percentage was a composition of the cement used in the concrete mix—typical additives being hydraulic binders, such as fly ash, fume, and slag—all by-products from industrial processes. In case of a change in percentage of the reuse, a potential carbon emission reduction can occur. Typically, these additives also have their own GWP, not stated transparently although they are sources of CO_2 emissions.

Regarding the surface coating, read on page 8 of the source [11], the electricity mix in China is stated with a GHG of 1194.03 g CO_{2ekv}/kWh, by Ecoinvent. In China the GHG emissions from electricity is presumably higher than electricity mixes in Norway where 98% of energy sources are from renewable sources, while we in China have traditional fossil sources such as coal, heavy fuel, etc. An alternative solution is to treat the surface at dock in Hanøytangen. Note that this alternative must consider labor cost changes and shipping distance recalculations.

3.1 Sensitivity Analysis of the LCA Results

As the steel reinforcing bars of the concrete hull are a matter of early-stage research, even stated by DNV as a 2023-Q1-starting industrial collaborative research project, an awareness disclaimer must be made to the reader that the 9% steel content was used for calculation simplicity while DNV uses 2% [12]. As 8% of total emission in the steel concept LCA calculations represents the steel reinforcement bars, this is a source of emission which could possibly affect the total GWP if a higher recycling rate is used in its production.

As steel is the main material used to manufacture the 30-unit hulls, the upstream process is highly determinant of the total emission stated in the results. Even a low change in the steel recycling grade percentage during production in China could be significant to total emissions.

4 Conclusions

In today's world, amidst growing environmental concerns and resource scarcity, sustainability in engineering and energy efficiency has become more paramount than ever before. With the increasing demand for energy and the depletion of natural resources, it is crucial that we find ways to reduce our carbon footprint and preserve the environment for future generations.

Wind power is one of the most promising sources of renewable energy, and it has the potential to provide clean, reliable power and a significant portion of our global energy needs. Wind power is also a promising step toward reaching the UN SDGs, including SDG 7: Affordable and Clean Energy, SDG 9: Industry, Innovation and Infrastructure, and SDG 12: Responsible Consumption and Production. By investing in sustainable engineering practices and embracing energy efficiency, we can create a brighter future for ourselves and our planet. We have the power to make a difference, and by working together toward a common goal, we can create a world that is cleaner, healthier, and more sustainable for all.

An LCA study has been a great hands-on approach to achieving and comprehending the actual carbon footprint when choosing between concept 1 (steel) and concept 2 (concrete). This study has allowed us to compare the environmental impacts of the two materials over their life cycle, from the extraction of raw materials to the manufacturing, transportation, and installation, of the FOWT structures.

An environmental approach to industrial decision-making can make a difference and help the energy sector reach the targets of the UN SDGs. By considering the environmental impacts of our choices, we can select materials and processes that minimize our impact on the planet.

This work aims to share the knowledge gained during this research, hoping it proves beneficial for readers from both academic and industrial backgrounds. The aim was to make it comprehensible for the reader, by formulating it apprehensible without the reader being required to possess significant knowledge on LCA as a scientific field. As a conclusion, LCA studies can be a valuable tool for identifying opportunities to reduce the carbon footprint of FOWT structures.

4.1 Limitations and Future Work

As a disclaimer, it must be noted that challenges of the study were mainly limitations of material database availability and data variations on the A1-A3 analysis specter.

- Lack of sufficient EPD's from steel and concrete plant material databases.
- Limited data availability from the actual steel plants in China other than the single source used in this project in OneClickLCA.
- Average travel speed variations: shipping vessel carrying the two steel structures.
- Emission reduction of the steel industry will further reduce the GWP of FOWT farms. In the future, more data needs to be collected to improve LCA reliability.
- According to the NVE, in southern parts of China, the raw material stage's mining processes has affected loss of ecosystems and biodiversity [8].
- Jotun Jotamastic 70: the product service life is highly dependent on the use conditions; the GWP was calculated for a one-time application, and it depends on whether it needs reapplication or maintenance within the 50-year lifespan.

4.2 Declaration of Interests

As transparency in research is important, the signatory author has performed a review process of a number of questions on matter of interest conflicts— from a financial, professional, and personal point of view. Ethical approval is not applicable for this theoretical study, and no monetary funding or endowment was involved. The author hereby declares that there are no known interests or personal relationships that have occurred to in any way influence the angle, methodology, or results of this study.

Acknowledgments This work is an extraction of the bachelor thesis of the first author, and we would hereby like to thank SEVAN SSP—whom we must acknowledge for entrusting us with the case-specific project-specifications and industry-relevant knowledge.

1 Introduction

Offshore wind farms initially had higher costs and lower reliability than did onshore wind farms, making the offshore wind industry less attractive with limited industrial support. Due to these issues, it was expected that offshore wind farms would not be financially viable until 2020. However, by the early 2000s, events such as the European Union (EU)'s acceptance of the Kyoto Protocol, energy security concerns, and economic crises had shifted public attitudes. This led to an increase in political and societal support for European offshore wind farms [1].

While offshore wind power is known for being environmentally friendly during operation, it actually produces emissions throughout its life cycle. This includes manufacturing, installation, transportation, maintenance, and decommissioning [2]. The study of the life cycle can be approached from various perspectives, such as economic and environmental considerations [3]. The environmental impact and energy efficiency of offshore wind technology can be analyzed using a variety of

accessible wind turbine models, with life cycle assessment (LCA) being the most common assessment approach [2]. The information gained from these analyses can be used for a more accurate economic viability assessment, such as the levelized cost of energy (LCOE).

2 The Life Cycle Assessment Concept in Offshore Wind Energy

2.1 General

Life cycle assessment (LCA) has versatile applications and can be helpful in a variety of ways, including [4]:

- Identifying strategies to enhance the environmental performance of products throughout their entire life cycle
- Informing decision-makers in the industry, government, or other sectors
- Choosing appropriate environmental performance indicators and assessment methods
- Supporting marketing efforts

A product's life cycle consists of five phases: extraction, manufacturing, distribution, usage, and end of life. The assessment approach is typically applied from cradle to grave but can also be utilized from cradle to gate, gate to gate, cradle to customer, gate to grave, or cradle to cradle. The cradle-to-grave approach is defined as a full LCA, starting from resource extraction (cradle), through the use phase, and ultimately to the disposal phase (grave) [4].

2.2 The LCA Framework

According to International Organization for Standardization (ISO) 14040 and ISO 40444, the LCA framework comprises four phases [5]:

1. Goal and scope definition
2. The life cycle inventory (LCI) analysis phase
3. The life cycle impact Assessment (LCIA) phase
4. Interpretation

Goal and Scope Definition The first stage of an LCA is defining the goals and scope, which is considered the most important phase because it establishes the research context, sets requirements for the modeling that will be performed, and plans the project [6].

The goals of this study are defined as follows:

- Filling the gap in the literature as there are few comprehensive LCAs of offshore wind farms. This can help developers and scholars track their progress toward sustainability goals and identify areas for improvement.
- Comparison with other renewable energies
- Public education
- Life cycle optimization
- Data collection and methodology improvement for further research

Moreover, design practitioners must identify four key activities throughout the goal and scope definition stage: (1) defining a functional unit, (2) establishing a clear system boundary, (3) selecting the environmental impact types, and (4) determining the level of complexity and data required for the study. The functional unit acts as a point of reference for the inputs and outputs of the product under investigation [4].

For an LCA, a logical functional unit could be the amount of energy produced. In this study, the functional unit is 1 MWh of electricity produced and sent to the grid through the wind farm's substation. In this step, the system boundary is determined. The system boundaries specify what is included and omitted from the evaluation. Small amounts of substances may be excluded from the analysis due to their minimal impact on the overall footprint. Figure 1 illustrates the defined system boundaries in this study.

Life Cycle Inventory Analysis The second stage of LCA is Life cycle inventory analysis, as stated in ISO 14040 [5]:

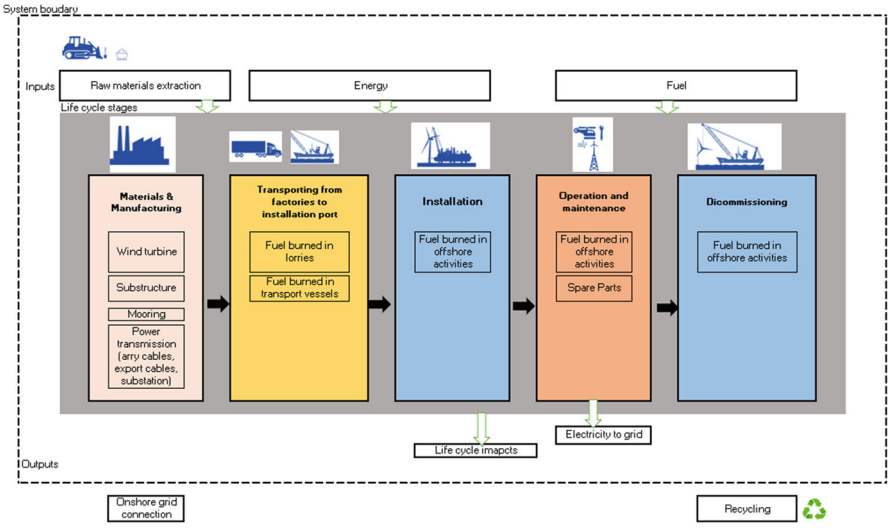

Fig. 1 System boundaries from Garcia-Teruel et al. [7] with some changes

Phase of life cycle assessment involving the compilation and quantification of inputs and outputs for a product throughout its entire life cycle.

The output of this stage is an inventory of basic flows, which serves as the foundation of the life cycle impact assessment. Data were gathered for each unit process under evaluation. These data include energy inputs, raw materials, emissions, and waste.

Life Cycle Impact Assessment (LCIA) The third phase of an LCA study is LCIA where the data from the life cycle inventory regarding basic flows are transformed into environmental impact scores. Typically, the life cycle impact assessment (LCIA) stage is fully automated, with the expert selecting an LCIA method and a few additional parameters using menus and buttons in LCA software.

The global warming potential (GWP) is the most well-known impact category. Several life cycle impact assessment (LCIA) models have been developed and used to assess the environmental impacts of products and activities, including ReCiPe (Resource Use, Emissions, and Health Impacts), IMPACT (Integrated Methodology for Impact Assessment of Chemicals, CML (Centre for Environmental Studies), Eco-indicator, EPS (Environmental Priority Strategies), USEtox (Unified System for the Evaluation of Toxicity), and TRACI (Tool for the Reduction and Assessment of Chemical and Other Environmental Impacts) [4]. The chosen methodology for this study is ReCiPe 2016 v1.03, midpoint (H) using the ecoinvent database by OpenLCA software [6].

Interpretation The interpretation stage is the final phase of an LCA, where the results of the previous phases are combined and evaluated in consideration of the uncertainties present in the data and the documented assumptions made during the study.

By applying the LCA methodology, the GWP of the wind farm is calculated to be 36.5 kg CO_2/MWh. Table 1 shows the contribution of each life cycle stage to the total emissions. Each of these stages is categorized into capital expenditure (CAPEX), operational expenditure (OPEX), or decommissioning expenditure (DECEX).

The results are in good agreement with those of similar previous studies. However, the contribution of operation and maintenance (O&M) is much lower in many studies due to their simplifying assumptions (except for the study conducted by

Table 1 Contribution of each life cycle stage to the total emissions

Stage	Category	Contribution (%)	Contribution (kg CO_2/MWh)
Manufacturing	CAPEX	50.64	18.48
Transportation			
Installation			
O&M vessel	OPEX	40.06	14.62
O&M spare parts			
Decommissioning	DECEX	9.3	3.4

Garcia-Teruel et al. [7], which has concluded a similar contribution of O&M to the total emissions). This study has shed light on this important stage of the wind farm life cycle.

Some previous studies on LCOE have concluded that O&M costs are in the range of 30% of the total cost [8]. The assumption of CAPEX of approximately 4 MEUR/MW (Million Euros per Megawatt) can be justified by utilizing historical patterns in adjusted and normalized offshore wind capital costs, whereas DECEX can be in the order of 0.5 MEUR/MW [9].

3 Levelized Cost of Energy

3.1 General

The levelized cost of energy (LCOE) is an economic metric often presented as a monetary unit per kilowatt-hour (kWh) and is used for comparing different competing energy resources [10, 11]. Parameters that may influence LCOE of a wind farm include the type of renewable energy resource, the technologies used and their efficiencies, the type of project, the countries in which they will be built and operated, and capital and operating expenditures [12]. LCOE is defined as the ratio of the net present value of lifetime costs to the net present value of lifetime generated energy.

3.2 Probabilistic LCOE Methodology

Methodology Based on the definition provided above, the levelized cost of energy (LCOE) can be probabilistically calculated as shown in Eq. (1)

$$\mathrm{LCOE} = \frac{\frac{1}{\gamma_a}\widehat{\boldsymbol{X}}_{\boldsymbol{c}}.\mathrm{CAPEX} + \frac{1}{\gamma_a}\widehat{\boldsymbol{X}}_{\boldsymbol{d}}.\mathrm{DECEX} + \widehat{\boldsymbol{X}}_{\boldsymbol{p}}.\mathrm{OPEX}}{\boldsymbol{X}_{\boldsymbol{eff}}.\boldsymbol{X}_{\boldsymbol{w}}.8760.N_{\mathrm{WT}}.P_{\mathrm{WT,nom}}.\gamma_c} \tag{1}$$

in which, $\widehat{\boldsymbol{X}}_{\boldsymbol{c}}$ is the random variable representing uncertainty in the capital expenditure, $\widehat{\boldsymbol{X}}_{\boldsymbol{d}}$ represents uncertainty in the decommissioning expenditure, $\widehat{\boldsymbol{X}}_{\boldsymbol{p}}$ represents uncertainty in the operational and maintenance expenditure, $\widehat{\boldsymbol{X}}_{\boldsymbol{eff}}$ is the random variable representing the uncertainty in predicting the average energy production in a wind farm, $\widehat{\boldsymbol{X}}_{\boldsymbol{w}}$ is the random variable accounting for the decrease in energy production due to the wake effect in subsequent wind turbines, N_{WT} is the number of wind turbines in a wind farm, and $P_{\mathrm{WT,\ nom}}$ is the nominal power capacity of the wind turbine.

γ_a is the annuity factor defined as in Eq. (2):

$$\gamma_a = \frac{1}{d}\left[1 - (1+d)^{-N_{\mathrm{LT}}}\right] \tag{2}$$

d is the discount rate and N_{LT} is the lifetime of the offshore wind farm. Here, a simple discounted cash flow approach is used taking into consideration the time value of money. It is assumed that the total investment cost can be uniformly distributed over the lifetime of the offshore wind farm and that annual operating expenditure (OPEX) will remain the same for all years during the lifetime. The variable nature of power generation and energy mix in the energy market and grid management is not addressed in this analysis. The decision criterion for LCOE (EURc/KWh) can be presented as explained below in Eq. (3):

$$\mathrm{LCOE} \leq \gamma_p P_c \tag{3}$$

where γ_p is defined as the correction factor for LCOE due to the uncertainties involved in the above-stated random variables and P_c is defined as the characteristic LCOE. The characteristic value is usually specified with a specific confidence level. Due to a lack of proper statistical data, a typical characteristic value of 5–15 EURc/KWh is assumed for LCOE when compared to other energy sources. This assumption may be somewhat arbitrary, but it is utilized in this chapter to evaluate the impact of this definition on the probabilistic analysis. It should be noted that no calibration was performed in this study to account for the single safety factor of γ_p. Therefore, a factor of 1.0 is considered here.

The Monte Carlo simulation (MCS) technique is applied in this study to accurately model the LCOE distribution, particularly its tail behavior. The advantage of the MCS method is that it converges on the exact results when enough simulations are carried out. However, the method can be time-consuming, especially when estimating small failure probabilities. In this study, a sufficient number of simulations is considered. For an overview of the computational methods for probabilistic analysis, refer to Melchers et al. [13] and Faber [14]. The Strurel program is used for probabilistic analysis, whereas Strurel 3.14 is used for sample analysis and parameter estimations [15].

Modeling Random Variables

Uncertainties. The following section discusses and quantifies model uncertainties in expenditures, prediction of average energy production, wake effects, and the capacity factor. Due to a lack of sufficient statistical data, a normal distribution (with a bias of 1.0) is assumed for all expenditure random variables. This assumption is made to illustrate the effect of randomness on the results. For the expenditure random variables, it is assumed that OPEX can range roughly from 0.5 to 2 EURc/KWh and DECOM from 4 to 5 EURc/KWh, whereas LCOE can range from 50 to 80 EURc/KWh [16]. Energy losses due to the wake effect may vary between 2% and 7% depending on the wind farm configuration and the correlation between wind turbine availability and wind power production [17]. Both capacity factor and annual energy estimation introduce uncertainty in the energy output of a wind farm. Different sources provide different capacity factors ranging from 0.2 to 0.6 [18, 19]. A modern

Table 2 Summary of random variables and design parameters used in the probabilistic formulation

Variable	Description	Distribution type	Mean value (μ)	Coefficient of variation (CoV)
$\widehat{X}_c$	Capital expenditure estimation error	Normal	1.0	0.2
$\widehat{X}_d$	Decommissioning expenditure estimation error	Normal	1.0	0.2
$\widehat{X}_p$	Operational and maintenance expenditure estimation error	Normal	1.0	0.2
$\widehat{X}_{eff}$	Predicting the average energy production in a wind farm	Normal	0.4	0.5
$\widehat{X}_w$	Wake effects	Normal	0.85	0.5
CAPEX	Typical CAPEX estimate	Fixed value	4 MEUR/MW	–
OPEX	Typical OPEX estimate	Fixed value	0.1 MEUR/MW/year	–
DECEX	Typical DECEX estimate	Fixed value	0.4 MEUR/MW	–
N_{WT}	Number of wind turbines in the farm	Fixed value	250	–
$P_{\mathrm{WT,nom}}$	Nominal power of the wind turbine	Fixed value	5 MW	–
γ_c	Capacity factor	Normal	0.6	0.5
N_{LT}	Design lifetime for the wind farm	Fixed value	25 yrs	–
γ_a	Annuity factor	Fixed value	10%	–
P_c	Characteristic LCOE	Fixed value	5, 10, 15 EURc/KWh	–

wind turbine typically has a capacity factor of around 0.6 [19]. It is important to acknowledge that the available data for statistical analysis are limited. When estimating expenditure errors, a coefficient of variation (CoV) of 0.2 is used, whereas a CoV of 0.5 is assumed for prediction errors in average energy production and wake effects. For the capacity factor, we assume a mean value of 0.6 and a CoV of 0.5. It is crucial to highlight that the selection of random uncertainty (CoV) and design parameters in this example is arbitrary. However, as a general rule, more uncertainties are assigned to energy output variables than to expenditure variables.

Random Variables. Based on the data discussed above, Table 2 outlines the key parameters for a hypothetical design case for a wind farm consisting of 250 5-MW floating wind turbines.

3.3 Probabilistic Analysis

Results and Discussion Monte Carlo simulations (MCSs) are used for probabilistic analysis. A fitted distribution of LCOE was created by fitting the parameters of a library distribution to sampled data. In this chapter, the simulation results are fitted to

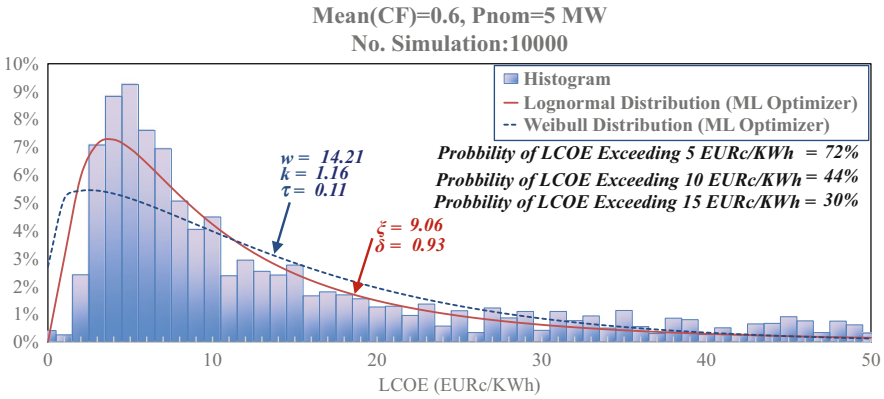

Fig. 2 Log-normal and Weibull fits to the simulated LCOE distribution histogram; wind farm with 250 wind turbines with a nominal capacity of 5 MW; capacity factor $\gamma_c = N(0.6, 0.2)$; Monte Carlo simulation (1.0E + 4); characteristic LCOE (P_c) assumed to be 5, 10, or 15 EURc/KWh

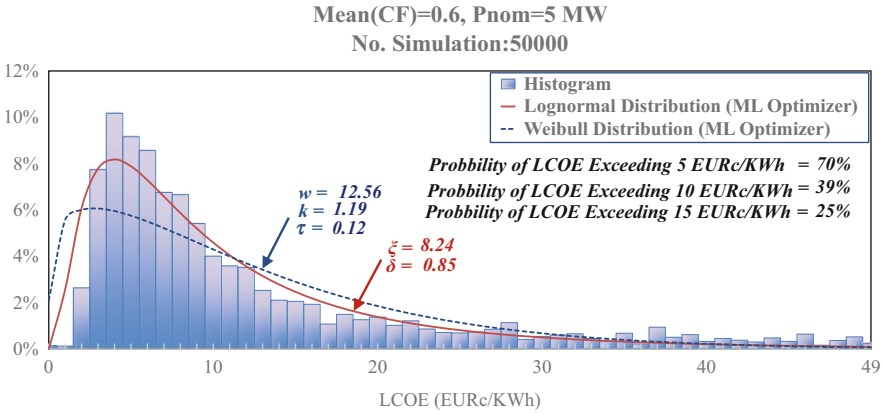

Fig. 3 Log-normal and Weibull fits to the simulated LCOE distribution histogram; wind farm with 250 wind turbines with a nominal capacity of 5 MW; capacity factor $\gamma_c = N(0.6, 0.2)$; Monte Carlo simulation (5.0E + 4); characteristic LCOE (P_c) assumed to be 5, 10, or 15 EURc/KWh

Weibull (minimum) and log-normal distribution by means of a maximum likelihood (ML) optimizer.

Figure 2 shows the results of MCS with 10^4 simulations using six random variables as outlined in Table 2. It is evident that the log-normal distribution provides a more precise fit compared to a Weibull distribution. The probability of surpassing the characteristic design value is also depicted in Fig. 2. To confirm the adequacy of the number of simulations for this analysis, another analysis with 5×10^4 simulations was performed. The result is shown in Fig. 3. The findings indicate that 10^4 simulations are adequate for comparing cases, as the percentage of exceeding the characteristic value only marginally decreased.

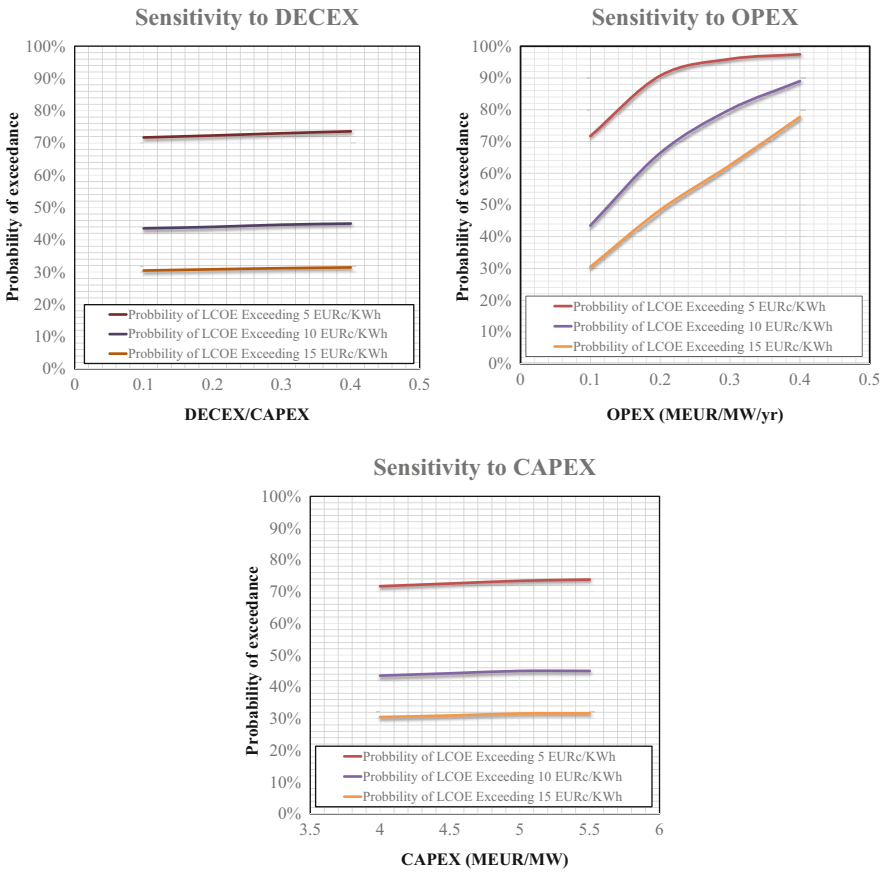

Fig. 4 Sensitivity analysis of variations in expenditures

Sensitivity Studies Sensitivity analysis was conducted to assess the impact of expenditure assumption on LCOE. Sensitivity involves variation in DECEX/CAPEX ranging from 0.1 to 0.4, OPEX ranging from 0.1 to 0.4 MEUR/MW/yr, and CAPEX ranging from 4.0 to 5.5 MEUR/MW. The results are shown in Fig. 4. It is evident that the probability of LCOE exceeding the characteristic value is not significantly affected by variations in the DECEX/CAPEX and CAPEX values. However, for OPEX, it is observed that LCOE is sensitive to an increase in annual OPEX. However, the probability of LCOE exceeding 5 EURc/KWh becomes less sensitive when OPEX is increased beyond 0.3 MEUR/MW/yr.

4 Conclusions and Recommendations

A life cycle assessment methodology was proposed for a typical wind farm. By applying this methodology, the global warming potential (GWP) of the wind farm was calculated to be 36.5 kg CO_2/MWh. In general, a good agreement was observed

with the literature regarding CAPEX, DECEX, and OPEX. The results highlight the significance of different types of expenditures. A new methodology was introduced for probabilistically estimating the levelized cost of energy (LCOE) of the wind farm. Monte Carlo simulations were performed to predict the distribution of LCOE. The assessments were based on simplified assumptions regarding uncertainties in the random variables. Sensitivity studies were also conducted to evaluate the impact of assumptions in the types of expenditures on LCOE.

Based on the assumptions made in this analysis, the calculations indicate that LCOE will not be significantly affected by varying the level of DECEX/CAPEX or by increasing the amount of CAPEX. For OPEX, the probability of LCOE exceeding a defined characteristic LCOE (P_c) increases by increasing the level of OPEX from 0.1 to 0.4 MEUR/MWh/yr. Other wind farms may yield different results. It is important to note that the results are dependent on the assumptions made regarding the uncertainty in the capacity factor, expenditure estimation, error in predicting wind farm efficiency, and wake losses, as actual data for these parameters are limited.

The methodology presented in this chapter will be useful for determining the feasibility of wind farms during preliminary studies. More effort should be made to gather and organize investment data and address the uncertainties associated with them. By conducting a more accurate evaluation of the LCOE distribution, a more informed decision can be made to determine the viability of offshore wind farms.

1 Introduction

The rapid urbanization of modern society has prompted a global concern over energy consumption. Since the first energy crisis in the 1970s, there has been a substantial international emphasis on researching building energy efficiency [1]. Building operations account for 30% of global final energy consumption and 26% of energy-related emissions. Of these, 8% are direct emissions in buildings, and 18% are indirect emissions from the generation of electricity and heat that is utilized in buildings. While severe temperatures drove increased heating-related emissions in specific places, direct emissions from the building sector dropped in 2022 compared to the previous year. This was the case, notwithstanding climate change. The energy consumption of the building industry grew by around 1% in 2022 [2]. With a commitment to reducing emissions intensity, India aims to achieve a 33–45% decrease in national gross domestic product (GDP) emissions by 2030 compared to 2005 levels. Despite the impending construction of 70% of the required structures by 2030, this sector continues to contribute significantly to greenhouse gas emissions [3]. Buildings in India currently consume around 34% of energy, with commercial buildings accounting for 8.29% of total consumption [4]. By 2030, we expect the total built-up area of commercial buildings to reach 1.9 billion square meters, a threefold increase from the 2015 figure of 847 million square meters [5]. India's pioneering energy conservation building code (ECBC) aims to achieve energy neutrality in commercial buildings within the Indian context [6]. The building envelope plays a crucial role in heat transfer into a building, impacting the energy load in conditioned buildings. To address heat transmission challenges and facilitate ECBC adoption in the nation, suitable construction solutions for opaque exterior walls are imperative.

Thermal transmittances of walls are vital thermophysical properties significantly influencing a building's energy efficiency and play a critical role in determining a building's energy needs and understanding heat loss [7, 8]. They regulate heat exchange with the external environment, impacting the energy demands of heating, ventilation, and air conditioning (HVAC) systems [9–11]. Despite insufficient ECBC implementation and slow code acceptance in India, the long-term viability of these regulations depends on market sustainability. The deployment of ECBC and other energy efficiency measures has the potential to save a large amount of energy

in buildings that are located in India [12, 13]. Drywall, also known as plasterboard, wallboard, gypsum board, or gyprock, is a composite panel made of gypsum plaster sandwiched between two robust paper sheets. With nearly half the mixture consisting of paraffin capsules, the new drywall incorporates minuscule paraffin beads to collect and emit heat, representing a significant advancement in sustainable construction technology. This versatile construction method, weighing eight to ten times less than traditional systems, offers faster construction while providing a smooth finish and crack-free surfaces [14, 15]. Additionally, up to 20% of the gypsum used in drywall production can be repurposed from waste generated at manufacturing facilities or construction sites. This study employs an evolutionary optimization model to evaluate the suitability of various materials for assessing thermal transmittance in commercial building opaque wall assemblies. The goal is to ensure ECBC compliance in different Indian climatic zones, promoting wider acceptance within the building industry. This information is valuable for practitioners conducting energy audits and scholars seeking contemporary insights. ECBC for commercial buildings in 2017 specifies U-factor or thermal transmittance requirements in a parametric framework for different climatic zones in India. Compliance levels include ECBC, ECBC+, and ECBC Super, each offering varying energy efficiency improvements. This research provides an overview of compliance requirements and energy-saving uses of plasterboard, emphasizing its sustainable growth and administrative advantages on building sites.

2 Methodology

Every new building greater than a connected load of 100 kW is required to adhere to the energy conservation building code (ECBC) compliance procedure, encompassing a set of obligatory regulations related to energy utilization in the building. Following consultation with experts on ECBC and referencing the ECBC user guide, diverse methods for achieving ECBC compliance have been delineated. To allow for a degree of flexibility in design and construction, the code compliance requirements can be satisfied through the following approaches as deemed appropriate (see Fig. 1) [16].

2.1 Prescriptive Approach

The prescribed technique establishes the required minimum energy efficiency features for different components and systems within the envisioned buildings. Specific standards are outlined for the building envelope, HVAC systems, service hot water and pumps, lighting systems, and electrical power. Compliance can be achieved by

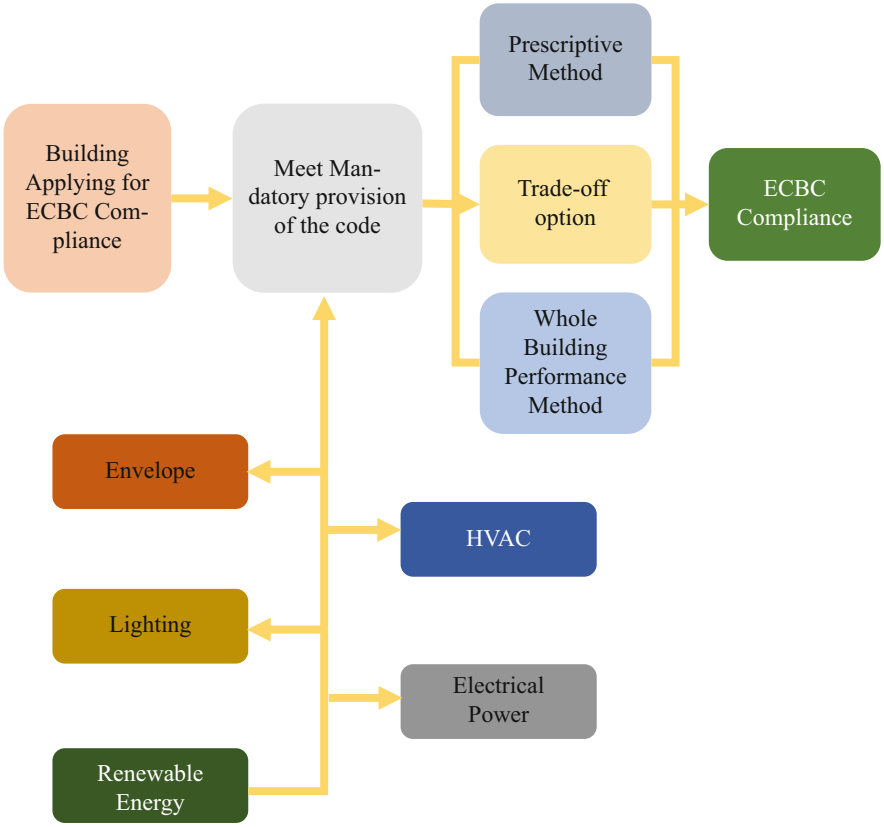

Fig. 1 Methods for ECBC code compliance

meeting the fundamental requirements outlined in the code. However, the code also allows for surpassing these standards, leading to enhanced energy efficiency. The energy conservation building code (ECBC) introduces the trade-off option for the building envelope, enabling a trade-off between the efficacy of one envelope component and another without compromising the overall efficiency level stipulated by the code.

2.2 Building Envelope Trade-Off Approach

This approach utilizes a systems-based method, enabling a decrease in the thermal performance standards of specific exterior components while enhancing the efficiency of other building elements. For example, choosing higher wall insulation

could potentially ease the U-factor requirement for windows, and vice versa. Trade-offs typically apply to significant building components such as roofs, walls, fenestration, overhangs, etc. Compared to adhering to recommended values for each element, this strategy provides more flexibility in building design. However, trade-offs are limited to building envelope components, and adjustments to lighting or HVAC systems, for instance, are not feasible through this approach. Consequently, opting for the trade-off choice necessitates more computations than selecting the prescriptive approach. The surface area of each external and semi-exterior surface must be individually calculated, with computations carried out separately for each direction.

The building envelope is considered compliant with the code when the envelope performance factor (EPF) of the proposed building is lower than that of the standard building, which strictly adheres to the prescriptive requirements for the building envelope. This approach does not apply to buildings with a window-to-wall ratio (WWR) exceeding 40%. The trade-off method does not include provisions for skylights. To ensure compliance with ECBC using the trade-off method, the calculation of the envelope performance factor should be conducted in accordance with Eqs. (1) through (4) [6]. EPF of the envelope is the summation of the EPF of the roof, wall and fenestration. The EPF of both the wall and roof is assessed by taking into account the individual area and thermal transmittance values of each component. Additionally, a multiplication coefficient is applied to adjust for the influence of the local climate. Similarly, to evaluate the EPF of fenestration components, coefficients are employed for each direction, and other parameters such as thermal transmittance, area, and solar heat gain coefficient (SHGC) considered.

$$\mathrm{EPF_{Total}} = \mathrm{EPF_{Roof}} + \mathrm{EPF_{Wall}} + \mathrm{EPF_{Fenest}} \tag{1}$$

$$\mathrm{EPF_{Roof}} = C_{\mathrm{Roof}} \sum_{s=1}^{n} U_{\mathrm{R}} A_{\mathrm{R}} \tag{2}$$

$$\mathrm{EPF_{Wall}} = C_{\mathrm{Wall}} \sum_{s=1}^{n} U_{\mathrm{W}} A_{\mathrm{W}} \tag{3}$$

$$\begin{aligned}\mathrm{EPF_{Fenest}} = {} & C_{1\mathrm{Fenset,North}} \sum_{w=1}^{n} U_{\mathrm{G}} A_{\mathrm{G}} + C_{2\mathrm{Fenset,North}} \sum_{w=1}^{n} \frac{\mathrm{SHGC_G}}{\mathrm{SEF_G}} A_{\mathrm{G}} \\ & + C_{1\mathrm{Fenset,South}} \sum_{w=1}^{n} U_{\mathrm{G}} A_{\mathrm{G}} + C_{2\mathrm{Fenset,South}} \sum_{w=1}^{n} \frac{\mathrm{SHGC_G}}{\mathrm{SEF_G}} A_{\mathrm{G}} \\ & + C_{1\mathrm{Fenset,East}} \sum_{w=1}^{n} U_{\mathrm{G}} A_{\mathrm{G}} + C_{2\mathrm{Fenset,East}} \sum_{w=1}^{n} \frac{\mathrm{SHGC_G}}{\mathrm{SEF_G}} A_{\mathrm{G}} \\ & + C_{1\mathrm{Fenset,West}} \sum_{w=1}^{n} U_{\mathrm{G}} A_{\mathrm{G}} + C_{2\mathrm{Fenset,West}} \sum_{w=1}^{n} \frac{\mathrm{SHGC_G}}{\mathrm{SEF_G}} A_{\mathrm{G}}\end{aligned} \tag{4}$$

2.3 Whole Building Performance Approach

An alternative method for ECBC compliance is the Whole Building Performance (WBP). Under this approach, a computer-based hourly energy simulation model of the proposed design is created, and its energy usage is compared with that of a typical design to ensure compliance with ECBC, as illustrated in Fig. 2. The simulation encompasses thermal, visual, ventilation, and other energy-consuming aspects of the building, factoring in its orientation, construction materials, façade, climatic conditions, and internal and external environments. Following all the necessary prescriptive criteria of the code, if the energy consumption in the standard design aligns with the maximum allowed for that specific building, compliance is achieved. With the WBP technique, a "Proposed Design" needs to be modelled, its annual energy usage calculated, and then compared to the "Standard Design" using their Energy Performance Index (EPI). Additionally, the simulations must adhere to the ECBC's standard energy modelling technique.

2.4 Building Representation

This study examined the energy consumption of a hospitality building using eQUEST software. The utilization of plasterboard technology has seen substantial growth in the Western world over the past decades. However, its adoption in India remains limited due to a lack of awareness. Considering that nearly 70% of the building stock expected by 2030 is yet to be constructed in India, plasterboard

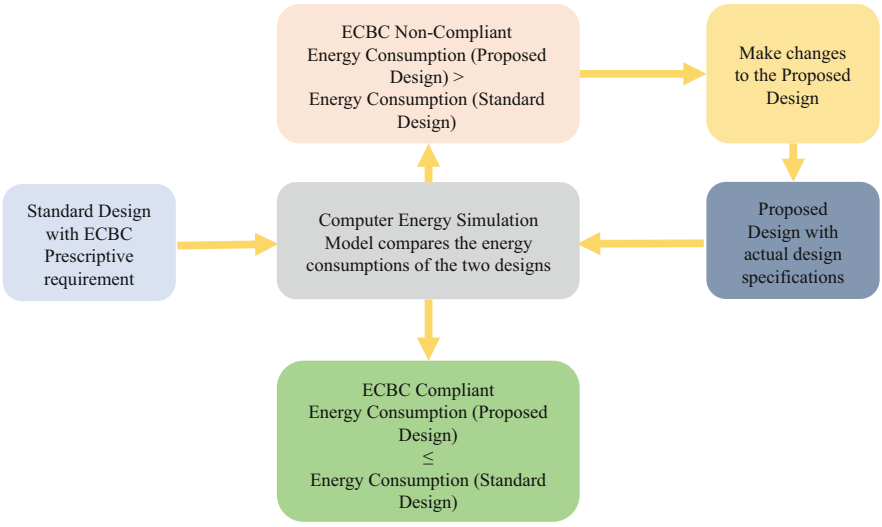

Fig. 2 Whole building performance approach

technology emerges as a viable option for sustainable development. This technology can replace traditional systems, reducing the reliance on fossil fuels, electricity, and emissions associated with building energy use. Additionally, these systems are introduced as environmentally friendly materials, with a focus on recycling the majority of used materials, thereby diminishing environmental pollutants after the building's demolition. A zoning plan was developed for every floor and integrated into the simulation model as illustrated in Fig. 3. Each zone received a specific set of characteristics, encompassing lighting power density, equipment power density, occupant density, infiltration rate, outside air requirement, and an occupancy schedule. Additionally, each zone was attributed physical properties, such as floor-to-floor height, material density, conductivity, and fenestration area. The occupancy schedule for these zones has been referenced from ECBC [6]. The overall built-up area considered for the analyses is 26,315 m^2. Table 1 elucidates the diverse composition of materials under consideration, while Table 2 presents the thermal properties of these compositions and other input parameters employed in the analysis.

3 Results and Discussion

The study involved creating a model with consistent dimensions but different combinations of external and internal wall materials, followed by performing energy simulations specific to New Delhi. The subsequent sections present the analyzed data from diverse material compositions. Figure 4 illustrates the monthly energy consumption for different scenarios, considering traditional materials such as fired clay brick (FCB), plasterboard (PB), and autoclaved aerated concrete (AAC). Based on the findings of the investigation, it is evident that plaster boards and AAC materials use less energy when compared to fire clay bricks.

As shown in Fig. 5, the building that was created using PB on both the exterior and internal walls was able to save 9% of the total amount of energy demand. This is in comparison to the structure that was made with conventional construction materials, which included FCB on both the exterior and interior walls. Additionally, in comparison to the conventional type of building, the building that was constructed with PB on the exterior and FCB on the interior walls system was able to save 8.03% of the desired amount of energy. When compared to a structure that was created using conventional construction materials, it was discovered that the energy demand reduction in the case of FCB on external walls and PB on inner walls was 1.17%. When compared to the structure that was created using conventional construction materials, such as FCB on both the exterior and interior walls, the energy reduction was determined to be 8.69% when the building was constructed using PB on the outside and AAC block on the inner walls. Buildings that are constructed with AAC

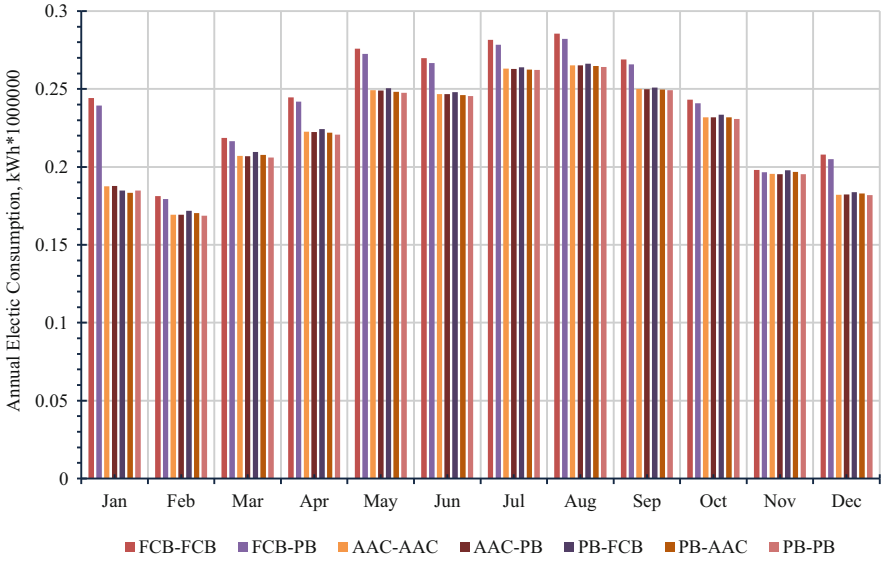

Fig. 4 Monthly energy comparison of different exterior and interior wall configurations

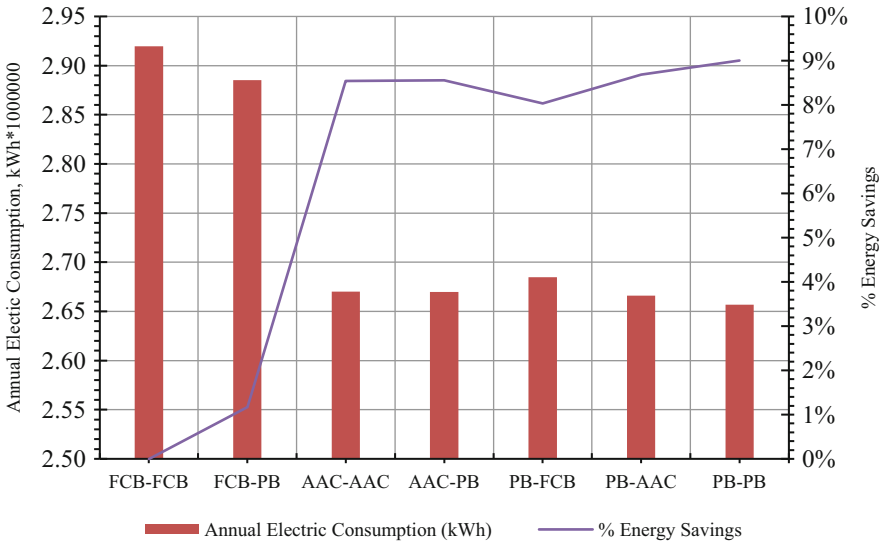

Fig. 5 Annual energy comparison of different exterior and interior wall configurations

blocks on both the exterior and interior as well as the walls save 8.54% of the amount of energy demand when compared to buildings that are constructed with traditional building materials. On the other hand, buildings that are constructed with AAC blocks on the exterior and PB blocks on the interior and walls save 8.56% of the amount of energy demand when compared to buildings that are constructed with traditional building materials.

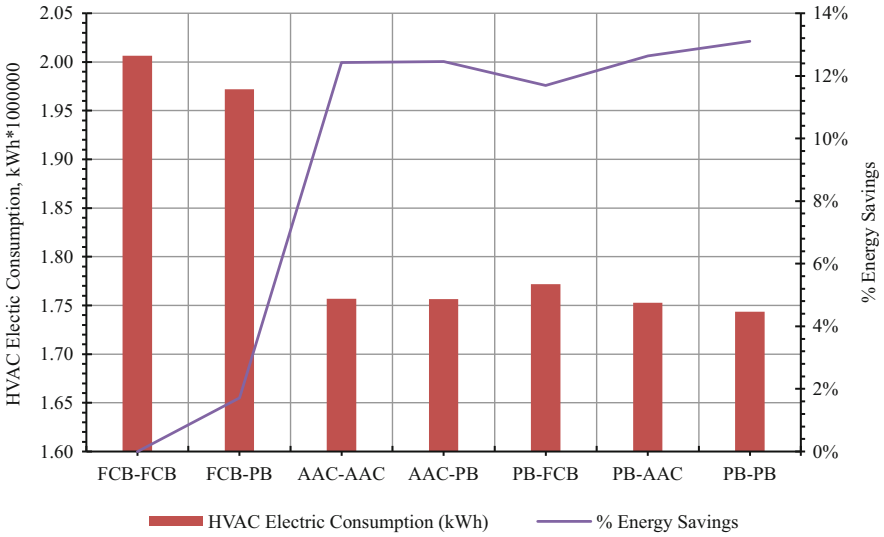

Fig. 6 Annual HVAC energy comparison of different exterior and interior wall configurations

As can be seen in Fig. 6, the structure that was built with PB for both the exterior and internal walls demonstrated a 13.10% reduction in the energy demand for heating, ventilation, and air conditioning (HVAC) in comparison to the structure that was built with conventional materials such as FCB on both sides. Additionally, in comparison to the traditional construction, the building that used PB on the outer walls and FCB on the interior walls was able to achieve an 11.69% reduction in the amount of energy that was required for HVAC.

When the energy demand for HVAC systems was compared to the building that was constructed using standard construction materials, the combination of FCB on the outside walls and PB on the interior walls resulted in a decrease of 1.71%. Furthermore, in comparison to the standard FCB construction, the use of PB on the outer walls and AAC block on the internal walls led to a reduction of 12.64% in the amount of energy required for HVAC.

When compared to conventional construction materials, a structure that was made completely out of AAC block, both on the outside and the inside, demonstrated a 12.43% reduction in the amount of energy used for HVAC. When compared to the traditional FCB construction, the building that had AAC block on the outside and PB on the inside walls was able to save 12.45% of the energy consumption for heating, ventilation, and air conditioning.

4 Conclusion

The utilization of plasterboard technology has witnessed a substantial surge in the Western world over recent decades. However, in India, its adoption remains limited primarily due to a lack of awareness. This innovative technology has the potential to

replace traditional building systems, thereby mitigating the consumption of fossil fuels, electricity, and emissions associated with energy use in buildings. Moreover, these systems are introduced as environmentally friendly materials, emphasizing the majority of the used materials can be recycled, reducing environmental pollutants following building demolition.

The findings of this study underscore a significant reduction in electricity consumption achieved by implementing a plasterboard system instead of traditional brick materials in the exterior walls of hotel buildings across different climatic zones in India.

Beyond reducing energy consumption, the use of plasterboards also facilitates the effective implementation of Energy Conservation Building Codes. Traditional materials, such as fired clay brick with a total thickness of 280 mm (25 mm plaster + 230 mm FCB + 25 mm plaster), exhibit a thermal transmittance of 2.11 $W/m^2 \cdot K$, surpassing the values stipulated in the codes. In contrast, the thermal transmittance of AAC blocks with similar thickness and layer composition is 0.67 $W/m^2 \cdot K$. Furthermore, plasterboards with a total thickness of 157 mm demonstrate a thermal transmittance of 0.37 $W/m^2 \cdot K$, falling below the prescribed value of 0.40 $W/m^2 \cdot K$ specified in the codes. This highlights the potential of plasterboard technology not only in enhancing energy efficiency but also in aligning with and exceeding regulatory standards for sustainable construction practices. This study demonstrated a noteworthy 9% decrease in electricity consumption when employing a plasterboard system instead of traditional brick materials for the exterior walls of hotel buildings. Furthermore, there was a 13% reduction in cooling load by replacing traditional bricks with plasterboards.

1 Introduction

As per reports from the IEA, OECD, and the UN Environment Programme, cities account for two-thirds of global energy consumption, 50% of global waste, and over 70% of worldwide energy-related CO_2 emissions. Key contributors to these figures are the transportation and building sectors. Projections indicate that by 2050, over 70% of the global population will reside in cities, leading to an increased demand for spaces such as housing, retail, and industry, accompanied by the requisite urban mobility and energy infrastructure [1]. Given this scenario, cities, including their buildings and neighbourhoods, present a significant opportunity for substantial carbon emissions reduction if planned with that goal in mind. A key aspect of this effort involves the reuse and transformation of existing urban areas, aiming to curtail

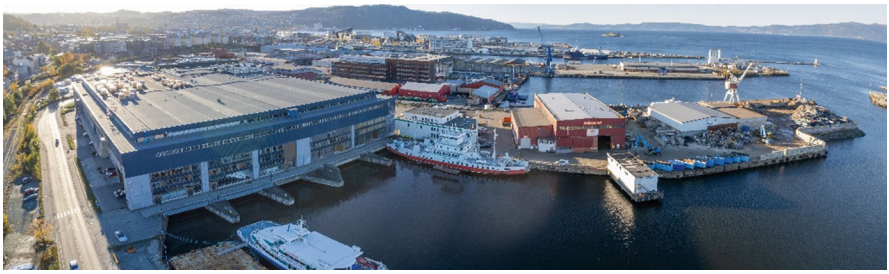

Fig. 1 Nyhavna [6]

the necessity for new construction on undeveloped land and thus contribute to the preservation of nature and farmland [2].

This chapter investigates the transformation process of an urban harbour area, Nyhavna (New Harbour), in Trondheim, Norway, with a focus on converting it into a neighbourhood reducing its carbon emissions towards zero as defined by the Research Centre on Zero Emission Neighbourhoods in Smart Cities (ZEN) [3]. Urban transformations are complex, involving numerous stakeholders with diverse interests and ambitions. Little existing research explores how to organize and lead such a process at the neighbourhood level to achieve ambitious environmental goals like ZEN or other related ambitions such as Positive Energy Districts (PEDs) [4].

The research questions guiding this study are: How does the chosen pathway for the planning process of Nyhavna impact the harbour area's transformation into an attractive, zero emission neighbourhood? What challenges arise, and which strategies are essential for maintaining high ambitions over time? First, literature on transformation of harbour areas is presented, before giving the context of Nyhavna. Then the case study research approach is explained [5], involving a document analysis and qualitative interviews with experts engaged in the pre-early-planning process. The analysis focuses on (1) the early planning phase, (2) the different perceptions of the future of Nyhavna and (3) the early efforts to bring the plans and visions to life. The chapter contributes to understanding factors influencing climate-neutral neighbourhood development and concludes with practical recommendations for development of urban transformation projects based on the case of Nyhavna (Fig. 1).

2 Transformation of Harbour Areas: Commodifying the Waterfront

The urban transformation of harbour areas into housing and retail areas is a phenomenon that has gained momentum over the last few decades. This process involves repurposing formerly industrial or underutilized harbour zones into

mixed-use spaces that combine residential, commercial, and recreational elements. The factors that have contributed to the emergence of this trend are multiple. Many harbour areas were historically industrial zones, hosting shipping ports, warehouses, and factories. As cities have shifted away from heavy industry, these waterfront areas became obsolete, prompting the need for alternative land use. The harbour areas are often centrally located and increasing populations in urban areas demand living space. Waterfront areas became attractive, and usually as well economically profitable and often expensive living spaces [7]. Over the last 50 years, urban regeneration has evolved from a focus on physical transformation to a more comprehensive vision that emphasizes improving the quality of life for inhabitants as well as an environmental focus, highlighting the process as placemaking an existing urban context alongside sustainable effects [8].

In the Norwegian context, Aker Brygge and the subsequent waterfront developments in Oslo, have been criticized for becoming neighbourhoods for the affluent. This is also something that is feared at Nyhavna [9]. Despite the initial aspirations, the Fjordbyplan ("Fjord-city-plan", approved 2008) has not realized its goal of social diversity in the Oslo harbour area [10]. Oslo, like many other cities, has witnessed a shift towards market-driven urban planning strategies, prioritizing economic development, private investments, and the market forces in shaping the cityscape. Røe [10] suggests that the implemented strategies may not have effectively addressed the socio-economic and cultural diversity desired for the district. This discrepancy can be attributed to various factors, such as market dynamics, policy implementation challenges, or unforeseen consequences. One significant aspect highlighted by Røe [10] is that the Fjordbyplan was not legally binding. This lack of legal obligation might have allowed for deviations from the initial vision during the implementation phase, allowing developers and investors to prioritize profit-driven projects over the inclusivity and diversity goals outlined in the plan. This suggests that the planning decisions were rather influenced by economic considerations than by ideas of social equity and diversity.

Andersen and Skrede [11] demonstrate how private interests are 'de facto' city makers in the Norwegian planning regime, while the municipalities' planning authority mostly have a regulatory role. It is a fact that planning proposals are mainly submitted by private corporations, pursuing own interests, and executing the plans. Andersen and Skrede [11] describe this planning regime as adhering to a neoliberal logic, where the strong position of private interests is shaping the city development. In their analysis of the municipal master plan in Oslo, they state (in line with Røe [10]) that the municipality has failed to realize its ideals of a socially just municipality, due to the strong positions of private interests in city development. This is despite Norway being an affluent and equality-oriented country [11]. One example Andersen and Skrede [11] describe, is the development at Furuset, located East in Oslo. Here, the municipality planned for an ambitious environmental concept, but experienced at the time a lack of interest from the private housing developers. The developers' perceptions were that the potential buyers of this area, with a lower socio-economic status, would not have the ability to pay the accompanying extra

costs. These kinds of concepts for buildings were regarded by them as more suitable for a waterfront development, where they estimated a higher profit due to more affluent customers.

Stakeholders may have competing interests and different conceptions of what an 'inclusive and attractive', 'zero-emission', and 'sustainable neighbourhood' is. The complexity of competing conceptions is explored by Guy and Farmer [12] showing how different logics of ecological placemaking is competing in representations of sustainable architecture. Through a study of buildings and a literature review of books, articles, and reports, Guy and Farmer [12] identify six distinct and competing conceptions of ecological placemaking. They treat these competing views as different environmental discourses, not as static concepts. Of these, three are relevant to this chapter: the eco-technical, the eco-centric, and the eco-social. The eco-technical logic suggests that the environmental problems can be addressed through science and technological- and structural solutions. In contrast, both eco-centric and eco-social logics, emphasize the need for a fundamental change of values to solve environmental issues. The eco-centric view is more individual and lifestyle oriented, with a perception that the built environment in general has a negative environmental impact. The eco-social advocates for a community model that serves common needs and goals.

Guy and Farmer studied the social construction of sustainable architecture at building level, but the concepts can also be a fruitful lens on sustainable urban planning [13] and representations of sustainable neighbourhoods [14]. Kittang [13] illustrates the contradictions between the municipality's eco-technical discourse conflicting with consultants and architects more eco-centric logics in the development of a low-emission neighbourhood in Trondheim.

Urban transformations are complex, affecting the social, institutional, cultural, political, economic, technological, and ecological context of an area [8]. Multiple actors such as local governments, companies, entrepreneurs, households, as well as regional or national governments represent different roles, interests, and loyalties, that shape an urban development [8]. Against this backdrop, it's evident becomes why there is no simple picture of an urban transformation process that all would agree on.

3 The Case of Nyhavna

In Trondheim, Nyhavna's transformation is the city's third urban waterfront development, following Nedre Elvehavn (1990–2016) and the ongoing Brattøra port. Nyhavna was established in the end of the nineteenth century and is a diverse port- and industrial area near the waterfront, just a 15-minutes' walk from the historical city centre. The peculiarity of the area are the submarine bunkers from WWII, Dora 1 and Dora 2. Around 2000 people have their workplace at Nyhavna today [15]. Warehouses and large industry buildings are in use by both traditional- and

small-scale industries, maritime businesses, and various creative industries. Many of the companies present at Nyhavna have long term lease agreements, the longest lasts until 2120.

For understanding the planning process, it is relevant to know that there are three major landowners at Nyhavna: Trondheim Municipality, Trondheim Port Authority and Bane NOR Eiendom AS. The port authority is a self-financed intermunicipal company. Bane NOR Eiendom AS is a state-owned company responsible for the national railway infrastructure. Changes in the Norwegian port legislation ('Havne- og farvannsloven') in 2020 allowed for the redeveloped of port areas. This led to the establishment of Nyhavna Utvikling AS in January 2021, a real estate company with two shareholders: Trondheim municipality (67%) and Trondheim Port Authority (33%). Their properties at Nyhavna are demerged into Nyhavna Utvikling AS. Essentially, most of the plots (ca 85%) within the municipal sub-plan are publicly owned, but the ownerships are organized as AS/companies.

The Planning and Building Act determines how the country's land should be used and regulated. Spatial planning is important to ensure that land use is purposeful, efficient, and rational. A typical municipal planning hierarchy starts with the municipal master plan, which includes both a societal part and a land use part. The land use part should show where development can take place in the municipality and which areas should be used for what purposes. The next step is a municipal sub-plan or an area regulation, depending on whether it is a private or public developer. These are used if the area to be regulated encompasses multiple properties or larger areas. The final step in spatial planning is detailed regulation for each individual sub-area. For all types of plans under the Planning and Building Act, it applies that only mapped information, along with any accompanying regulations, can have legal effect. Like most major port areas, Nyhavna follows this structure, and in addition, there is developed an ambitious Quality program (QP, in the following) [16] to guide the development of Nyhavna. A Quality program for urban development is a tool used to plan and manage the development of urban areas with a focus on ensuring high quality in design and functionality, often aiming to integrate various aspects of urban development, including architectural design, infrastructure, sustainability, social inclusion, and economic viability. The application of such programs can vary depending on local conditions, legal frameworks, and political priorities. The QP at Nyhavna is advisory, not legal, and forms the basis for further work on plans and initiatives in Nyhavna [16].

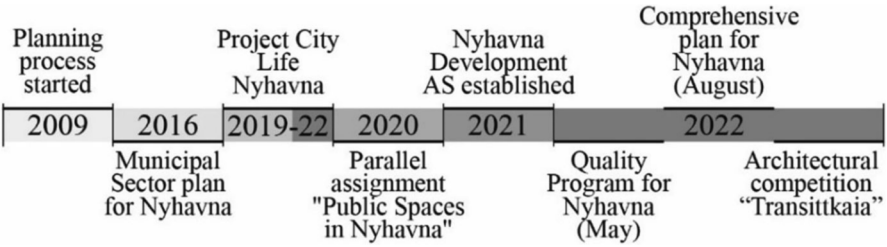
4 Methodology

This study of the case of Nyhavna started off by unravelling the threads of the process that lead to description of the future vision for Nyhavna in the QP. The main stakeholders involved in the pre-planning phase of the area were identified. These were relevant for explaining the process until this milestone and the way envisioned ahead for the early planning phase.

Qualitative interviews were conducted with seven respondents in six interviews with main players influencing this stage of the process represented—the Municipality (planners), the plot owners and a politician. Qualitative interviews are a useful method when there is not only one answer to a question and when the intention is to inquire on people's personal experiences and motivations [17]. The interview data were transcribed and then manually coded and analysed with the approach of a thematic analysis [18]. The data of the interview is supplemented through information from documents and text analysis of public available information, such as newspaper articles, planning documents, and public hearing documents, validating information from the interviews from a different angle [5].

5 Planning for an Ambitious Nyhavna

5.1 Planning Process: The Municipality's High Ambitions for Nyhavna



The planning process for the transformation of Nyhavna began as early as 2009, initiated by the Building Council. The municipal sector plan has been developed by the Municipality of Trondheim in collaboration with Trondheim Port and was adopted in 2016. The purpose of the plan '*is to ensure overarching, long-term strategies and frameworks for the transformation of Nyhavna from an industrial port to urban purposes, while also safeguarding long-term needs for port activities*' [19]. The plan description also clearly states that Nyhavna should be developed into a densely built urban area, including housing.

Nyhavna is divided into 10 different sub-areas, and a comprehensive regulatory plan will be developed for each sub-area. There are specific requirements for the preparation of regulatory plans. Regulatory provision § 3.2, basis for all regulatory plans, states that before the first regulatory plan, a Quality program for public spaces and an environmental monitoring program must be approved by the municipality and serve as the basis for all plan proposals. Additionally, § 3.3 states that a cultural heritage program must be approved before the approval of the first regulatory plan within the preservation of cultural heritage consideration zone [19]. A municipal sector plan is standard for such areas at that time, aiming to address the structure at an overarching level while details will be addressed at the regulatory plan level for each sub-area.

In 2019, a three-year project leader position under the Municipal Director's professional staff was established to facilitate participation and communication between the different actors at Nyhavna. One of the tasks was developing a strategy- and action plan for different initiatives, and implement these, contributing to make Nyhavna a more attractive district both temporary and in the long run.

The parallel assignment 'Public Spaces in Nyhavna' [20] was commissioned by the Municipality of Trondheim and Trondheim Port Authority as a follow-up of the Municipality sub-plan. Four chosen teams delivered a wealth of ideas for the design

Table 1 Simplified process timeline

of urban spaces, both as principles and as concrete solutions. The parallel assignment, together with other studies on cultural heritage, cultural industries, marine industries, environment/energy, technical infrastructure, sea level rise, and urban life form the basis for the QP for Nyhavna. The approval of the QP in May 2022 [16] (Table 1).

5.2 The Battle of the Narrative for Nyhavna

With the fabulous, holistic ambitions for the area, there come along many stakeholders and possible conflicting interests and perceptions of the future of Nyhavna. The first public hearing of the QP initiated a more extensive public debate on the plans for Nyhavna, but also city planning in Trondheim in general. A general agreement on the overall strategic aims is identified, but the interpretation of values and practical implications varies.

From the perspective of the urban planning office, the interviewees stated that the primary purpose of the QP is to communicate their overall visions and ambitions, particularly to landowners, politicians, and other stakeholders in Nyhavna, as well as to the public. With ten strategic aims in the QP, the representatives at the urban planning office wanted to 'formulate intentions that will stand the test of time, are easy to communicate and are setting a mood' for the future of Nyhavna. They aimed at being both concrete and open to interpretations at the same time. One interviewee says: '[The Municipality] plays a crucial part in creating the narrative that one is involved in something greater than just individual [organizations] goals'. According to Sandercock [21], storytelling as a tool in public planning process can work as a catalyst for change by being an inspirational example and shaping a new imagination of alternatives.

The QP visualize future scenarios of Nyhavna and targets a broad audience with a reader-friendly layout accompanied by pictures, maps and architectural illustrations. Additionally, it incorporates examples from inspirational international city

development projects. People are prominently featured in most of the pictures and illustrations. A vibrant city district is illustrated, and the document can be viewed as a representation of an idealized future city life [10] in Nyhavna.

Developers at Nyhavna raised concerns in the public hearing of the QP [22] about illustrations used in the QP, not being in line with the legal guidelines in the Municipal sub-plan, giving the impression of unrealistic future solutions. One stakeholder highlights the lack of a plan illustrating how the prominence of private cars in the neighbourhood can be substantially reduced. An envisioned mobility hub is seen as part of the infrastructural development prioritizing less private car use, but this analysis is not yet carried out. Another stakeholder points out a lack of clear area designation in the QP. This stakeholder states they are looking for a perspective that is rooted in a pragmatic approach to urban development, emphasizing the importance of realistic, achievable plans. Concerns are also raised about the reliance on repurposing areas without adequately addressing the challenges and timelines associated with major infrastructural changes. This critique underscores the need for a unified approach that ensures all planning efforts are synchronized, thereby avoiding conflicting directions that could hinder the area's development in the long run.

Actors within music, arts and various creative industries, and the alternative neighbourhood of the adjacent urban ecological experimental area Svartlamoen express concerns about Nyhavna becoming a place like other harbour development areas, with only the upper class able to reside, or rent businesses [23]. The QP emphasizes the importance of preserving diversity and culture through its strategic aim, number 7, 'letting arts and culture characterize Nyhavna'. It suggests investigating various business models for culture-led regeneration. However, if wanting to preserve and support the current renting (sub-)cultural actors at Nyhavna, these proposals would necessitate taking concrete supporting actions, a fact that commentators claim they haven't observed thus far [23].

The discussion surrounding Nyhavna has evolved from a culture-driven regeneration strategy to one that also includes perspectives from the industrial sector [24]. This represents a shift in the urban discourse concerning Nyhavna. There is broad political agreement that the heavy industry is conflicting with urban city development of the area and will be relocated, but the future of lighter and small-scale industry has gained political attention to remain at Nyhavna. During the initial public hearing of the QP, actors within lighter industries and maritime businesses expressed their dissatisfaction with having been grouped together with arts-related entities in the Program for Creative Industries [25]. They advocated for a separate program tailored to the needs of the future of ocean space related actors and small-scale industry at Nyhavna, emphasizing the importance of access to test facilities near water. This feedback led to the development of the Industry program, which is on public hearing until March 2024. These actors also argue that their presence will contribute with an environment for innovations and green technology, aligning with the ambitions outlined in the QP. Nyhavna is pictured as the future of 'Silicon Harbour of Norway' and as a 'Norwegian ocean space technology capital' [26].

Each of these perspectives contributes to the complex tapestry of Nyhavna's future. The discussions around the QP highlight both the challenges and opportunities inherent in balancing various interests and visions for a district on the verge of significant transformation.

5.3 Bringing Nyhavna's Visions to Life

The QP states that '*many actors will have to contribute and stretch far if we are to achieve an ambitious urban development at Nyhavna where environmental, social and economic sustainability aspects are taken care of*' [16, p. 6]. The representatives from the urban planning office also emphasize that many of the qualities they aim to achieve cannot be realized without the cooperation of landowners.

Once the QP, with its innovative ideas, was unleashed, the municipality's role underwent a significant transformation. They transitioned from being the inspirational actor to becoming the majority owner of Nyhavna Utvikling AS, which operates as a commercial developer with the expectation of financial returns. Consequently, their influence, now exercised through this ownership position, shifted from a frontstage to a backstage role. While municipal influence persists, the dynamics of the arena have changed. The planning authority is subsequently tasked with approving the plan proposals submitted through Nyhavna Utvkling AS. This dual responsibility poses challenges, acknowledged by Municipal employees and other involved parties, as highlighted in the interviews. From the developers' side, one interviewee stated that the lack of understanding of other parties' roles and the accompanying responsibilities, is one of the major problems they experienced in the early planning phase. Once the roles change, or are not clearly defined, this can be a breeding ground for conflicts.

The transparency and detailed nature of the QP are considered assets, yet they also raise concerns among landowners about managing the multitude of goals. Demanding terms like 'must' and 'should' are often employed, indicating equal importance for all described actions. One developer highlights a concern regarding the QP being taken too literally, with an expectation for the fulfilment of every ambition, due to the lack of a clear hierarchy of goals. The QP is politically adopted as a *vision* for the Municipality's ambition for the district [16]. Meanwhile, representatives of the municipality refer to it as 'an operating document'. In the interviews, the developers report difficulties in navigating between various documents guiding Nyhavna's development, including the Municipal sector plan and the QP. There is ambiguity regarding which documents hold authority and significance. The lack of juridical status of the QP, and misalignment with the municipal sector plan are highlighted as concerning in the interviews.

The expected financial return for Nyhavna Utvikling AS by developing the area is not quantified, but according to one interviewee, it should be comparable to private development companies, where 15% margin is common. The developers operate within market principles. At the same time, there are expectations that Nyhavna

should provide affordable housing accessible to the general public, including socially disadvantaged groups. However, there is little information on how this will be achieved beyond municipal rental housing. The study on housing-related social measures, planned in spring 2024, may provide potential solutions. Affordable housing can be a challenge once return margin should be achieved, and goals such as high energy efficiency and zero-emission goals can increase the costs due to new technologies [27].

The topics addressed by the ZEN-related goal number 6 have attracted numerous stakeholders interested in the environmental dimension. Statkraft stated in the (restricted) public hearing comments [22] that they wish to be involved in further planning of solutions for thermal energy for Nyhavna. Consequently, the support and collaboration of actors striving for the future decarbonization of the energy system for the area are promising. The active application of the ZEN centre's definition and indicators serve as a guideline in this case [3]. This goal appears therefore to be among those that are concrete enough for implementation. Based on the interview data, this seems not the case for goals missing a practical approach or operationalization.

Perceived challenges in balancing ambitious goals, discussing returns, and dealing with financial uncertainties complicate the ongoing processes. Comments show that costs associated with implementation appear to be unclear and the hearing input to the QP from two of the developers highlight the challenges associated with unclear and extensive costs related to implementation. Control over land-use and land development is key to the success of international harbour transformation projects [7]. According to one interviewee (former employee, Municipality), a less fragmented ownership structure could have been beneficial for sharing targets and economic risks. Even though there are few actors and a good starting point, a common ownership structure could, according to the interviewee, have a) led to the need to agree on a common picture of goals, and b) to financially greater strength. This would in turn as well have given the muscles to take culture actors seriously, instead of displacing the economically weak cultural segment.

The engagement and interest among the energy- and technology actors related to the technological development of the ZEN ambition, in combination with a possible willingness to invest, may indicate that the more lifestyle- and value-oriented eco-centric and ecosocial logics [12] will be less prominent than the eco-technical in the further development of Nyhavna.

6 Conclusions

Experience from the work of the ZEN centre illustrates that there is no one-fits-all recipe to transform a neighbourhood to an ambitious, sustainable area. Drawing on the experience from ZEN there are however recurring tendencies when working with the implementation of high ambitions. Not only must the technical systems be in place, but how the holistic planning process is structured to achieve common goals

and ambitions is equally important. Ambitious projects at the district level deal with process related complexities such as diverse stakeholder interests, lack of procurement practices, and uncertainty in technical and management processes [27]. The early phase is the most relevant time for anchoring ambitions and to forge a common vision and objective [27, 28].

It has been put down a considerable effort in definition of ambitions and visions for Nyhavna. The complexity seems however, not be able to be processed through the tool chosen—the QP. The subsequent hands-on and practical implementation document appears to lack, leaving many doors open for guessing on how to move forward. A relatively open municipal district plan, followed by an ambitious QP, has proven to be quite challenging to manage, according to several of those who have been interviewed. Whether this would have been easier with a different sequence, where the QP had resulted in a municipal district plan, can be considered, as prioritization would have been necessary and there could have been less discussion regarding legal status. This point was underscored by Røe [10] who pointed to the Fjordbyplan in Oslo lacking legal binding. This absence of legal obligation may have permitted departures from the initial vision during the implementation phase.

In the context of Nyhavna, the ZEN ambition appears currently to be among the more tangible goal of the QP, due to its defined categories and indicators, while several other goals remain diffused. Even though, it is still demanding to apply these throughout the steps of the planning and decision-making processes in the respective projects. It is important to point out that urban development in Nyhavna will occur gradually and unfold over several decades. How the goals are implemented in future zoning plans and further realized through construction remains uncertain.

In summary, the main conclusions are:

- The hierarchy of goals must be clearly defined.
- The ownership structure of a neighbourhood is crucial determinant.
- Continuous stakeholder involvement must be defined clearly.
- The planning hierarchy can impose barriers to ambitious goals.

1 Introduction

With 50% of the global population living in urban areas, cities consume about 75% of the world's energy production and account for 70% of the annual global carbon emissions [1]. Cities encompass a huge potential to advance the reduction of energy consumption and support the clean energy transition, by, for example, improving energy efficiency [1]. Therefore, energy planning in cities plays a pivotal role and needs to be aligned with long-term urban strategies [2] and better integrated with urban planning [3].

Positive Energy Districts/Neighborhoods (PEDs/PENs) is one of the concepts put forward in 2018 by the European Union's Strategic Energy Technology Plan

(SET-Plan) to help realize the objective of a net-zero carbon future in our cities [4–6]. A reference framework definition for PEDs/PENs was proposed in the White Paper on "PED Reference Framework for Positive Energy Districts and Neighbourhoods" prepared by Joint Programming Initiative (JPI) Urban Europe and SET-Plan 3.2 Programme on Positive Energy Districts [3]:

> "Positive Energy Districts are energy-efficient and energy-flexible urban areas or groups of connected buildings which produce net zero greenhouse gas emissions and actively manage an annual local or regional surplus production of renewable energy. They require integration of different systems and infrastructures and interaction between buildings, the users and the regional energy, mobility, and ICT systems, while securing the energy supply and a good life for all in line with social, economic, and environmental sustainability." [3]

The PED's reference framework is quite wide to allow for local variations, still aiming at creating a common vision, and does not include quantitative criteria, which may make categorizing an urban development project as a PED, difficult. Aside from the relatively broad definition in the SET-Plan, a clearly agreed definition of PED does not yet exist (see, e.g., [5, 7–9]).

By February 2020, 29 PEDs and 32 sites with aspects relevant to PEDs, were implemented in Europe, as registered by the Joint Programming Initiative (JPI) Urban Europe [7]. The implementation of PEDs calls for new solutions not just in the form of innovative and integrated technologies but also within "social, economic, financial, environmental and legal/regulatory" areas [2]. Thus, PEDs provide a broad set of challenges, including new regulatory frameworks, new planning practices, financing, and organizational forms.

The challenges in the implementation of PEDs have been treated in the existing literature [4, 6, 8], and the following elements emerge as crucial to enable the deployment of PEDs: integration of technical and non-technical solutions, holistic planning, regulatory protocols and business models, stakeholder involvement at an early stage, and collaboration [6].

Sassenou et al. [4] review the existing literature and point out that there is an urgent need for clarification of terminology with regard to energy concepts to support PED deployment. According to a study by Krangsås et al. [8], challenges in the field of governance score the highest, also confirming the findings of Bossi et al. [10]. The development of PEDs demands new forms of collaborative governance and a holistic approach. The plurality of the stakeholders involved and their interests and goals, as well as the complexity of the decision-making processes, the need to find the right business model(s) and to design an appropriate market, demand for coordination [8].

This paper contributes to the discussion around collaborative governance, multi-stakeholder orchestration, and leadership in PED projects by exploring what forms of leadership have been adopted and/or can be identified in the existing literature on PED projects and how leadership is exercised. The structure is the following: in Sect. 2, we lay out our analytical framework by presenting in more detail the topics of stakeholder collaboration, co-creation, and leadership in sustainability projects in general and in PEDs in particular and we suggest introducing theories from strategic management to better understand leadership roles in PED projects. In Sect. 3, we

present the methodology adopted for searching existing published research on leadership and co-creation of PEDs; and in Sect. 4, we summarize the findings. In Sect. 5, we discuss the findings and suggest how the proposed framework of leadership roles may aid in the future to study formal and informal leadership roles in PEDs and we draw the conclusions in Sect. 6.

2 Co-Creation and Leadership of Positive Energy Districts: An Analytical Framework

2.1 Stakeholder Collaboration and Orchestration in Sustainability Projects

Finding innovative solutions to solve complex problems requires the involvement of several actors from both the public and private sectors [11]. However, the role of the stakeholders in PED development projects is not strictly defined and may shift during the initiation, design, planning, and implementation stages of the process [12, 13]. The stakeholders participate with resources, competencies, and knowledge, and hold at the same time their own power, interests, goals, and definitions of value [8]; therefore, it can be complex to coordinate them [4]. Factors that foster collaboration, such as stakeholders' alignment and knowledge integration, are reviewed by Hamdan et al. [13]. Collaboration among stakeholders is recognized as a vital enabler for the planning of PEDs, but, from a project management perspective, the variety of stakeholders contributes to increasing the complexity of the project [13]. It is also suggested that the dynamics and the outcomes of interactions among stakeholders are less understood [13].

The core characteristics of co-creation in green transition-related projects are analyzed in Hofstad et al. [11], where co-creation is understood as a form of collaborative innovation [11] and heterogeneous actors are working together to generate innovative solutions. Spanning from this analysis, a list of core tasks for co-creation leaders was proposed, which includes, among other functions: establishing trust; building collaborative platforms and arenas; managing conflicts; exerting boundary spanning; stimulating mutual learning; motivating and unifying stakeholders around creating common public value; and managing risk [11]. It is also stated that leadership is usually distributed (i.e., different involved actors take on specific responsibilities), and public actors have a coordinating role. Furthermore, Hofstad et al. [11] stress that co-creation leadership is challenging, and common barriers include the absence of formal authority, complexity of processes, poor or weak alignment among actors, and goals and solutions that may change in time [11].

The aspect of collaboration among stakeholders from different organizations was studied by Gray [14] with a domain- and process-oriented approach. The domain approach shifts the focus from the single organization to the interdependencies among stakeholders' perspectives, toward the challenges at hand. Conditions

facilitating inter-organizational collaboration are suggested for each stage of the collaboration process (problem-setting, direction-setting, and structuring). Gray suggests that analyzing the negotiation processes among stakeholders belonging to "non-formally established networks", could be beneficial for the conductor of the collaboration for understanding how to promote collaboration, and it is concluded that comparative studies are needed to derive general principles [14].

2.2 *Public Sector Leadership and Co-Creation in Sustainability Projects*

The role of the public sector has evolved in the last decades from a bureaucratic and top-down fashion to a more inclusive and collaborative one. The management paradigms the public sector has been through are known in the literature as Traditional Public Administration (TPA), New Public Management (NPM), and New Public Governance (NPG) as presented, for example by Tortzen [15]. Briefly summarized, as compared to TPA, NPM emphasizes the efficiency and quality of services, while the focus of NPG is co-creation and collaboration in networks and partnerships. Torfing et al. [16] suggest that the role of municipalities has drifted toward a form of governance similar to the system that existed before current welfare systems were established and link this change to the rise of "co-creation" as a way to solve problems by gathering competencies also from outside the municipalities and which is characterized by an active participation of diverse actors. The tendency for the co-creation mode of working seems to be the result of an increase in expectations from citizens, in combination with a decrease in available resources in municipalities [16], and of the increased complexity of problems to be solved [17, 18]. These are, among other factors, also seen as drivers for public innovation [19].

The concept of co-creation was originally developed in the private sector, and it was concerned with the involvement of the customer in creating a product that would satisfy its needs. Torfing et al. [17] point out the relevance of co-creation for the public sector with regard to the aspect of creating services for the satisfaction of the user; further, they highlight a distinction between co-creation and co-production, as in the latter the actors are the providers and the users of the service, and the focus is toward a specific service/product. Co-creation, instead, refers to the process between public and private actors aimed at collectively solving shared problems and creating public value. Furthermore, Torfing et al. [17] draw attention to the difference between the concepts of social innovation and collaborative governance. Social innovation comprises initiatives by civil society that arise to respond to social needs not supplied by the public sector, while co-creation involves interaction between, and concerted efforts by, private and public actors. On the other hand, collaborative governance does not aim to create innovative solutions, but multi-stakeholder collaboration is rather a way of governing. It "aims to make or implement public policy or manage public programs or assets" [20].

Co-creation has been extensively studied [15–17, 21, 22]. Despite this, Sillak et al. [22] claim that a more structured approach to co-creation is needed and proposed a framework for the assessment of co-creation processes for energy transitions based on three aspects, that is, involved actors, tools to enhance collaboration, and outcomes. Torfing et al. [16] also argue that attention should be directed toward the effects of co-creation and the leadership of co-creation processes.

2.3 Leadership Roles in PED Projects and Theory

Collaboration among stakeholders that belong to "non-formally established networks" is necessary when complex problems arise [14], often also called "wicked problems" in the literature (see, e.g., [23, 24]). A diverse set of stakeholders must be involved to solve "wicked problems" (see, e.g., [14]): engagement will also contribute to create a sense of ownership [11] and increased acceptance [13]. Nonetheless, collaboration among stakeholders needs to be coordinated and supported.

Leadership by the public sector is considered important to initiate and support PED initiatives [2]. However, the formal leader of PED projects is not always the public sector in practice and the leadership needed for a PED project to be successful may not rest only with the formal leaders and managers. PED projects can be initiated and led by either public, private, or non-profit actors, including associations, public institutions, or private companies, and the heterogeneity of actors involved in PEDs makes it hard to point out an ideal lead organization a priori. Nevertheless, we argue, that understanding leadership roles and functions is of a more generic character and will be relevant no matter who is the formal initiator of a PED project. The different leadership roles needed to implement a PED project are thus an important area for research. Who does what, when, and how? And are these leadership roles definable as part of a formal organizational structure, or do they emerge more informally and ad hoc?

Torfing et al. [17] highlight aspects of public leadership of co-creation processes and suggest established leadership theories (e.g., distributed leadership and horizontal leadership, among others) that emphasize that aspect. Many aspects of leadership of co-creation highlighted in the study by Torfing et al. [17] are relevant also for the leadership of PED projects, for example, delegation of tasks among stakeholders, framing stakeholders' contributions, and leading without a strong traditional authority.

One perspective for researching effective leadership, as presented by Jacobsen and Thorsvik [25], is to study what the leader typically does, and it is referred to as a leader's role. One such approach to defining leadership roles is Mintzberg's theory on managerial roles [26], developed from the observation of corporate managers' and leaders' practices together with an analysis of existing literature on the topic. Mintzberg suggests leadership roles can be categorized into three main groups, that is, interpersonal roles, informational roles, and decisional roles [25, 26].

Table 1 Leadership roles according to [26]

Main categories	Domain	Sub-categories
Interpersonal roles	Making contacts and creating a network	Figurehead role Leader role Liaison role
Informational roles	Processing information	Monitor role Dissemination role Spokesperson role
Decisional roles	Making decisions and strategy	Entrepreneur role Disturbance handler role Resources allocator role Negotiator role

Interpersonal roles are related to activities for establishing or maintaining contact with external actors, nurturing relations with the core work team, and fostering potential new collaborations. Informational roles regard the "processing of information" [26], where the flow of information is going in both directions from and to the organization, while decisional roles revolve around the process of decision-making, which in turn is related to identifying possibilities, discarding non-productive issues, or solving problems that may affect the efficiency of processes, choosing how to use resources, and negotiating collaborations [25, 26]. Table 1 illustrates the three main categories and the sub-categories; more details can be found in [25].

Earlier, we discussed the need to further understand leadership roles in PED projects. The existing literature emphasizes the need for multi-stakeholder collaboration and co-creation as a dominant way to orchestrate stakeholder contributions. In the previous section, it was shown how a strand of literature focuses on inter-institutional/-organizational collaboration and co-creation and sheds light on the importance, as well as complexity, of co-creation, the leadership of co-creation processes, and the coordination of stakeholders' resources. To enhance our understanding of leadership roles, we introduced the theory by Mintzberg, taken from strategic management literature, which focuses on leadership roles. However, we do not necessarily argue that all these leadership roles are needed in every project, and we also do not assume that the leadership roles above are necessarily attached to a formal position, that is, project manager or communication manager. Some leadership roles are only needed for short periods and may be filled informally by a person or group that "steps" up. How leadership roles are enacted and filled in practice is thus important to be understood to advance our knowledge of PED co-creation processes. We suggest that combining elements from the collaborative governance literature with approaches from the management literature could contribute to the existing PED pilots and cases in Europe and common practices of leadership therein. This will build a starting point to draw guidelines for effective leadership of PED processes and stakeholder coordination.

3 Methodology

Literature reviews (broad and narrow) were chosen as the method to investigate: the importance of the leadership and co-creation topics for PED development projects and the existence of research on the topics, with a special focus on the coordination of people and processes (as discussed in the previous section). A broad search was carried out with Google Scholar (as the search is done everywhere in the publication) and a narrower one with Scopus. The keywords "Positive Energy Districts" and "leadership" or "co-creation" were searched for. As expected, the search with Google Scholar gave a larger number of entries than Scopus, but as the relevance was decreasing, we confirmed by reading the abstract that many of the entries did not contain research or results on the topics we were searching for.

A literature search was carried out with the search engine Google Scholar using the keywords "Positive Energy Districts" and "leadership" and the exact phrase "Positive Energy Districts", in the time range 2018–2024, as 2018 is the year when the concept of PED appeared in the SET-Plan (see introduction). The findings amounted to 391, sorted by relevance and in pages of 10 entries each. The decrease in relevance was confirmed by reading the titles and, if unclear, the abstracts of the papers; the first three pages of entries were analyzed, and it was decided to analyze four entries in depth. These papers were selected as they discuss challenges and the state-of-the-art of PEDs; we deemed them very relevant, especially to confirm that leadership and collaboration among stakeholders are topics that affect the deployment of PEDs. One paper discussing stakeholders' interaction was also included. Papers with an applied approach or focusing more on technical planning were not prioritized in the analysis. We found that sometimes the word leadership was used in a more generic way, for example, to describe the role of cities and PEDs in the energy transition. The keyword Positive Energy District was found somehow to be limiting; some relevant results were found referring to zero-emission neighborhoods or sustainability projects instead of PEDs, and these were included in the analysis.

Similarly, a literature search was carried out using the keywords "Positive Energy Districts" and "co-creation" and the exact phrase "Positive Energy Districts," in the time range 2018 to 2024. The search returned 258 results sorted by relevance. As above, the decrease in relevance was confirmed by reading the titles and, if unclear, the abstracts of the papers. Thus, the first three pages of entries, where each page had 10 entries, were examined and it was decided to analyze 9 papers in depth. Three of these overlap with the previous search. As above, recent reviews or papers reviewing challenges in PEDs were included to confirm the importance of the topic. The other 6 selected papers were included in the in-depth study because they discuss governance, frameworks for collaboration, or tools or methods used to map or coordinate stakeholders. It is worth noting that, despite the large number of entries found containing the keywords, the word "co-creation" referred in several publications to a way of establishing specifically citizen engagement, which is not as broad as stakeholder collaboration, and for this reason, after reading the abstract, they did not seem relevant to our study and were excluded from the in-depth study.

Similar searches were carried out in Scopus. The searches of the same combination of keywords are limited in Scopus to the abstract, title, and keywords and only among peer-reviewed publications. The searches returned one entry for leadership and seven for co-creation. Three out of the seven entries about co-creation overlapped with the results from the Google Scholar searches. Only the paper on leadership was added to the in-depth study because it discusses leadership approaches (top-down vs. bottom-up) and factors that help or hinder stakeholder collaboration according to practitioners involved in PED pilot cases.

In total, based on the two searches, 11 papers were analyzed in depth.

4 Findings

The selected literature confirms the importance of (collaborative) governance and stakeholders' involvement in PEDs [6, 8] and underscores a need for further research focusing on the topic. In a recent review paper by Sassenou et al. [4], the same is attested also when the search is extended to nearly and net-zero districts literature. Furthermore, finding appropriate governance models and promoting stakeholder collaboration will have a high impact on most of the other challenges involved with PED development projects, such as market design, planning and decision-making processes, and balance of energy demand and supply [8]. However, methods and tools for motivating stakeholders and establishing "a common vision and shared values" are needed according to Sareen et al. [6]. Stakeholder collaboration is sometimes interpreted as a dimension of social innovation [27] or a factor that can contribute to reaching the social objectives of PEDs [28].

The examined literature supports the statement that co-creation and stakeholder engagement are crucial for developing PEDs (e.g., [4]). Most of the papers focus on conditions to enable co-creation or ways to promote it. As an example, an open innovation approach, a quadruple helix participation model of collaboration, early involvement of stakeholders (already in the idea/project development stage), and making results available are indicated in [29]. In [30], stakeholders' analysis and "business models for sustainability" are presented as tools to map interests and align goals, and therefore coordinate and support co-creation processes.

Mattsson et al. [31] investigated what kind of organization appears to be in a better position to lead PEDs and the type of PED initiative (top-down or bottom-up) that turns out to be more successful by interviewing practitioners involved in PED pilots in Sweden. The study found that communication and transparency support PED development projects and that PED pilots contribute to improved collaboration and knowledge sharing. Nonetheless, different goals among stakeholders may hinder collaboration and it is suggested that "creating a common picture" could help counteract this [31].

A better definition of energy concepts (meanings and methodologies for calculations) in relation to PEDs, for example, energy demand and consumption, energy production and supply, energy balance, and energy performance, as well as a

common terminology, is also seen as crucial for the deployment of PEDs and communication among stakeholders [4]. This will also ease the transferability of results and experiences among pilots. As an example, efforts on collecting and comparing results are ongoing, for example, database development [9], but the categorization is complicated by the lack of agreed terminology. Different terminologies (low, net/nearly zero energy/emission) also make it difficult to compare results and for non-expert, readers to follow the development in the field [7]. Mattsson et al. [32] organized a workshop with practitioners and researchers working on PEDs in Sweden, and from the discussion on drivers and challenges to setup PEDs, they concluded that collaboration and leadership were "mentioned as important drivers" [32], and their lack is seen as a challenge.

In sum, we can conclude that the literature has so far given more attention to formal structures and framework conditions in facilitating processes and negotiations among stakeholders or actors, than to leadership roles or dynamics among stakeholders. Little was found that explicitly discussed how leadership is exercised so we could not identify, in the analyzed material, forms of leadership or leadership roles.

5 Discussion

Complexity and a lack of formalized regulatory and institutional settings strengthen the need for co-creation and collaboration as important framework conditions for PED development. However, this literature review shows that there seems to be an absence of literature on PEDs that focuses on the orchestration of processes and leadership roles, although the literature on multi-stakeholder collaboration and co-creation suggests that leadership is important. One of the possible weaknesses of the existing literature is the focus on collaborative governance structures rather than collaborative processes, that is, there is a stronger focus on what conditions need to be in place and less on the actual practices. For this reason, this study introduced theories of leadership roles from strategic management literature that have a stronger focus on roles, functions, and processes.

The leadership roles' framework was proposed by Mintzberg in 1973 [26] after observing the practice of several managers/leaders. These leaders had a formal leadership position in a corporate setting where responsibilities were formally distributed and an organizational hierarchy or structure was defined. The stakeholders involved in the creation of a PED participate in the development process and often make decisions under the orchestration of a formal leader, such as a public sector actor. The collaboration framework in most PED projects is, however, much less well defined than in a formal organization. The formal leader in a PED project cannot always dictate what other participants should do, and the roles or responsibilities, unless agreed by all the stakeholders, are much more diffuse. Thus, while the leadership roles are clearly assigned in the organization of a corporation, PED projects may entail more uncertainty on how these roles are enacted or assigned, and how they may be distributed among stakeholders.

Research is thus needed on leadership roles and functions by looking at practices so far in PEDs to understand what leadership roles are usually necessary, who assigns them or who takes them on, and to answer the question if more formal structures would enable more efficient PED development processes or not. Such insights into the organizational processes of leadership may help the acceleration of PED implementation, and other collaborative sustainability initiatives, in the future.

Based on the literature review and theories of leadership roles, we propose further research that is more focused on organizational processes rather than framework conditions for PED deployment, posing the following questions for further research:

- What leadership roles are needed and when they are needed?
- How are leadership roles "filled" both formally and informally, and when?
- Do certain organizations or actors take on some leadership roles more naturally than others, and why?

As PED pilots and PED-relevant cases around Europe are building experience in the implementation processes around the development of PEDs, the investigation of these processes, including the involved actors, responsibilities, and decision-making criteria, in existing PED pilots seen from a leadership roles perspective could help improve our understanding of success factors and thus support and ease transferability of knowledge and experience.

The main limitation of this study is represented by the fact that the literature search was quite narrow as well as the in-depth analysis focused on the keywords Positive Energy Districts and Leadership provided few results. As discussed above, more results could have been found by extending the search to a wider area (zero neighborhood). Results from Smart Cities that can be transferred to the goals of PEDs could have also been relevant. However, this study was meant as an exploratory exercise and wanted to highlight needs and suggest the potential of using existing strategic tools to support stakeholder collaboration in PED development.

6 Conclusions

The role of the public sector has been well-defined in traditional urban development projects, where the public sector has, for example, supported developers following procedures and filling requirements, and actors involved in such processes have had clear roles with assigned responsibilities. However, the increased complexity of urban projects, additional requirements called for by climate change and restricted budgets, have forced a change in the role of the public sector and in the type of collaboration with external actors. PED initiatives are still in an early phase and involve uncertainties, partly due to a still vague definition of the PED concept, which makes assessment of the results difficult. The roles and responsibilities of the involved actors are often vague or not well-defined and may change during the design and development process. Collaboration is voluntary and is driven by interests of different kinds. Leadership is not bound to any established structure of governance, and the way decisions are taken, is not clear.

Tools for promoting co-creation and stakeholders (especially citizens) engagement are developed and tested in several research and innovation projects, and research on the role of cities and new tasks for public managers was found. Nonetheless, the way leadership roles are exercised needs to receive more attention to ease the transfer of learnings from pilots and tests and create best practices and guidelines for practitioners. While there is an emphasis on the importance of the engagement of multiple stakeholders in designing PED projects and a co-creation process in making decisions, our literature search showed that little attention is paid to the various leadership roles and the involved processes in these projects. A multi-stakeholder perspective is present no matter who leads the initiative (public, or private; for-profit or non-profit organization); however, leadership roles and tasks, and who takes them on, seem to be only superficially discussed in the existing literature on PEDs. It is therefore suggested to conduct further research on the leadership aspects of PED planning and implementation. The leadership roles framework proposed by Mintzberg [26] provides an existing analytical framework to analyze processes and roles in PED development projects from a strategic management perspective. Studies examining leadership roles, as they appear in different PED projects—paying attention to relations between actors, flow of information and decision-making arenas, criteria, and steps could provide valuable insights into what leadership roles are needed for successful PED implementation.

1 Introduction

The term "sustainability" was first introduced in the Brundtland Commission re-port "Our Common Future" in 1987 [1]. Here, sustainability was defined as "meeting the needs of the present without compromising the ability of future generations to meet their own needs." The report divided sustainability into three parts, environmental, economic, and social aspects. Later, during the conference "World Summit on Social Development" in 1995, the understanding was further developed to emphasize that "economic development, social development, and environmental protection interact and reinforce each other mutually" [2].

M. Kioumarsi, B. Shafei (eds.), *The 1st International Conference on Net-Zero Built Environment*, Lecture Notes in Civil Engineering 237,
https://doi.org/10.1007/978-3-031-69626-8_149

Norway as a nation has a considerable amount of history in terms of sustainable development, going all the way back to 2002 when the first national strategy was drafted [3]. The strategy plan was developed with United Nations sustainability goals in mind. Currently, Norway ranks 7th with a score of 82 out of 100 among all other UN member states [4]. The score is a representation of the total progress made for UN's sustainable development goals. With this in mind we set out to find what sustainability means for engineers in Norway on a personal and work-related basis.

The goal of this study is to analyze the position of sustainability in the construction industry in Norway by mapping engineers' perspectives on the matter in this field. The study aims to encompass the significance of sustainability in individuals' personal lives, in the professional sphere, and generally within the industry. The following research question is formulated to steer toward this goal: *What is the perspective on sustainability in the construction industry today, and how can it be improved further?*

To assess the role of sustainability in the construction industry in Norway, data was collected by conducting interviews. Ten interviews have been conducted with actively working engineers, varying in levels of experience and holding different roles in projects.

2 Background and Theory

2.1 Origin of the Term Sustainability

Sustainable development was first introduced by the conference "World Commission on Environment and Development (WCED)" in 1987 [1]. The report "Our common future" which was issued during the conference defined sustainable development as "... development that meets the needs of the present without compromising the ability of future generations to meet their own needs." The key aspects that were recognized as a part of sustainable development were environmental, economic and social aspects. They were used to establish the foundation upon which further development could be made. The purpose of the report was to shed light on the negative impact that human activity has on the planet and highlight the importance of altering our practices. Today the conference is largely seen as an important milestone that sets the tone for future progress regarding sustainability [2].

During the conference "World Summit on Social Development" in 1995, the understanding of sustainability was updated [2]. The aim was to put a greater focus on the social aspects of sustainability. As a result of the conference, the three aspects of sustainability were considered equally important and interdependent on each other. All three had to be included and well-balanced in order to achieve sustainability.

2.2 Three Aspects Within Sustainability

The social element of sustainability is deeply intertwined with both the environmental and economic aspects. Achieving social equity is an important pillar for establishing a well-functioning society [5]. Areas highlighted as crucial are poverty alleviation, health care, quality education and protection of human rights. By adhering to policies that protect human capital, a well-adjusted society can be created. Policies that ensure that the working conditions are humane, and that people are compensated in a fair manner are the cornerstones of achieving social sustainability.

Environmental sustainability often takes center stage when sustainability is mentioned. One reason for this can be the growing concern about climate change. There is a strong link between the environmental aspects and climate change. It is heavily publicized that the recent changes in weather patterns are the result of human activity. These changes are often intricately linked to increasing greenhouse emissions resulting from polluting industrial processes and improper waste management [6].

Economic sustainability is to ensure economic growth without compromising on the environmental and social aspects. Some aspects of it are balanced economic growth and efficient resource use. A balanced economic growth must benefit all segments of society. It ought to ensure growth in the whole world, not just individual societies. A challenge while pursuing a sustainable economy is to cover human needs while staying within the limits of the earth's tolerance [7].

2.3 Previous Studies

Abdulmaksoud et al. [8] carried out a study on perceptions of sustainability in the construction sector [8]. The report stated that "Sustainability has a solid understanding on a broad level; however, in construction, there is no consensus about what it encompasses." The study indicates that it is necessary to increase the common understanding of the word and raise more consciousness around the topic. The study also shows that the social and economic aspects do not get the same attention and end up as less important as the environmental aspects. They have pointed out that it is essential to develop guidelines and common definitions to make it easier to interact with the building sector.

Fufa et al. [9] presenting user perspectives on the reuse of construction products in Norway [9]. The study indicates that there is a struggle in the Norwegian market between containing costs and at the same time front sustainability in projects. The findings show that customers seem to be more concerned about the economy than the environmental impact [10]. Another factor is a lack of understanding of how to reuse, and the need for a clear and balanced definition. The report cites that "*Laws and regulations, testing, documentation and certification, and economic subsidies are mentioned as the top three measures to address the current barriers*."

Moreover, Knoth [11] has studied perspectives on the reuse of construction products in Norway. They have done interviews, and "lack of information" is mentioned as the biggest challenge related to reuse. It is also suggested that "*reuse in Norway could be greatly advanced by more communication and cooperation between different actors in the value chain.*" Additionally, the government offers little to no incentives or regulations. They need to adjust the policies in favor of reuse.

Cerin et al. [12] have studied business incentives as an approach to sustainability [12]. The report states that "*Public and private demands for sustainable development put pressure on firms to develop strategies that include environmental concerns.*" Furthermore, companies often possess the competence to optimize the total life cycle environmental performance of their products. The lack of requirements and incentives from the authorities may be a factor that contributes to sustainability being opted out.

3 Method

This study utilizes a qualitative method based on a series of semi-structure interviews. The semi-structured method gives the possibility to follow a set of predefined questions, and at the same time gives flexibility to make changes during the interviews. The goal is to get the participants to feel safe and to answer freely and express honestly about the subject [13].

For the study, 10 interviews have been conducted with active engineers in the Norwegian construction sector. Seventy percent of the participants work in big-size companies, while 30% work in small to medium-sized companies with less than 100 employees. All the respondents have an engineering title and at least 4 years of relevant experience working as an engineer.

An interview guide was developed with three parts; the introduction, the main part and the cool down [13]. The order of the questions was changed depending on the answers that were given. This way the participants could answer more freely, and it contributed to a natural flow in the conversation. Toward the end of the interviews, some lighter questions were included to ease the conversation, facilitating a natural conclusion. Participants were given the opportunity to ask questions or add comments by the end of the session.

Before collecting the main data, the interview guide was tested with a pilot interview to assess the effectiveness of the questions. After the pilot interview, the questions were reviewed and adjusted slightly to improve the flow of the interviews. Ahead of the interviews, all respondents received a consent form to sign, together with the interview guide and some information about the study by email. The interviews were conducted one-on-one and recorded via Teams, lasting between 45 and 60 min.

3.1 Review and Analysis of Collected Data

Following data collection, the transcript program "Autotekst" from the University of Oslo was utilized to transcribe the interviews automatically. Subsequently, each interview transcript was thoroughly analyzed and summarized. Given the semi-structured interview method, participants' opinions were closely monitored throughout the text, employing inductive reasoning to draw general conclusions when necessary.

After closely examining the individual interviews, they were compared to each other to look for similarities and differences in the answers, checking for patterns and thematic areas.

4 Results

The informants' opinions are reflected and presented in five categories throughout the chapter, where relevant quotations will be presented. They are as follows: Sects. 4.1, 4.2, 4.3, 4.4, and 4.5.

4.1 Individual Understanding of Sustainability

In order to assess the participants' understanding of sustainability, they were asked how they understand the word sustainability and what sustainability and environmental awareness mean to them personally and in everyday life.

When the participants were inquired about their understanding of sustainability, 8 out of 10 primarily emphasized the environmental dimensions of sustainability. The majority talked about energy use, reduction in CO_2 emissions, the future of the planet and natural resources availability. Some mentioned the importance of taking care of the planet, not just for the present generation, but also for future generations to come. The participants also talked about the importance of finding sustainable solutions, and responsible use of natural resources.

Two participants brought up social aspects of sustainability. They talked about the importance of people having their basic needs covered. They mentioned that it is important to take into account the working conditions and how those can affect the health of the workers. One participant said that sustainability is also to "... make sure that you have sustainable production with the people who stands and works with the products, tests the products, supervising, and making sure that there are good working conditions and that whole bit too." He added that humans are resources and if people have their basic needs covered, they will be better members of society.

Some of the participants said that they gave importance to sustainability and the environment in their everyday life, while others believed that it was not a thought in theirs. One interviewee said that he tried to contribute by focusing on everyday

choices that are environment friendly. For example, he said "... I don't have a car. I usually cycle or walk if I'm going somewhere, or I just use public transportation. I'm frugal with the use of energy and things like that. Sometimes I'm wondering if I'm a bit stingy...." Another participant spoke about this by saying "... I'm probably not one of the most environmentally conscious, but I find it more rewarding when I know something is environmentally friendly than doing things that are not environmentally friendly."

While some participants actively made choices that they considered environment friendly, others talked about being affected by economic factors. A participant shared his thoughts on electric cars and heat pumps, which are generally considered more environment friendly than the alternatives as a car on fossil fuel, or not having a heat pump. He stated: "I drive an electric car. Whether the motivation behind it is to be environmentally conscious, or simply because of all of the incentives that are available ..." and "I haven't installed a heat pump at home, but if the electricity gets expensive enough, then it can be considered. ..." He later added that he thinks electric cars and heat pumps are better for the environment, but his choices are affected by the prices. There were several people who brought up electric cars as an example, and they mostly reasoned their choices with the prices or subsidies.

One participant additionally linked his understanding of sustainability to the upbringing of his children, by expressing "... I am concerned that my children should have a safe and good place to grow up. And sustainability is important for that to happen." The social aspect was brought up by a few, and the importance of sustainable food production was also referred to.

4.2 General Thoughts About Sustainability

The participants were asked general questions about sustainability in projects. These questions were about sustainable projects, the implementation of sustainability in projects, and who is responsible for ensuring implementation of sustainability in projects.

In response to what the participants considered a sustainable project, there was a strong focus on the environmental aspect. One participant mentioned, "One should try to use materials with low carbon footprint. Attempt to use recyclable materials. Recycled materials. And then, it's about the energy use in the building. It should be energy neutral." Another participant spoke about "... ensuring that there is not a significant impact on society or resources" and being mindful of ecosystems that are affected. Additionally, attention was drawn to "CO_2, transportation to and from places, the entire life cycle, life cycle costs, and emissions." The choice of energy source was also highlighted as crucial in defining a sustainable project, as "the building is supposed to stand there and live for 60−100 years" and therefore "it's important to look at the entire period, not just the construction period."

Another participant, also focusing on the environmental aspect, stated, "A lot revolves around the choice of products. This means minimizing the impact on the environment when producing products and making the right choice when selecting

the components these products are built from. It is important to consider the product's life cycle and that it is possible to recycle the product when we are done with it. Transport is very important. Transport is a significant thief when it comes to energy consumption and materials." However, he concluded by bringing in social aspects, saying, "Another important factor is the people who work in the production of these products; they must work under good working conditions. This is also sustainability."

A couple of participants also mentioned economic aspects associated with the concept. It was stated that a sustainable project is "...one that achieves economic gain, so the company doesn't go under. If you look at it from an environmental perspective, a sustainable project is a project with high environmental ambitions." The participant brings in the environmental aspect, similar to the majority of those interviewed.

In response to the question of who is responsible for promoting sustainable solutions in construction projects, most participants agreed that the project owner bears responsibility for their project and, consequently, has a duty to set requirements for other parties involved in the construction process. However, it was acknowledged that no single party carries the responsibility for everything.

Another participant, who also believes that implementing sustainability in projects is a shared responsibility among all actors, says, "It's probably not just one of them. It's probably everyone. The municipality and the state have a responsibility to force the industry over through regulations. The project owner has a responsibility to facilitate the implementation of sustainable construction projects. The consultant is crucial in the planning phase... The contractor has a responsibility to make sustainable purchases."

The government's responsibility was emphasized, "They have the authority to impose on the industry through mandates and regulations." Furthermore, it is mentioned that the government can demand more from the construction industry, but "Many politicians may not fully understand sustainability and often use it as a trendy term without much knowledge." Several agree that it needs to be more requirements, but also incentives and support to implement measures for more sustainability, because "Where funds are limited, sustainability is deprioritized."

It is also noted that, in addition to requirements, flexibility should be shown in cases where the requirements are unreasonable. A highlighted example is that the construction of zero-emission buildings can be costly and not an absolute necessity.

4.3 Attitudes on Sustainability in the Construction Industry

The industry's stance toward sustainability has been examined and the main features of thoughts and clear extremes are presented. It has also been explored if competence development is encouraged, whether the industry is willing to choose less tested solutions, and what hinders and promotes sustainable development.

One participant noted, "We are evolving. We have started with emission-free construction sites and waste management. Something is happening. I believe the industry's stance is that it should change. But it changes very slowly, because there are few who take the lead and responsibility." Several participants expressed that the industry has a visible wish for progress in a sustainable direction. They mention that an increasing number of companies talk about working on sustainability in their projects. Within companies, participants experience that there are more demands for actions that contribute to reducing the companies' carbon footprint but adds that he thinks it's due to the opportunity to promote his own company.

Some participants emphasized that companies talk about being sustainable but have few projects to showcase as examples of their sustainability efforts. One participant says, "...there are some projects where we earn extremely little money, and we know it before we enter the project, but it's a landmark project ...." She is talking about how companies sometimes enter projects they know will yield very little profit, but they do so to use the project to send specific signals externally. These few projects are often the ones repeatedly highlighted in the companies' marketing.

Many believe that companies focus on measures that provide them with visual documentation of the effort they have put in. Several certifications have been developed, which can be achieved by meeting requirements in specific categories. Certifications are often considered indicators of how environmentally and sustainable a company is. However, it may contribute to a focus on visible measures rather than the entire value chain. One participant notes that "It seems like they are more concerned about the products or solutions they buy to save energy. It's not so much about what has happened along the way before the product reaches them."

There can also be ethical dilemmas associated with proposing sustainable solutions, such as reuse, as it may lead to fewer hours and less work for the company. One participant has considered the thought that "The best thing for my company is to tear everything down and start over because then I get a lot of work. But that's not what's best for society." She mentions that it's a thought she has had, although she hasn't changed her approach due to it. However, she acknowledges that it can be a challenging issue, especially during economic downturns.

Another issue raised is the lack of a defined responsibility allocation for who would be held accountable if a solution ends up being unsuccessful. One participant says, "If you choose a solution that turns out to be poor, expensive, or doesn't work, the responsibility falls on the advisor." She continues by stating, "There's probably a need to look at a distribution of responsibility. If you're going to be willing to push forward less proven solutions, the project owner probably has to expect to share some of that responsibility."

Another challenging issue mentioned is reuse and ensuring the quality of reused products and materials. While reuse is perceived as a sustainable alternative, it requires that products maintain a certain quality in accordance with the country's requirements. "There is much more that can be done regarding things related to the building, such as floors, roofs, and windows. When you look at an electrical installation in a building, there is limited room for reuse. Because there is very little that can be reused, and there is not much flexibility in the choice of materials. Much

is determined through regulations and laws." He believes that some disciplines are not well suited for reuse, and in those cases, there is limited scope for employees working in those areas.

Difficulties can also arise when attempting to incorporate reused products in projects, as it requires extensive collaboration between parties. "we don't have any processes for reuse ... Where should we store products before assembling them again?" The participant mentions that effective and clear logistics solutions are required for storing reused products throughout the process. She further asks, "Who will take responsibility for complaints?" When there isn't a well-established system for reuse, including storage, transportation, and warranty possibilities, it becomes more challenging to choose it as an option.

4.4 Sustainability in Own Work

Engineers' individual initiatives to choose sustainable solutions differ. So does the training they receive in the workplace on this topic. Some prioritize sustainability in their work, while others give it minimal consideration. Some participants said that they have received offers to take courses centered around sustainability. Others mentioned that their company focused on the internal transfer of knowledge. A few said that they hadn't heard about any offers to take courses to extend their knowledge of sustainability related to their work.

The respondents placed a pronounced importance on the individuals as well. It was made clear that engagement with sustainability-related courses can vary considerably. Overall, it was noted that organizational commitment to sustainability is typically manifested through initiatives, such as lunchtime lectures. Such measures were intended to serve as forums for deeper exploration and understanding of sustainability.

Several participants expressed that they didn't have an influence over decisions since the project's framework was already established. When asked if they felt heard when proposing an idea, some respondents answered, "No, if it has economic disadvantages, it can probably be stopped" and "Not always. In my role as a consultant, I have no influence. But if we have a specific standard that we follow, that's something we can point to." Often, economics was pointed out as a recurring factor influencing decisions in a project. However, several participants also felt that there was room to suggest sustainable solutions, but the feasibility was not always straightforward.

The theme of recycling and reuse was repeatedly brought up as a topic that many participants considered sustainable but was not well-executed, or hard to implement in projects. One participant mentioned, "Especially reuse is talked about a lot. It's easy for me to talk about, but it's very difficult for those I collaborate with to relate to" and another stated, "We need a registration system to assess capacity for reused material so that we can incorporate it into the project. When I suggested this, I got no response. That left me a bit frustrated." They expressed a need for regulations before they can use it actively in their work.

4.5 Perspective of Future Outlook on Sustainability

The participants were asked about their thoughts on how sustainability within the construction industry will develop over the next 10 years. There are varying views on the anticipated progress. Two participants who believe there will be an increasing focus on sustainability commented: "... a lot because of the climate changes we are now witnessing. It's no longer just something Greta Thunberg talks about, but something we actually see and experience, causing massive destruction for countries undergoing it." By being drivers and active in sustainable development, companies can use this to promote their own businesses and gain economic benefits.

Another participant believes that if not Norway, the EU might introduce policies that force the state to impose stricter requirements on the construction industry. It seems that there is not much confidence in Norwegian authorities significantly tightening requirements but rather that demands and initiatives must come from elsewhere.

One participant also linked the expected development in sustainability to the economic situation. He discussed how an uncertain economy could deprioritize efforts to achieve long-term goals, instead focusing on short-term concerns. He believed that climate goals might be challenging to attain and could risk being sidelined when the economy declines. Without clear and stringent requirements from authorities, he thought that sustainability in the construction industry might be deprioritized.

The majority predicted significant changes related to requirements and standards. The rehabilitation of buildings and the reuse of components were also mentioned as possible focal points in the industry. Furthermore, a better market for reused components and a significant improvement in legislated rights were suggested.

But for sustainable development it is expressed that we need a clear understanding of what it is. This is proposed through a comment that "In 10 years, we may have progressed further in specifying what it is, and the public understanding may have significantly increased."

5 Discussion

When asked about the participants' actions related to sustainability in private life, profitable alternatives were prioritized, over alternatives that are usually seen as more environment friendly. An example is electric cars which seem to be popular due to government subsidies. Similarly, energy use was deemed important, but the participants did not show any desire to reduce their energy consumption with the reasoning that it can have a positive effect on the environment. The same applies to heat pumps, which were only seen as an option if it was economically profitable to install. In other words, sustainable choices tend to be prioritized, when they are also considered to be favorable for the individuals, not because they are understood to be

sustainable. This is supported by previous research, where findings suggest that people do think about their energy usage, but do not sacrifice their comfort to save energy.

The study has been conducted in Norway, where a high quality of life may impact the perspectives on sustainability [14]. The participants overwhelmingly focused on the environmental aspect of sustainability, with less attention given to social and economic aspects. It indicates that the term is defined based on the situation of the individual or the society. Therefore, a need to concretize what the term "sustainability" actually means, may arise. This will contribute to an increased awareness and better understanding of what the term entails.

The government can regulate the construction industry by reinforcing laws and regulations. They should take part in the responsibility and make it viable for companies to try out new solutions in an effort to help companies transition to more sustainable practices. This can be achieved through subsidies or ensuring that banks loan out money with more favorable terms. By interpreting the answers from the participants, it was clear that the industry requires regulations from the state. It is important to note that such incentives should not have a negative impact on the market while they are developed.

Several companies seem to have the desire to appear sustainably conscious. Internally it is not always reflected. Some of the participants talked about frequent courses and skill development related to sustainable practice, while others were unfamiliar with such courses being available to them through their workplace. The participants who got the chance for further development through their work seemed more positively inclined toward sustainability and were visibly more motivated about the impact of their work. The employee's point of view often tends to influence whether there is a focus on implementing sustainable solutions in projects or not. Therefore, companies should take responsibility for developing their employees.

The different parties involved in a project have individual responsibilities for implementing sustainability, but this can lead to conflicts over who is responsible if something goes wrong. One solution is to reconsider the distribution of responsibility, so all parties would share some of the blame. Under the current distribution, a participant experienced that consultants may hold back less proven solutions in fear of being left to bear the responsibility all alone. To encourage parties to propose and implement innovative solutions, one can explore solutions where responsibility is shared among all of the involved parties. It must be rewarding for everyone to implement sustainability in projects. Tenants can also have more strict and clear requirements for the building owners. Then the builder has to build based on market demand.

There are no effective systems related to reuse, with slow development in the area. It also appears that the industry does not perceive the existing regulations as adequate. It was made clear that the requirements did not address the needs of the industry. This indicates a need for more guidelines and requirements to facilitate a smooth project flow and make material reuse more straightforward.

6 Conclusion

The goal of the study has been to analyze the perspectives on sustainability in the construction industry. This has been done by conducting interviews with ten engineers with varying levels of experience. The interviews have included questions related to the engineers' individual understanding of sustainability in their private and working life, attitudes toward sustainability in the industry, sustainability in their own work and their perspective of future outlook on sustainability.

Even though most of the participants did not perceive themselves as environmentally conscious, there were indications that they considered sustainable and environmentally friendly alternatives to be more positive and rewarding. This also reflects the building industry, where companies have an increasing activity in regard to sustainability. A dominant factor mentioned during the interviews is the marketing of one's own company as sustainable to secure a larger market share. However, this contributes to a willingness for development in the field. To force the construction industry the government needs to impose stricter requirements and regulations. Subsidies and better loan terms can be used as encouragement and a light push of the industry in the right direction. The industry should also take responsibility into its own hands and start implementing measures that results in providing the necessary opportunities for the development of new and innovative solutions. It is proposed to do it through an even distribution of responsibility.

To answer the research question, the industry is showing an increasing interest in ensuring sustainable societal development but still faces many obstacles that need to be overcome. In this progression, it is essential not to wait for others, but for companies and individuals to take the lead themselves. The responsibility lies with everyone, and the work must be done collaboratively.

1 Introduction

In recent decades, European countries have been facing shared healthcare challenges arising from several fronts that require significant improvements in the efficiency and effectiveness of national healthcare service delivery.

The latest pandemic emergency has highlighted the need to improve the emergency preparedness of national healthcare services, thus requiring more flexible and resilient systems. This awareness is coupled with a growing demand for healthcare services—due to ageing populations, the prevalence of chronic diseases, medical advancements, etc.—which, in turn, clashes with economic constraints and workforce shortages. In light of these challenges, it has become increasingly evident that primary care plays a crucial role in improving the efficiency, effectiveness and adaptability in response to emergencies and evolving health needs [1–3]. Consequently, many European countries have been reorienting their healthcare policies towards enhancing local care services, strengthening existing or developing new

facilities based on primary care. This model aims to bring care closer to where people live, thereby offering a more convenient, accessible, reliable and familiar point of contact for healthcare services, ultimately leading to reduced unnecessary hospitalisations and increased patient satisfaction.

Second, there is an urgent need for healthcare buildings to become more energy-efficient, aligning with broader global efforts to mitigate climate change and reduce carbon emissions. It is widely acknowledged that healthcare facilities are among the most energy-intensive buildings, mainly due to their continuous operation [4–7]. At the same time, in the building sector, there is a noticeable trend towards considering sustainability and comfort levels as interconnected priorities because embracing environmental and sustainable building practices also entails designing high-quality spaces that promote better health conditions for building users [8].

This is tied to another observation: in healthcare facilities, the built environment plays a significant role with a direct impact on both the end users' well-being and clinical outcomes [9–11]. Certainly, the design of physical environments can facilitate healthcare and non-healthcare activities to be performed. Additionally, the scientific literature in this field demonstrates that the healthcare-built environment can have both physical and psychological impacts on end users, including patients, staff, visitors and the local community, with consequences on their experience and satisfaction [12, 13]. As a result, the perceived comfort level for users is increasingly being regarded as a key metric of the effectiveness of healthcare buildings [8].

1.1 The Role of Building Performance Evaluation

In this evolving context, in which efficiency and effectiveness—partly derived from economic constraints—are the driving forces behind a transition towards new organisational models, building performance evaluation has become a critical aspect of the construction and operation of buildings.

In the past decades, the assessment of built environments has evolved from traditional methods like post-occupancy evaluation (POE) to a more comprehensive approach known as building performance evaluation (BPE) [14]. POE focuses on gathering feedback once the building has been used for a certain period of time, to assess whether design requirements and users' needs are met by the design. In contrast, BPE involves assessments that may occur throughout the building process, from the initial brief to the post-occupancy phases, to ensure that built environments fulfil users' needs and achieve clinical outcomes, economic feasibility and long-term sustainability.

In the present context, in which new organisational models have few prior examples to reference, uncertainty may arise regarding the most effective design and construction choices. Particularly in healthcare facilities, design entails a delicate balance between various needs and requirements. For example, functional layouts may not always align perfectly with the most effective energy-efficient solutions or environmental requirements can sometimes pose challenges to flexible

design solutions. Then, it becomes significant to determine relevant priorities to achieve optimal building performance.

This underscores the need for BPE tools that may provide a rational basis to guide designers and local public authorities to optimise care facility design choices according to the needs and objectives to be prioritised. By adopting these tools, evaluations can generally result in the early detection and resolution of potential design issues and provide assurance that the facilities not only adhere to regulatory standards but also provide a high-quality environment that serves their intended purpose.

1.2 Research Objectives

At the moment, in the European context, existing evaluation tools primarily focus on hospitals or healthcare facilities in general, while there is a lack of studies centred on the evaluation of primary care environments. Although tools developed for hospitals or healthcare premises, as well as those originating from distant contexts, may offer relevant methodologies and outcomes, it is important to recognise that the primary care facilities in Europe have unique objectives and characteristics that require specific considerations when evaluating these healthcare settings (e.g. they cater to community health needs, they place emphasis on prevention and health promotion, etc.).

This chapter is part of a broader research that, in light of previous considerations, aims to streamline the development of evaluation tools for healthcare-built environments that are suitable for the current transition phase underway in European countries.

The goal is to establish a consistent and systematic approach to evaluating the design quality of primary care facilities throughout the design process, as well as post-construction and occupancy, to support effective implementation of high-quality and sustainable interventions, and to facilitate the exchange of information that can inform future design and projects.

Consequently, the aim of this chapter is to analyse validated evaluation tools for healthcare-built environments to provide a comprehensive understanding of their main characteristics, thereby developing a guideline framework that prompts reflection on the potential to either adapt existing tools or develop new ones tailored to assessing local care facilities.

2 Methods

This research comprised a literature review conducted through keyword searches across three main repositories (i.e. Scopus, Science Direct and Google Scholar), aimed at gathering relevant information regarding the existing tools and methodologies for evaluating healthcare-built environments. The literature search yielded the

[a]For a more comprehensive understanding of the analysed tools, this column directly references the tools' websites as well as the reports and research papers outlining the tools' development process and the their features

identification of several tools, among which nine were selected for further analysis, based on their international relevance and reliability as well as availability of information (Table 1).

Moreover, additional grey literature was retrieved by specifically searching for each of the selected tools; this included the main websites, reports and documents provided by the developers and users of the tools as well as research papers presenting or adopting the selected tools. The available information was then screened, read and analysed.

Additionally, thematic analysis was applied using a comparison grid aimed at collecting and comparing the attributes of the selected tools, as listed in Table 2.

Each attribute was analysed using comparative tables in Excel spreadsheets. The features of each tool corresponding to the attributes were listed and summarised to derive the aggregated results for each attribute.

3 Results and Discussion

This research reviewed and analysed the existing healthcare built environment evaluation tools to discuss the relevance of building performance evaluation and post-occupancy evaluation in contributing to the future development of more

Table 2 Attributes included in the comparison grid

effective and sustainable design of local healthcare facilities. This review allows summarising the key characteristics of the existing tools based on their identified attributes, extracted from information sourced from websites, reports and research papers.

The following paragraphs illustrate the main attributes in relation to the aim of this chapter. In the following paragraphs, the numbers in brackets indicate the quantity of tools associated with the specific attribute or feature.

3.1 Target Audience

The user groups explicitly mentioned as targets by the different selected tools are presented in Table 3. They mainly refer to five different categories: (i) healthcare stakeholders, (ii) design and construction stakeholders, (iii) academia, (iv) public authorities and (v) the general public.

Healthcare stakeholders (e.g. clients, facility owners and managers, planners, etc.) are cited by eight tools, with the majority focusing on healthcare organisations and providers (6). Architects, designers and contractors are one of the groups targeted by seven tools, primarily focusing on design firms and teams. Mention of governmental bodies is limited to one tool, whereas another underscores the applicability of the tools for healthcare trusts and local authorities. Researchers are also a category of interest, with few tools (2) including them within their scope. Lastly, healthcare facility end users, encompassing patients, staff and visitors and the general public, are referenced by four tools.

3.2 Focus and Aspects Investigated

The focus of the evaluation tools has been categorised according to the four aspects investigated: (i) design quality, (ii) user perceptions, (iii) health outcomes and (iv) sustainability. Almost all of these tools mention focusing on design quality (8), whereas few focus on user perceptions (2), health outcomes (2) and

Table 3 Target audience addressed by the selected tools

General public	x	x		x						3

sustainability (1). Only one tool assesses building performance based solely on user perceptions.

Most tools explicitly affirm to focus on one of these aspects, with only a few reviewing multiple aspects (3), particularly: (i) design quality, user perceptions and health outcomes; (ii) design quality and health outcomes or (iii) design quality and sustainability. The more comprehensive tools are typically designed to be adopted across various stages of the design process, beginning with an expert evaluation of project quality during the initial design phase and extending to gathering feedback on the building performance during post-occupancy phases, when they may also resort to user perceptions and assessments of health outcomes.

It must be noted that, although "sustainability" is directly mentioned by only one tool, when looking at the tools' evaluation domains and criteria, environmental performance and passive or active sustainable design solutions to reduce the environmental impact and enhance energy efficiency are often included in the assessment (6).

3.3 Application Phases

The tools are designed to be used in single or multiple phases of the design and construction process, in particular: (i) planning, (ii) brief, (iii) design,

(iv) construction and (v) post-occupancy. The majority of them are relevant to the briefing (5) and design (8) phases, whereas only few of them are expected to be adopted during the planning (1) and construction (2) stages. Additionally, all tools are suitable for post-occupancy studies, whereas only two tools are exclusively devoted to POE. This stands in contrast to most tools, which—in line with the progressive shift towards BPE—offer at least two or three potential application stages, usually including the briefing, design and operation phases.

3.4 Data Collection Methods

The data collection methods proposed and employed by the selected tools for the assessment of healthcare built environments (Table 4) can be classified as "objective", based on objective physical measures (i.e. taken by means of instruments) or expert judgements as the result of analytic processes of knowledge, or as "subjective", based on users' observations and perceptions shaped by the interpretation and experience of places by those who use them [23].

Among these, checklists are generally used to collect information about project quality (7), based on scoring systems that allow translating qualitative data and observations into quantitative metrics and results. On the other hand, design quality in existing buildings is often evaluated through questionnaires administered to patients, staff or even caregivers or visitors assisting patients within the facility (3). Sometimes, the scorings resulting from checklists or from the sum of individual questionnaire responses are discussed through workshops (3) or focus groups (1).

3.5 Expected Outcomes and Impacts

The tools discussed in this research propose and articulate several outcomes and impacts they seek to achieve, which can be categorised as both direct and indirect. Direct outcomes are relevant to the facility under assessment, whereas indirect impacts extend to broader implications for the design and construction practice beyond the specific project.

In this research, the outcomes and impacts explicitly mentioned in the tools' presentations and reports have been categorised into five main areas of influence: (i) appraise, (ii) compare, (iii) support, (iv) improve and (v) contribute.

Appraise Evaluating the quality of healthcare spaces, albeit from different perspectives, is the primary goal of all the discussed tools. Under this category, the illustrated outcomes are:

- Evaluate the design quality (7): The majority of tools resolve to evaluate the "quality" of the design. The concept of quality is indeed multifaceted and challenging to define [32]. Therefore, it is not surprising that this concept is interpreted differently across various tools, either in terms of building performance and effectiveness, as well as environmental quality, as the performance of design spaces against key healthcare goals, or as a synthetic overview of different "layers" of quality (environmental, organisational, social, etc.).
- Ensure that the design requirements are met (4): Several evaluation tools are aimed at verifying that the project or facility is effective in meeting the preset design and performance goals, whereas others tend to assess the design against specific evidence-based design (EBD) goals.
- Evaluate design against user needs (5): This category includes the evaluation of users' perceptions or satisfaction levels, the assessment of how well the design contributes to the physical support and well-being of end users or to population health or the extent to which spatial–physical features are successfully based on user-centred design.
- Identify strengths and weaknesses (6): Most tools list the identification of issues and weaknesses among their intents and may also pinpoint design strengths. This is oriented to the identification of areas for improvement either during the initial design stages or when opportunities arise for facility renovation or improvement.

Compare The comparison of healthcare facility performance is presented as an opportunity to assess design alternatives or for benchmarking purposes. More specifically:

- Evaluating design alternatives (5): The evaluation of building performance can be beneficial when faced with several design proposals or competing schemes, by facilitating direct comparisons, by informing design choices that align more closely with the project's vision and requirements and by understanding the trade-offs between choices; moreover, adopting assessment tools may provide a rational basis for the evaluation and selection of alternative proposals in

competitive procurement processes. Overall, this practice may also provide a rationale for long-term planning, prioritising investments in new projects or existing building stocks.
- Benchmarking (3): Some tools propose their utilisation for benchmarking, either of cost and quality, against the results from other users of the tool, or benchmarking against facilities of other healthcare providers.

Support The use of evaluation tools can be advantageous in guiding and supporting stakeholders along the implementation of different phases of the design process. More specifically, as often argued by the tool developers:

- Inform decision-making (5): Building performance evaluation offers stakeholders a structured approach to inform, support, facilitate and optimise decision-making processes. Evaluation tools serve as supportive instruments to manage existing healthcare facilities or invest in new projects, especially for existing facilities to be renovated. They also inform client and user choices during the project briefing stage and facilitate decision-making or justification regarding future actions and expenditures.
- Facilitate stakeholder engagement and discussion (4): Another advantage of adopting standardised tools is that they provide a means to engage stakeholders with a structured discussion agenda. They establish a framework to guide stakeholders in effectively communicating, discussing, setting and tracking design quality goals for the project; they may also aid in monitoring design aspirations and managing expectations throughout the process. For instance, a checklist can be used as a basis for collaborating with the facility owner to determine the appropriate standards, thus facilitating comprehensive discussions about "quality" and requirements. In addition, this approach ensures clarity of understanding and a shared vision, allowing for the comparison and integration of views among different participants during the design, procurement and construction processes.

Improve The term "improve" encompasses efforts directed towards enhancing the quality of the project, with a focus on achieving optimal value and integrating evidence into the design process.

- Improve quality (8): The majority of tools claim their effectiveness in driving improvement and enhancing the quality and value of built environments in healthcare settings: first of all, they aid in identifying and resolving issues or identifying key areas for improvement; they provide consistent and useful feedback to the design, construction and maintenance processes for effective building production and use and also inform ongoing building adjustments to accommodate changing organisation needs; they allow fine-tuning the building in response to user needs and feedback and also support constant monitoring of quality improvement processes and, lastly, in the long term, these tools foster the upgrading of existing estates.
- Aim for the best value (5): According to developers and users, the utilisation of several tools can result in projects deriving increased value from building design, ultimately resulting in the best value for investment and achieving excellent

design outcomes. This is primarily attributed to their ability to collect regular and usable feedback that can support in better planning the investments based on different priorities.
- Apply evidence-based design (2): Incorporating research and evidence derived from best practices can direct design choices towards the achievement of high-quality built environments. The use of tools can guide design teams in consciously focusing on lessons learnt derived from evidence-based design, thus underpinning the design and commissioning processes with a firm evidence base. This ensures that essential evidence-based design elements are integrated into the design.

Contribute This term refers to broader impacts, beyond individual projects, which comprise generating knowledge and evidence to support EBD implementation in the healthcare design practice and leading to a potential improvement of future designs.

- Support evidence-based design (2): Obtaining feedback from existing projects and facilities contributes to the ongoing cycle of evidence-based design and construction, by providing insights into the correlation between the physical built environment and its effects on health outcomes, health organisations, user satisfaction and occupant well-being.
- Improve future designs (4): Establishing an association between a particular design solution and its effectiveness can present valuable insights into how to adjust repetitive design solution that can be used on a recurring basis; it can also inform future interventions, by capitalising on user feedback and preferences about the environment. Eventually, this knowledge can inform future projects and contribute to the improvement of the overall design quality in similar types of facilities.

4 Conclusions

Based on the presented analysis of tool attributes, a framework has been conceived with the aim of guiding the future development of evaluation tools for local care facilities.

This framework aids researchers in designing new tools by drawing on past experiences, offering an "orientation map" detailing the relationships between the following attributes: (i) target audience, (ii) aspects investigated, (iii) application phase, (iv) data collection methods and (v) expected outcomes and impacts (Fig. 1).

The development of these tools should be approached with the awareness that the presented methods may facilitate the assessment of different domains, ranging from the functional to the social and environmental aspects of building performance. However, not all domains may be equally significant in the specific context of local care facilities. For instance, functional requirements such as flexibility may

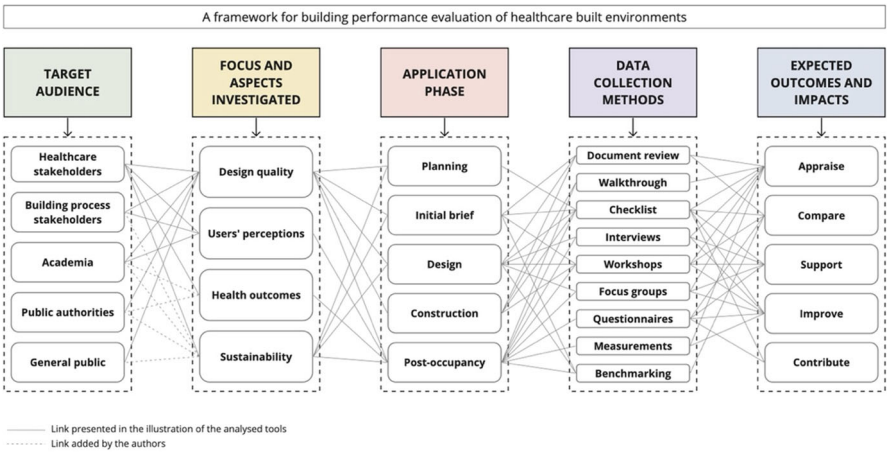

Fig. 1 A framework to support the development of healthcare building performance evaluation tools based on existing experiences

conflict with the optimisation of building systems; in the case of community facilities, resilience and adaptability present great opportunities for the reorganisation of the layouts according to contextual needs. This may enhance their overall utilisation, effectiveness and cost-efficiency, albeit at the expense of energy efficiency.

Consequently, evaluation tools can offer feedback on several evaluation "areas", pinpointing those that are the most critical for the specific typology of care facilities being addressed, therefore establishing a "weight" for each domain. As design poses challenges related to the right balance between functional, social, energy performance, this information can be then used to develop and refine decision support tools to be adopted in the briefing and design phase, to support design decisions by streamlining the prioritisation of design objectives.

1 Introduction

A relevant approach to improve the sustainability of new construction and renovation projects is to limit the consumption of virgin materials by using reclaimed construction products and elements. A reclaimed construction product is one that has been previously used in a building or infrastructure project and that has been dismantled and prepared for being used again in a building or infrastructure project. In this study, we consider that a reclaimed construction product can be used in part or in whole, for the same or a different function, and on the same site or a different site, it then becomes a reused product. Reuse differs from recycling, which implies that energy is used to reprocess products into new products, materials, or substances

[1]. The chosen reuse definition differs from the definition in the EU Waste Framework Directive (WFD), which restricts reuse of products for their original intended purpose [1]. However, following the WFD definition may hinder the rate of reuse, as current practices demonstrate the challenges and limitations associated with using products again for their original purpose. An early example of the extensive use of reclaimed materials in contemporary architecture is the Villa Welpeloo built in Enschede, the Netherlands, in 2005 (architect: 2012Architecten) [2].

Reusing construction products avoids the consumption of virgin products (with all resource extraction, manufacturing, and transport it usually requires) and delays the waste treatment of that product, but also often involves some preparation activities and transport. Whether reuse will lead to environmental, economic, and social benefits depends on various parameters, including the transport to their new use, the interventions needed to put them back into the value chain, such as testing, cleaning, and repair, their remaining service life, and functional performance [3].

Currently, the sustainability of using reclaimed products in construction works is evaluated following various methods and assumptions. Additionally, there is a need for a harmonized sustainability assessment framework to compare the environmental, economic, and social impact of reclaimed and new construction products over their whole life cycle [4, 5].

2 Objective and Scope

The objective of the research was (1) to evaluate the maturity of life cycle environmental assessment (LCA), life cycle costing (LCC), and social LCA (S-LCA) and their compatibility in the context of reclaimed and reused construction products and (2) to develop a harmonized framework for evaluating and comparing side-by-side the environmental, economic, and social impacts of reclaimed and new construction products. This chapter presents the results of the literature review, the developed life cycle sustainability assessment (LCSA) framework and an example of how the LCSA framework can support experts in comparing the sustainability of a pavement in Oslo, Norway, in reclaimed versus new paving stones.

3 Literature Review

3.1 Environmental LCA

LCA is an acknowledged and standardized method to assess the environmental impact of products and services over their whole life cycle [6]. LCA for construction products is covered by ISO 21930 [7] and EN 15804+A2 [8] standards, which are complement by several standards at building and framework levels. There exist several product-specific and generic databases of life cycle inventory and impact

Table 1 Original and adapted nomenclature of the life cycle stages

Life cycle stage	Life cycle stage name [8]	Adapted name for reused parts
A1	Raw material supply	Dismantling of the product
A2	Transport (to manufacturing)	Transport to reconditioning and testing facilities
A3	Manufacturing	Reconditioning, incl. testing
A4	Transport (to construction site)	Transport from seller to building site
A5	Construction/installation	Construction/installation
B1–B7	Operational stage	Operational stage
C1–C4	End-of-life stage	End-of-life stage
D	Potential benefits and loads outside the system boundary	Potential benefits and loads outside the system boundary

assessments of construction materials and products, such as Ecoinvent [9] and Environmental Product Declarations (EPDs). The EN 15804+A2 standard for LCA of construction products provides a nomenclature for the different product life cycle stages of construction products, ranging from A1 to C4, and D (Table 1), but this nomenclature is usually not used in LCC and S-LCA of construction products.

Many studies have shown the environmental benefits of using reclaimed construction products through LCA [3, 10]. A methodological aspect that can greatly affect LCA results is the allocation approach [11]. The EN 15804+A2 [8] standard requires that loads and benefits related to the reuse of secondary materials and products to be allocated following a cutoff (or recycled content) approach, meaning that the environmental impacts from the primary production are allocated to the primary products, while the secondary products are considered burden-free, except for any impacts resulting from the reuse process. Impacts related to future reusability are not part of the product system under study but are reported in a separate module (Module D).

3.2 Life Cycle Costing

Some authors consider that there are three different approaches of LCC [4, 12, 13]. Conventional LCC considers the costs borne by one actor (usually the producer or the consumer) and does not cover all life cycle stages [4, 13]. It is the LCC approach covered in ISO 15686-5 [14] and NS 3454 [15], which is commonly used in Norway. The scope of a conventional LCC is considered less comprehensive than those of an LCA [13]. Environmental LCC is meant to have scope (system boundary and functional unit) in line with the scope of an LCA and includes direct costs for the different actors over the value chain, hence internalizing the costs of externalities (such as for a manufacturer, the cost linked to repairs, and final disposal) for different actors [13]. Societal LCC considers direct costs and costs of externalities for the

whole society and aims to covers environmental and social effects; hence, it is not complemented by an LCA [13]. EN 16627 [16] specifies the calculation methods to assess the economic performance of a building. It is based on the principles of LCC defined in ISO 15686-5, adapted to the European context [16].

3.3 Social LCA

Social LCA (S-LCA) follows the ISO 14040 framework for LCA [6] and includes four phases: goal and scope definition, life cycle inventory, impact assessment, and interpretation [17]. Social-LCI is developed for indicators (e.g., regular and documented payment of workers, number of employees earning wages below poverty line) linked to impact subcategories (e.g., fair salary) that can be linked to impact categories (e.g., working conditions) [17, 18]. The impact categories and subcategories assessed in S-LCA are linked to stakeholder categories (workers, local community, society, consumers, value chain actors, and children), which can be directly affected positively or negatively during the life cycle of a product [17].

UNEP Social LCA guidelines published in 2009 and revised in 2020 [17] is a widely used and up-to-date guidance document, which is accompanied by Methodological Sheets for Subcategories in Social Life Cycle Assessment (S-LCA) published in 2021 [18]. The ISO standards "Principles and framework for social life cycle assessment" is under development. Two of the "pilot projects on guidelines for S-LCA of products and organizations," published in 2022 by life cycle initiative and social life cycle alliance are aluminum profile and steel production cases. These pilot projects can be used for guidance for construction product S-LCAs. Although S-LCA has been used for evaluation of building materials [19], building construction [20], and recycled construction materials [21], its application on reused construction materials is not common.

S-LCA can be applied in two levels, either together or separately: (1) hot spot analysis using available databases like Social Hot Spots Database (SHDB) and Product Social Impact Life Cycle Assessment (PSILCA), which provide social impacts of industries in different countries, and (2) site-specific S-LCA by collecting inventory data for the investigated facility. Compared to LCA databases, the current social databases are less detailed, with social impacts reported per sector and country. For example, it is not possible to distinguish between different types of mineral construction products. However, social databases allow quick comparison of risks related to different producer countries for the same sector or risk mapping.

3.4 Combined LCA-LCC-SLCA Assessments

The European Standard EN 15643:2021 [22] provides a framework for the sustainability assessment of buildings, including their environmental, economic, and social

performance; it does not apply to construction products. Some methodological choices that assessors can make within the framework defined by the standard, such as the definition of the system boundary, affect the way the benefits of reuse are calculated [11, 23]. These benefits also depend on assumptions on uncertain parameters, such as the technical performance of the reclaimed product or its remaining service life.

4 Methods

4.1 LCSA Framework Development

The LCSA framework has been developed as part of the REBUS research project [24], which identified user needs, developed guidelines, and recommendations to increase the reuse of building products in Norway. The project lasted from 2020 to 2023 and focused on five types of products: paving stones [10], interior glass partitions, windows and doors, ventilation components, and sanitary equipment. The scope of the project has influenced the development of the LCSA framework (especially, as it builds on the CEN standards), its applicability to other countries, and product types has not been assessed. The LCSA framework was developed based on findings from the review of the literature (summarized in Sect. 3) and on expert knowledge among the REBUS project partners, including discussions with a consultant specialized in the reclaim of construction products. Methodologically, the underlying principle is that the framework should not prevent the assessor from testing different methods (e.g., different allocation, system boundary, and life cycle costing approach), but that the assessment should be conducted following at least one specific approach: a cutoff (also called "100:0" and recycled content) allocation in the LCA and S-LCA and a conventional LCC approach.

4.2 Pavement Case Study

The case study consists of the comparison of reclaimed and new paving stones for their environmental, economic, and social performance. The functional unit is defined as 1 m^2 of pavement, built in Oslo in 2021 with granite stones, sand, and gravel. The options compared are (1) a pavement with 100% new granite stones (small version) produced in Sweden and (2) a pavement with 100% used granite stones (small version) reclaimed from a street in Oslo. In both cases, the layer of paving stones (10 cm) lies on a layer of new sand (5 cm) and gravel (40 cm).

For the LCA and LCC part, the inventory and assessment data were extracted from a previous report by Fufa et al. [10] where different options and scenarios are evaluated. In the report, the LCA and LCC analyses are conducted in Microsoft Excel and following the standards EN 15804+A2 and NS 3454. The environmental

indicator they assess is Global Warming Potential (in CO_{2e}). Due to lack of EPD for granite paving stones produced in Sweden, Fufa et al. [10] use EPD data for granite paving stones produced in a neighboring country (Finland). The present study uses the now available EPD (number S-P-04621) for granite paving stones produced in Sweden [25], in order to be consistent with the results for the LCC and S-LCA. We follow here the same assessment method as Fufa et al. [10]. Since both options are expected to have the same impact during use and end-of-life, the system boundary for the LCSA covers the production, transport, and installation of the pavement (stages A1 to A5). For the LCA system boundary, Fufa et al. [10] follow a cutoff (recycled content) allocation approach and consider that, once deconstructed and stacked, the reclaimed stones are functionally equivalent to new ones. Therefore, the system boundary for the pavement in reclaimed stones only includes storing the stones in an open-air local storage, transporting some of them to a laboratory and testing them, transporting the rest of them to the re-installation site in Oslo and manually installing them. Fufa et al. [10] consider that, in the reclaimed option, only transport to laboratory and construction site are emitting GHG, the rest being mostly manual activities with neglectable energy consumption, material loss and waste treatment. The system boundary for the pavement in new stones produced in Sweden included material extraction, transport, and manufacturing of the stones, transport to site and manual installation. The system boundary for both options also included the production (in Norway), transport, and installation of the new sand and gravel.

For the LCC, A1–A3 covers the purchasing cost of stones, gravel, and sand. A4 includes the cost of transporting stones, sand, and gravel to the construction site, while A5 includs the cost of installing the pavement with new or reclaimed stones. The cost of testing new stones was assumed to be included in the purchased price. However, for reused stones, testing costs were not included in the purchased price. Even if the cost analysis from testing of the reused stone samples were conducted, it was excluded from the LCC analysis due to uncertainties in the cost scenarios. Data collection method for LCA and LCC can be found in the report [10].

For the S-LCA part, OpenLCA [26] was used with social impact data from SHDB 2019 with "Category Method with Weights" [27]. The social impact categories covered by this database and method are listed and described by Pelletier et. al [28] as: "Labour Rights and Decent Work (with indicator data for child labor; forced labor; excessive working time; wage assessment; poverty; migrant labor; freedom of association, right to strike, and collective bargaining rights); Health and Safety (with indicator data for injuries and fatalities; and toxics and hazards); Human Rights (with indicator data for indigenous rights; gender equity; and high conflicts); Governance (with indicator data for legal system and corruption); and Community Infrastructure (with indicator data for access to hospital beds; improved drinking water; and improved sanitation)." The cost data used as an input in S-LCA was the collected cost data [10], converted to USD_{2021} and without taxes. The reclaimed stones were considered to have zero social impact. The social impacts were accounted for the production of sand and gravel, transport of sand and gravel, and construction of the pavement.

5 Results

5.1 LCSA Framework

Based on the current state of the literature, we decided that the LCSA framework should support consultants and researchers with expertise in LCA, LCC, and/or S-LCA in conducting and reporting the assessment. Therefore, we developed (1) a set of methodological choices, (2) a data collection spreadsheet for general information about the product to assess and its inventory of processes and material flows, and (3) a reporting spreadsheet. The data collection and reporting spreadsheets are combined in a Microsoft Excel file, complemented by a glossary and user guide.

The spreadsheet is only meant for collecting and structuring the product, product inventory, and impact assessment data, and not to generate this data. The impact assessment data should be imported into the spreadsheet from an LCA, LCC, or S-LCA calculation tool. We developed the structure of the Excel spreadsheet based on the four-step approach in LCA of goal and scope definition, inventory, impact assessment, and interpretation [8].

Although Environmental LCC aligns best with LCA on a methodological level [13], we chose a conventional LCC approach (from the perspective of one actor) to simplify the assessment and avoid a formal distinction between internal costs and externalities. This way the costs reported by an actor can be directly reported in the Excel spreadsheet. Regarding the LCA allocation approach between use cycles, our framework requires to apply at least the cutoff approach, which is in line with the "polluter pay" principle in EN 15804+A2. The assessors may complement the assessment with other allocation approaches if it seems relevant for the case. In the inventory data collection sheet for the reclaimed and new products, the different life cycle stages are listed vertically. We also have adapted the name of the life cycle stages for the reclaimed/reused construction product (Table 1). Under each stage, the assessor can list the material flows and processes occurring within the stage. Each material flow and process can be described with the following categories: material flow or process unit (e.g., kg, m^2), amount per unit, cost per unit (both in NOK, including taxes and in USD, excluding taxes), country (where the material flow or the process takes place), and year (when the material flow or the process takes place). Under each life cycle stage, we have provided some examples of material flows and processes that are typically occurring in the different life cycle stages. Some of them might not be relevant for the product case to be assessed. To simplify the data collection, the assessor can answer a questionnaire which may eliminate irrelevant life cycle stages, material flows and processes, and copy values from the other product data collection sheet (Fig. 1).

Basic product characteristics

Functional unit (FU)	
Name of the new product	Pavement with new small granit stones from Sweden, local mate
Name of the used product	Pavement with used small granit stones from Oslo, local material
Declared unit	1 m2 of pavement in paving stones
Location of first use	Public pedestrian street in Oslo, Norway
Location of temporary storage and packaging (optional)	Oslo, Norway
Location of second use (Where is the product system intended used?)	Public pedestrian street in Oslo, Norway
Duration: How long will the product be used at this location?	40 years
Use: how well is the product neant ot be used?	Resistant, non-slippery, removable
Other characteristics (Optional)	

	Questions	Answers
1.	From the point of view of which **actor** is the assessment conducted? *Does not affect the inventory template but it is important information for the cost and social aspects.*	Building (site) user
2.	Is the location of the second use of the reclaimed product known? *If Yes, provide data for transport distances (A4) and installation (A5). If No, provide different values for*	Yes
3.	Do you have an **Environment Product Declaration (EPD)** for the **new product against which the reused product will be compared?** *If Yes, you can copy the LCA inventory and impact results of the new product from the EPD, but make sure that data and/or scenarios for Modules A4, A5, B and C are correct and realistics.*	Yes
4.	Does the EPD of the new product gives you data for stages A1-3 in a combined way? *If Yes, Only the A1-3 impact column show in the inventory template for the new product*	Yes
5.	Do you have data for the reclaimed product for stages A1-3 in a combined way? *If Yes, Only the A1-3 impact column show in the inventory template for the reclaimed product*	No

5.2 Pavement Assessment Results

The results of the LCA show that using reclaimed instead of new paving stones in pavements can result in a 90% reduction in GHG emissions (Fig. 2, LCA). These LCA results are similar to those obtained by Fufa et al. [10], which indicate a 93% reduction in GHG emissions by using reclaimed stones. The main contributor to GHG emissions in pavement with new paving stones is the transport of the paving stones (80%). The A1-A5 GHG emissions from pavement in reused stones mainly

come from gravel production (37%) and transport (34%). There are no GHG emissions from the manual installation (A5) of the stones. By choosing new stones from Sweden instead of Finland, the A1–A3 GHG emissions for the pavement increase by 40%, while A4 GHG emissions decrease by 38%. The production, transport, and construction of the pavement with new stones from Sweden potentially emits 35.4 $kgCO_2e$, while the one with stones from Finland emits 50.3 $kgCO_2e$.

The LCC results indicate that the reuse of paving stones increases the total costs (A1–A5) by more than 33% compared to using new stones (Fig. 2, LCC). The total costs of the pavement in reused stones originate primarily from the purchase of the pavement elements (47%) then from the installation onsite (40%). In contrast, for a pavement with new stones, it is first the installation (54%) then the purchase of the materials (30%). While reuse can significantly reduce the GHG emissions of the pavement, it makes it more costly, as in the KA13 building case in Norway [29].

Since the social impacts significantly differ from country to country for the same sector, S-LCA results depend on the country where the paving stone is produced in the new stones case. Here it is assumed that the paving stones are produced in Sweden in the new stone case, and in both cases, gravel is produced in Norway. The results show that the social impacts in all categories are 62% to 97% higher in the new stones case compared to reuse case (Fig. 2, S-LCA). In the new stone produced in Sweden case, 40% to 50% of the impacts come from production of the new stones and gravel, 38% to 49% come from construction, and 11% to 14% from transportation. To see the country differences in social impacts, two more options were evaluated; new stones produced in China and Portugal. Compared to a pavement in reused stones, a pavement in stones produced in Portugal scores 54% to 78% higher and a pavement in stones produced in China scores 105% to 340% higher.

6 Conclusion

The REBUS LCSA framework was developed to support assessors when comparing and reporting the sustainability of reused and new construction products. The framework shows it is possible to harmonize the various assessment methods and expand the scope of product assessment from purely GHG emissions to overall sustainability.

The case study demonstrates how the LCSA framework can be utilized to compare GHG emissions, costs, and social impacts using both existing and new LCI data and LCIA results. It also shows that the additional data needed to expand from GHG assessment to sustainability assessment in the case study is relatively limited. The results of the LCSA assessment of the pavement in reclaimed and now stones show that reuse can bring lower environmental and social impacts, while being more costly. Here it should be noted that, this study assumed a 100% reuse rate for the reclaimed paving stones and slightly higher GHG emissions can be expected when mixing new and reclaimed paving stones [10].

Among the limitations of the framework, the scopes of the LCC, the LCA, and S-LCA do not align perfectly. The LCC is conducted from the perspective of one actor in the value chain, while the LCA takes a global perspective. The S-LCA scope lies between these two and takes the perspective of a set of stakeholders within the value chain. To better understand the economic and social impacts, it would be necessary to take a multistakeholder perspective. Also, the framework has only been tested on one product (the paving stone) and has not yet been tested outside the REBUS research project. In the future, the framework should be tested by experts in one or more life cycle approaches for different actors in the reuse value chain (e.g., product resellers, building clients, architects, contractors, and waste handlers). It should also be noted that the framework does not set any rule for setting of the system boundary between the primary product and the reclaimed product (i.e., end of waste state) because this boundary is dependent on the type of product and the local market. The assessor must still choose the system boundary and ideally analyze the sensitivity of the results to different choices of system boundary.

Besides inherent limitations, this case study is, to our knowledge, the first comparative LCA, LCC, and S-LCA of a reclaimed construction product, and this paper contributes to the so far very limited exploration of LCC and S-LCA of reclaimed construction products. Looking at multiple aspects over the life cycle of the product reduces the risks of shifting the problem to another stage of the life cycle (e.g., from production to end-of-life) or to another sustainability indicator (e.g., economically beneficial but with higher social impacts). The LCSA framework can contribute to promoting a more holistic approach to sustainability that encompasses different environmental, economic, and social issues.

Acknowledgments This research was supported by The Research Council of Norway through the project "REBUS—Reuse of building materials—a user perspective," under grant no. 302754.

1 Introduction

Society has historically valued both human labor and natural resources, including the intermediate and end products produced. Discarding these artifacts was seen as squandering valuable effort and resources, and waste was historically an uncommon and avoided activity. This tradition was rapidly lost in many western countries, replaced by a more rapid linear approach whereby materials quickly went from cradle to grave in a linear system or economy. There has been a recent revival of the idea of moving back from this modern linear model, however, with increasing pressures from environmental degradation, climate change, material scarcity, and population growth.

Much of the current work surrounding circularity in the construction industry appears to track with the recommendations made with the last wave of research into

reuse—from the mid-1990s to the mid-2000s, several research projects were conducted, and a large body of research was published. This chapter draws heavily on that period of research, as it helps highlight that many of the reuse discoveries being made today have been well known for decades.

2 Reclamation Audits: *Ombrukskartlegginger*

The recent revival of Norwegian circularity has resulted in a flurry of activity, with one of the most notable being the new requirement for reclamation audits, requiring renovation and demolition activities in apartment blocks or commercial buildings meeting certain size or mass criteria (100 m^2 or 10 tons) to conduct an assessment of the reuse potential of the materials and elements scheduled for disposal [1, 2]. The few audits which have been published in Norway (available via interactive map [3]) appear to have started from scratch, without building on the decades of research which could inspire or inform a modern approach. The results of the few publicly available reports are qualitative, text-based observations and assessments, which don't necessarily follow European [4, 5] or Norwegian recommendations [2, 6], with regard to consistency of formatting and the provision of standardized or quantitative values.

Nearly 25 years ago, researchers at the University of Florida presented their "Building Deconstruction Assessment Tool" developed for residential buildings based on experiences derived from a short project, which showed that deconstruction was cost-competitive with demolition if the resale of recovered materials was included [7]. The assessment tool was made up of three sections, with increasing detail, including a preliminary evaluation, a regulatory cost estimate, and finally a detailed (component level) assessment and inventory [7]. The output was a building deconstruction feasibility score which yielded different recommendations (demolish, deconstruct, or move) based on the resulting score ranges [7].

The current approach toward reclamation audits in Norway is admittedly a first step, with no actual requirements beyond conducting the audit itself. The process is expected to grow and adapt in both content and application area, with more requirements expected to be introduced including greenhouse gas accounting [8].

Several minor revisions to the process could be expected to simplify and yield both better data and better results. The development and use of a common software tool for reclamation audits in Norway could provide more consistent formats and comparable results with systematic outputs. At a minimum, this consistency and comparability could be expanded with the use of a standardized, mandated spreadsheet for reporting (e.g., [4]). Along with a follow-up post-reclamation audit, the data could be used for both internal and external comparisons—such as comparing the total amounts indicated in the table with the quantities sent for reuse or attributed to different waste fractions, and developing a database of expectations based on different building attributes and archetypes.

3 Reuse and Availability

The new Norwegian requirement for reclamation audits highlights a known problem with timing and quality assurance: the items are generally documented in situ where they exist in a sort of Schrodinger's dilemma. The item and its quality are documented only at the time and place of the actual audit, which should identify and document reusable components [6], but the documented attributes and quality may change when the component is deconstructed and delivered to the site. The timing is also difficult without an adequate storage area—the timing of the deconstruction and the new construction would need to line up perfectly. With new materials purchased from logistics companies or middlemen, the deliveries can be scheduled to arrive exactly as they are needed. The old proverb "a bird in the hand is worth two in the bush" translates into Norwegian as ". . .worth ten on the roof" but rings equally true—uncertainty increases risk and decreases perceived value. Construction companies and contractors are restricted by deadlines and space limitations, and probable reusable materials do not fit well with rapid, choreographed modern construction practices—highlighting the importance of having public or private "reuse hubs" dealing in controlled or controllable reclaimed construction materials.

Increasing the risk and uncertainty from reclamation audits is the legacy of the past 75 years of modern methods of construction (MMC), which have involved rapid technological developments, including the introduction of new materials and methods which do not promote deconstruction, disassembly, and reuse [9]. For decades, researchers have been pointing out the flaws in MMC and calling for more methodical and conscientious approaches to construction—with an eye toward the future instead of the immediate present (see e.g., [10–13]).

A set of strategies (Fig. 1) developed decades ago shows an early version of the circular economy and EU waste hierarchy [14] applied to buildings [15, 16].

The four cascading strategies for material reuse apply at different processing levels and feed back into the relevant stage of the building life cycle:

1. Relocation (building level).
2. Reuse (component level—assembly stage).
3. Reprocessing (material level—manufacturing stage).
4. Recycling (material level—processing stage) [19].

The waste hierarchy itself has been around for nearly 50 years and has gone through multiple iterations. The Ladder of Lansink presented a seven-level top-down list: Prevention, Element reuse, Material reuse, Useful application, Incineration with energy recovery, Incineration, and Landfill [17, 18]. The Delft Ladder followed with ten stages, and the current EU waste framework directive (Fig. 2) trimmed back down to present a five-step "waste hierarchy" [14, 18]. The common denominator in all approaches to the waste hierarchy is that prevention is generally the preferred option, and disposal in a landfill is generally last. The current approach to reuse is well intentioned and a much needed (re)development, but it is attempting to put the cart before the horse. The top approach "prevention" should have been

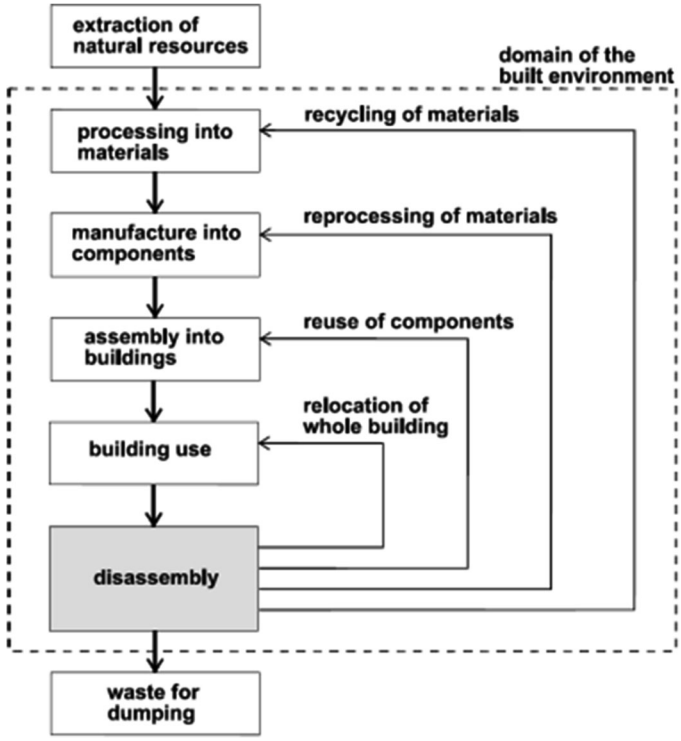

Fig. 1 Crowther's "Scenarios for Reuse in the Life Cycle of the Built Environment" [20]—diagram reused with author permission

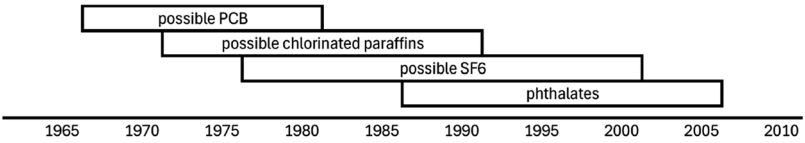

Fig. 2 Timeline of selected hazardous materials in insulated windows [41–46]

introduced at the design stage: "Prevention tries to prevent the production of waste. This step must be taken before a building is demolished, in the design and building stage" [18, p. 96]. As Crowther noted in 1999, with regrettable premonition, there are plenty of ". . .forgotten technological strategies that can enhance the possibilities of separating materials, components and whole buildings for reuse and recycling" [19, p. 35]. Most buildings being demolished today were not built with prevention in mind. Those that were designed with prevention in mind were built in a different era, before the rapid rise of industrialization, and are often old enough to be given protected status.

The traditions of building with reversible connections can be considered the original form of Design for Disassembly (DfD), whether ancient (e.g., stacking, layering, interlocking) or more modern (e.g., screws, bolts). These assembly

techniques allowed for straightforward disassembly or deconstruction, whether the design decision was intentional [20] or not [21]. Ancient forms of transportable housing (e.g., tipi, yurt, and lavvu) and their more modern equivalents, like the Dymaxion House in 1927, the BLPS House in 1937, the Geodesic dome in 1947, or the Nakagin Capsule Tower in 1970, also integrated reversibility and modularity into the designs [22–24].

Design for Disassembly reemerged in the 1970s as a response to environmental pressures, initially in the realm of product design—when extended to buildings this is also called Design for Deconstruction, both abbreviated DfD. Depending on construction and material type, reuse will likely be a losing effort without some form of DfD. Stick frame wood buildings, as are common in single family residential housing in much of the United States, may be the easiest of modern construction techniques to disassemble (deconstruct), though generally built with nails, and demolition remains the norm. The buildings are relatively small and low to the ground. Considering these conventional wood-framed houses in a study in the United States, Guy and McLendon found that their deconstruction is generally more expensive than demolition, but the extra expense may be offset by the sale of salvaged materials [25]. In their review of deconstruction projects for 12 wood-frame buildings built between 1900 and 1950, Chini and Nguyen found a wide range of recovery rates (28–82%) owing to a variety of factors [26]. They considered the effects of project factors on the diversion/recovery rates: building age, condition, and size, as well as lot size and site conditions, along with the presence of hazardous materials [26]. Lot size and access conditions are positively correlated, with larger lots and easier access leading to higher recovery rates [26]. The presence of hazardous materials entails extra time and costs, and lower material recovery rates [26], and complicates any attempt at generalization, as demolition with some materials (e.g., asbestos) may cause the entire waste load to be categorized as hazardous waste [27].

Considering that most everyone agrees that prevention is the most important part of the waste hierarchy, it is disappointing that, outside of academics endlessly pleading, nearly nothing has been done to promote it. This may be due to the principal-agent problem, whereby the one who pays is not the one who obviously benefits. "... the potential carbon benefits of reusing construction materials are not gained immediately but at the point of future retrieval" [28, p. 6]. Adding extra effort to design and construct buildings which will only benefit an unknown future owner and an unknown future society is a difficult proposition for private actors. The tragedy of the commons has been described since Aristotle [29], and yet we seem no closer to resolving it.

Back in 1995, Spence & Mulligan proposed tandem regulatory and industry approaches to help resolve some of these issues, including:

- Regulatory:
  - Carbon tax.
  - Resource extraction tax (minerals, trees, etc.)

  - Landfill waste charges.
  - Fines/charges for pollution.
- Industry (to reduce overall materials use).
  - Consider embodied energy (use low-energy materials and structural systems).
  - Low rise instead of high-rise buildings.
  - Use waste or recycled materials.
  - Reduce site and recycling waste.
  - Design for recycling, long life, and adaptability [30].

In the 30 years since these recommendations were proposed, some have been enacted, and others have been ignored. Oslo, for example, has been at the forefront of promoting the use of recycled and reused material, while at the same promoting a new policy toward more tall buildings downtown [31].

Laws and regulations are another approach to influencing (or imposing) change. The EU ecodesign regulation proposal is a promising step forward toward harmonizing European approaches to reducing waste and increasing circularity. It includes an important statement regarding the restriction of "substances that hinder circularity" [32, p. 26]. While the ecodesign proposal is an important step for sustainability and circularity in the EU and Norway, it includes text deferring to the Construction Products Regulation (CPR) [33], where except in "exceptional cases" . . . ". . .this regulation should not set requirements on final construction products when requirements on environmental sustainability for such products have already been developed under the [CPR]" [32, p. 96]. It will be interesting to see if the goals of the ecodesign proposal, which is written clearly and directly, will be properly filled through adherence to the CPR, which is a much more opaque and legally technical document, and one which "does not set product requirements" but defers responsibility to the Member States [33, p. 1].

The Norwegian Government Agency for Financial Management (DFØ) that directs public procurement has released a criteria set and web-based tool to guide sustainable procurement [34]. The criteria set includes a section on Circular economy, with a subsection on building for adaptability and reuse. The specific minimum criteria to be addressed for adaptability and reuse are "Adaptable buildings, Correct lifetime of component, Flexible joints, Labelling of materials and components for reuse, Sources of hazardous substances that restrict future reuse, Homogeneous materials, & Sensible layering" [34].

4 Risky Reuse

Many construction products currently in use in buildings contain materials or substances which are no longer acceptable or legal for introduction into buildings. While these products were accepted products at the time of installation, they are no longer approved and generally cannot be reused in Norway. It is likely that this trend will

continue, with products which are currently considered legal and safe being determined unsafe and/or having their approval revoked over time. Even well-intentioned changes may result in "regrettable substitution"—as we have seen with replacement plastics for water bottles [35–38]. Reuse professionals (and the circular economy "industry") will need to deal with the existing and future threat to circularity of currently inbuilt materials. REACH legislation has reduced the future risk, but the fields of health and science are in an endless state of discovery. Reversible connections and DfD could help reduce this unknown future risk by simplifying remediation, removal, and replacement. Windows and concrete slabs are used here as examples, but the list of risky materials and components is not short [39, 40].

4.1 Windows

The reuse utility of insulated windows is diminished owing to both the degradation of insulating properties over time and increasing insulation requirements in new construction. Insulated windows removed from their planned use (between interior and exterior) can find themselves reused in spaces where there is no formal requirement for insulating properties (e.g., partition walls), yielding their technical qualities mostly irrelevant. The possible reuse of these windows then becomes a question of whether it is safe or allowed to reuse them. With the investigation and testing of each product likely prohibitively time consuming or expensive, the simpler approach is to find and check the manufacturing date to see whether currently prohibited substances were used at the time of manufacture. With insulated windows, the construction dates where reuse should be avoided are overlapping and cover most of the past 60 years (Fig. 2), with lead, asbestos, and PCBs also occurring in paint, sealants, and putty [41–46].

4.2 Hollow-Core Concrete Slabs

In a reuse pilot, 21 hollow core slabs were removed from a government building being demolished in Oslo, cleaned and tested, and then used a few blocks away, in the ambitious project known as KA13 [47]. Lessons learned from the slab reuse in KA13 helped inform a new Norwegian standard on reuse of prefabricated hollow-core concrete slabs [48]. The slab reuse involved direct costs estimated to be 5–6 times the cost of new elements, not including extra time [49]. The extra costs were associated with disassembly and removal, extra processes due to bracing, supporting, drilling, cutting, and hoisting, testing, transportation, cutting, processing, cleaning, preparation, and assembly, extra labor for design and administration [49]. This was a novel project, and future costs will likely decrease due to experience, but much of the extra expense was due to the lack of planned reversibility and DfD.

4.3 Connections

Connections that are not intended to be reversible, such as those with glues, adhesives, mortars, or one-way mechanical fasteners, are problematic for multiple reasons. Not only do these connections make disassembly difficult or impossible, limiting reusability, but larger components (which could otherwise be reusable) may be rendered unusable due to attachment to a small but unusable fraction. One example of this problematic issue is with several decades worth of structural blocks which are built into Norwegian homes. Leca Isoblokk (expanded clay structural block with polyurethane foam core) from the 1980s to the 2000s contained CFCs and HCFCs in the foam insulation. The entire assembly is hazardous waste due to the irreversible bond between the hazardous and nonhazardous components. Removed blocks cannot be reused and must be destroyed in a specific manner. At least 17 different types of integrated hazardous materials have been identified in or attached to heavy building materials, spanning different usage periods—concentrated in the decades after World War 2, but ranging from years to centuries, up to the present day [50].

5 The Return

The recent flurry of activity toward circularity and reuse in the Norwegian building sector represents a rapid and ambitious return to the principles and design traditions common in Norway in the past [51]. The process is hindered, however, by a building industry that moves fast in some regard (such as integrating materials and methods that quickly become obsolete or contain future banned substances) and very slow in others (e.g., integrating digitalization, building typologies with a very long stock time). The implementation of reuse incentives needs to be matched with incentives for changing the construction process—to include a return to "innovations" such as buildings designed for ease of disassembly and adaptability [52]. This (return to logical design of long-life products) will require/entail a process change in the industry now, with benefits deferring to the future.

The current approach to circularity in the Norwegian construction industry appears to be an attempt to change one part of an interconnected system, without corresponding effort to change the rest. The actors appear to be adapting quickly, however, so there is reason to be optimistic. For example, one of the businesses providing reused products and reuse services showed an extremely complicated and convoluted pathway for the reuse of building materials—12 steps for the buyer, 8 steps for the seller, and 9 steps for the material [53]. This process has been addressed to some extent through both policy and business innovation in just 2 years. If everything moved this quickly the problem could likely be quickly solved—but the system is not generally so fast acting. One issue is that buildings generally have very long service lives, especially compared to most consumer

products, which means that it can take several decades before changes in building codes significantly affect the building stock. Another issue is meeting market demands, where the Norwegian government building commissioner, manager, and developer (Statsbygg) found that adaptive reuse would be chosen in only 1 of 6 scenarios, with decisions based on technical and functional factors, as well as cost, competition, and ability to "convince our client" [54, p. 107].

5.1 Incentives

Reuse is clearly societally preferable to waste, but if the economic system does not provide immediate, recognizable benefits, that preference is difficult to translate into action for actors driven or constrained by economic decisions, and other systems should be introduced to incentivize reuse. One approach to overcome the split incentive (or principal-agent problem) and narrow the barrier to action between those who endure costs (or take voluntary action) now to ensure that others in the future can benefit is to find a way to transfer some of those future benefits to the present. Two recent approaches in Norway have introduced methods for reducing this barrier. The FutureBuilt Circularity Index aims to "motivate circular principles in rehabilitation, demolition, and new construction, and set a standard for what should be the ambition level for a circular building" [55, p. 2]. An earlier version of the Circularity Index is integrated into the BREEAM-NOR v6.0 (Mat 06) certification for material efficiency and reuse [56]. The result is documented circularity potential certified by FutureBuilt and/or BREEAM.

6 Discussion/Conclusions

Many recent reports have been published regarding reuse and addressing the barriers to reuse in Norway [42, 57–60]. These reports provide an excellent and specific description of the issues facing attempts to increase reuse in Norway. Some of the main issues have been addressed through legislation since some of the reports were written. A recent change in Norwegian regulations has simplified reuse slightly by reducing the legal requirements for reusing construction materials [8]. But one of the fundamental barriers that remains is that buildings were not built with the intention of reusing the materials or components. They may be glued or nailed or mortared or otherwise irreversibly attached to other materials. As knowledge increases, we find that some of the technological marvels we were quick to integrate into our buildings turn out to have drawbacks. Many of these are now classified as hazardous waste. When these disparate materials are connected, they lose their salvageability and their reusability [61].

The strides being made toward reuse in Norway, and especially in Oslo, include incredible advancement in desire, intent, and ambition toward reuse. But these ambitions are hobbled by the past 50 years of architectural "progress"—where

buildings were built quickly and efficiently, but with little to no thought for future generations, for material scarcity, or for a planet in peril. Economic decisions with life-cycle costing, high discount rates, and no regard for uncertainty have led to a situation where the existing building stock, with embedded materials and building methods, is a hindrance to the present. While the current generation tries to do better, the decisions of those in the past slow or prevent them from success.

6.1 Looking Forward

Legislation like the REACH directive, the EU ecodesign proposal, and the EU taxonomy and Level(s) may help with the retransition to a more circular economy. But what will likely be needed to have a larger effect is a more profound shift in material valuation. One of the pioneers of the circular economy, Walter Stahel, stated that this shift could be accelerated with ". . . .one simple shift in public policy—adapting the tax system to the principles of sustainability by not taxing renewable resources including work" [62, p. 1]. Omitted but implied is that taxation of nonrenewable resources should make up the lost tax income. In their article on rebound, Ottelin et al. are much more specific about the economic shift that is needed: "Our findings highlight the limitations of circular consumption in today's economic systems, and the need for stronger policy incentives, such as shifting taxation from renewable resources and labour to non-renewable resources" [63, p. 1]. This would change the entire valuation structure of building materials and elements going forward and put us on the pathway toward the sustainable future of construction—a future we have known how to achieve for decades but have drifted away from. Unfortunately, it can do little to help with the oft-polluted outflows from the buildings being removed from stock today.

1 Introduction

Recovery and recycling of wood and timber products is an application of circular economy principles to the construction industry [1]. However, the construction industry has not yet widely adopted the principles. According to a recent European Union (EU) Commission report on the construction industry [2], only 29% of companies engage in any form of reuse or recycling of construction and demolition waste (CDW). Within CDW, wood is one of the best materials with respect to circularity [3]. Wood and timbers are renewable resources that can be recycled multiple times in multiple formulations for multiple building lifecycles. At its end of life, wood can be converted to energy through incineration.

The specific circularity principles vary from industry to industry. Within construction, the circular economy is often described using ten "R" principles. These are described in the United Nations (UN) report [3, p. 4]. They are often listed in a hierarchy with recovery being the most basic form of circularity and each additional "R" level increasing circular value. Mrad and Frölén Ribeiro provide a definition of the ten "R" principles [4, p. 4].

- Recover: Material is incinerated to recover energy.
- Recycle: Material is processed to obtain new material.
- Repurpose: Using the discarded product or its parts for a different purpose.
- Remanufacture: Using abandoned parts for a new product with the same function.
- Refurbish: Updating or restoring an existing product.
- Repair: Repairing a product to continue its function.
- Reuse: Reusing a product discarded but in good condition and fulfilling its original function by another user.
- Reduce: Increasing the efficiency in product manufacture or use by consuming fewer natural resources and materials to make a product.
- Rethink: Enhancing product usage.
- Refuse: Removing functions to make products redundant.

These "R" principles form the basis for analyzing the value embedded in processes that are associated with the recovery and reuse of wood and timber from CDW.

2 Background

2.1 System Elements

The value engineering discipline seeks to optimize the perceived customer value as compared to the cost of a component or system. Value analysis is a core element of value engineering. When doing value engineering, the foundation of value analysis is the function analysis of a product or process [5]. Within the construction industry, value analysis is often used as a form of cost containment [6]. Through value analysis, unnecessary building components can be identified and eliminated to reduce costs. Value analysis has been used with various forms of construction. Heiza et al. [7] used value analysis with high-rise buildings as a problem-solving tool that contained cost and increased quality. The area of the world where value analysis is most commonly applied to construction projects is Asia [8]. In their study, Chen et al. found that although the value analysis application is highly variable, when used, it delivers excellent results. Gimenez et al. [9] highlight the benefit of value analysis at the time of the building design. Once the design is completed, the cost of changes often negates any benefit that could be realized from adopting value analysis recommendations.

2.2 Element Interactions

The recovery and recycling of wood from CDW is a focus of the advocates for circular economy adoption. "The greatest opportunity for improved circularity of wood in existing buildings is in the recovery, reuse and/or recycling of building demolition waste" [3, p. xi]. However, recycling wood from CDW is a complex business decision. There are many options for what to do with the wood [10]. The direct costs, logistics costs, and energy costs for each option frequently change. In addition, some of the options create potential revenue, and some of the options have permitting or other regulatory costs. A key CDW recycling subprocess is sorting and segregating different construction materials to determine what form of reuse or recycling is appropriate. This sorting can be done either manually or with automation [11]. However, there is a cost and purity tradeoff with the automation equipment. Wood waste that cannot be clearly identified and segregated can be used for filler in composite materials. However, the CDW wood is usually contaminated, and the mechanical properties of the composite material with that type of filler are inferior [12]. Another key for successful wood recycling is to develop an intentional process. Oliveira Neto and Correia found that an intentional reverse logistics plan contributed to the benefit from recycling [13].

3 Methodology

3.1 Process Flow Diagrams

Seven of the ten "Re" principles involve additional processing of CDW. Those seven are recover, recycle, repurpose, remanufacture, refurbish, repair, and reuse [4]. Each of these is the result of a process that starts with the wood elements of CDW and ends with that wood being in some state that creates new value. In addition, there is an eighth process that does not result in a new value. That process sends the wood products to a landfill for eventual decomposition. These eight processes can be represented with process flow diagrams. The process flow diagram starts with the generation of CDW and shows the steps required to complete each "R" process. The steps are shown in sequential order and are connected with arrows. Process flow diagrams create a visual image of a process that may take a long time and be spread across many locations.

Jahan et al. [14] created a high-level flow for the lifecycle of construction products that had five steps in sequence. These steps are (1) raw material extraction, (2) preconstruction, (3) construction, (4) renovation/demolition, and (5) end of life. The first two steps are associated with the initial fabrication of the construction products, and waste in those steps would be considered industrial waste, not CDW. The remaining three steps can and often do create CDW. For the purposes of this study, the starting point of the process flow will be the generation of the CDW, regardless of which step in the construction lifecycle the waste was created.

3.2 Value Engineering

The value engineering approach used in this study is based on the methodology recommended by the leading professional organization that provides certification in value engineering techniques, SAVE International. They recommend a value engineering process that starts with a function analysis using a Function Analysis System Technique (FAST) diagram. This identifies unneeded functions, missing functions, and prioritizes the existing functions. The identified functions become one side of a Function Cost Matrix. The other side of the matrix is the product architecture for a product analysis or the process flow chart elements for a process analysis. The matrix is used to create a functional value for each element.

Function Analysis System Technique (FAST) The FAST analysis is a method for identifying and organizing the functions of a product or process. Since this study is focused on the recovery and recycling of wood from CDW, the process perspective is used. The FAST technique starts by setting the boundaries or scope of the process being analyzed. Outside the process boundary on the left side is a higher-order function that normally reflects the ultimate purpose of the process. Outside the boundary on the right side are any causative functions or events that would initiate the process.

Within the boundaries are the functions or activities that occur within the process. On the left side are the primary function(s). These function(s) normally represent a final step in a process path. They are the outputs of the process. The primary function delivers the result of the process, secondary functions are enablers or enhancers of the primary function. One goal of a FAST analysis is to determine if there are more efficient ways to accomplish the secondary functions. If the primary function can be achieved without some of the secondary functions, those secondary functions should be eliminated since they are contributing little if any value.

When creating a FAST analysis, it is often helpful to navigate the diagram from left to right and then from right to left to identify any unneeded or missing functions. When going from left to right, the question "How?" is asked with each function to identify the preceding functions. When going from right to left, the question "Why?" is asked to understand the relationship with any succeeding function. Also, with each function, the question "When?" is asked to determine if there are other secondary functions that should be connected with each other. An illustration is found in Fig. 1.

Function Cost Matrix The functional cost matrix (FCM) combines the functions identified with the FAST analysis and the steps associated with processing CDW to identify the inherent value of each step. The format of the Function Cost Matrix is similar to that used with Quality Function Deployment (QFD) [15]. In the FCM, functions are listed across the top of the matrix and the process steps are listed down the side. In one variation of an FCM, actual cost values to accomplish each process step are allocated across the functions. A second variation of the FCM uses the QFD approach for analysis. In this case, the functions are prioritized using a scale of 1 to 5 with "5" being the highest priority. The process steps are then correlated to the

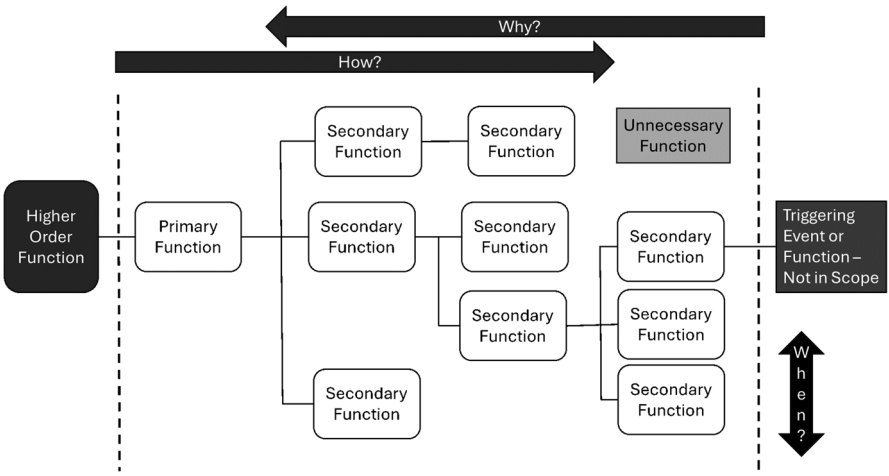

Fig. 1 FAST analysis template

functions based on how significantly they directly contribute to the functional performance. The correlations are rated as high, medium, low, or no correlation. Using the standard QFD approach, the high correlation is given a multiplier of "9," the medium has a multiplier of "3," the low has a multiplier of "1," and no correlation has a multiplier of zero. These multipliers are used with the priority of the functions to determine a correlation score for that step/function relationship. The total score of a step reflects that step's contributed value to the overall process. When using the QFD approach, the scores reflect a relative value between seps.

The perceived customer value or score of each step is then compared to the total cost for that step. If the cost is significantly higher than the value, consider redesigning the process to minimize the cost at that step. If the value is significantly higher than the cost, assess whether the method of accomplishing that step is fully meeting the customer quality expectations. If not, consider improving the performance of that step, even if it means spending more money to do that step well. Improving the performance of that step will increase the value of the entire process in the eyes of the customer. If the cost and value are approximately the same, the effort associated with accomplishing that step is appropriate.

4 Analysis

The analysis in this study is based on using information from other studies and reports created by the EU or UN. This is an analysis of a generalized model of the industry, not a specific company or case study. Therefore, the analysis provides relative values for the process steps, not absolute values. Absolute values will depend on the specific organizational capabilities, geographical location of sites, and the current regulatory environment for the region being studied.

4.1 Value Engineering

The process flow diagrams show an idealized view of the processes that result in the eight potential "R" dispositions of wood that are found in CDW. The steps are at a relatively high level. In many cases, when a company decides to adopt one of these processes, it will need to establish a set of detailed steps to accomplish the task described in this high-level step. The particular steps often depend on the construction site and the organization's infrastructure and capabilities. For instance, depending on site locations, shipping waste to an incinerator may be a short haul by truck or a long haul involving rail shipments and multiple trucks. For this reason, it is impossible to set exact detailed steps that apply in every case. The process map is found in Fig. 2.

The process starts with the creation of CDW during construction or deconstruction. A decision is made to recover the wood and use it again in the construction of another building or to allow it to be transformed into another product, material, or physical state. If it will not be used for production, it must be shipped to the appropriate facility and either dumped in a landfill or processed to be transformed into energy, a different composite material, or a different fiber-based product that is not used in construction. If it is to be reused in construction, then a decision is made concerning how it is to be used. If no modification is required, once it is inspected, it is sent to an appropriate distribution channel for resale. If modifications are required, then it must be sent to the correct facility. Often minor repairs can be made at the point where the sorting occurs. An example would be to trim a beam to a shorter length and remove an end that was compromised during demolition. That beam can then be inspected and returned to the supply chain. In some cases, the modification may be more extensive, so the wood is sent to a manufacturing facility to be refurbished into construction materials. Again, once inspected, it can be returned to the supply chain.

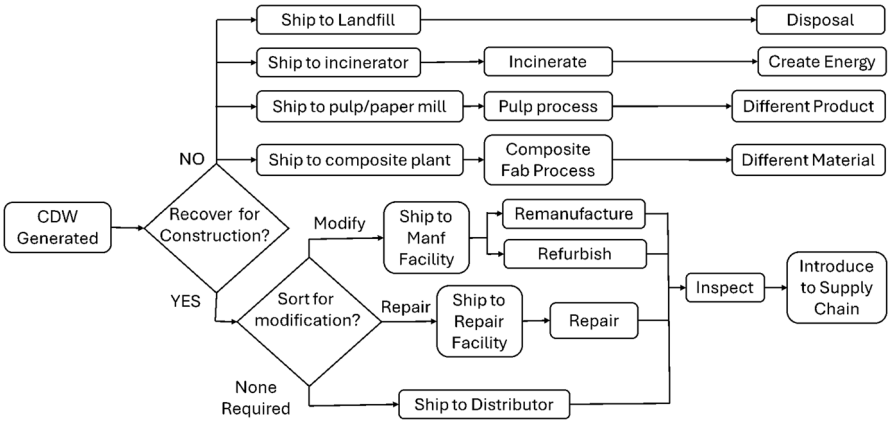

Fig. 2 Process map for CDW waste recovery and disposition

4.2 FAST Analysis

The FAST analysis of wood recovered from CDW is somewhat complex. There are two higher-order functions that are mutually exclusive. One is the reintroduction of the wood items into the construction supply chain. The other is the transformation of the wood into another form. A specific wood item could go through the first higher-order function many times throughout its lifecycle. However, once it has been transformed, it is no longer possible for it to be a wood element in construction so it will not be CDW. In fact, depending on the transformation, it may not exist at all.

Since there are two higher order functions, there are two FAST analysis diagrams. Figure 3 is the diagram for wood components reentering the construction supply chain. This occurs either as a component in its original family or as a wooden item that has been remanufactured into a new wooden construction component. The component may be undamaged and ready for immediate reuse. It could require minor repairs before being returned to the supply chain. In some cases, it requires restoration or refurbishment before reentering the supply chain. In all cases, the documentation for that item should be updated to show the history of the component. Once the CDW has been selected for disposition back into the construction supply chain, a decision is required to determine which approach is appropriate. This FAST analysis diagram is the ideal state, so no unnecessary functions are shown. If an organization does their own internal FAST analysis, they may discover other unneeded functions embedded in their process.

The second higher-order function is to transform the wooden elements within the CDW into a new state. In this case, the FAST analysis diagram has four primary functions that reflect the four different types of transformation. Each of these primary functions has a secondary function that represents the transformation process and a function that represents the selection process. In addition, there is again the function

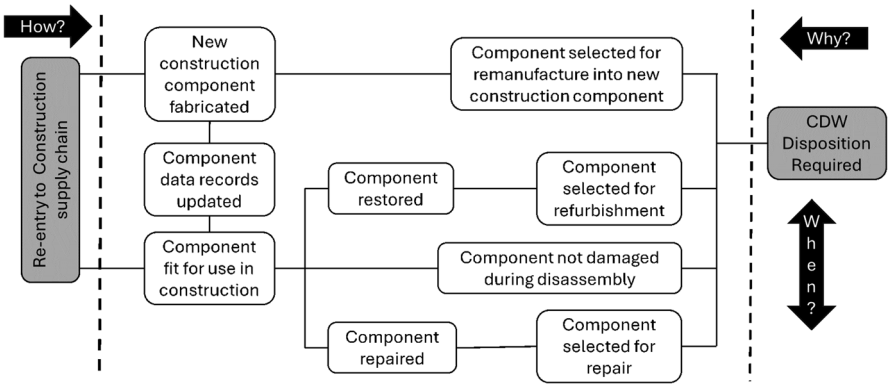

Fig. 3 FAST analysis when wood component reenters the supply chain

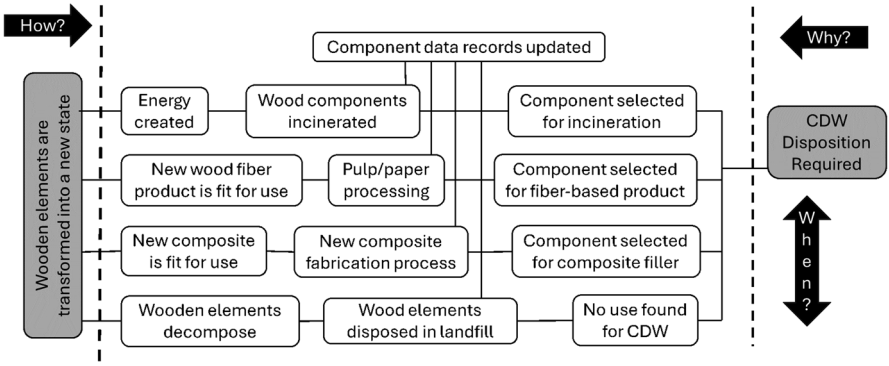

Fig. 4 FAST analysis when wood components will not reenter the supply chain

of updating the documentation based on the disposition of the CDW wood elements. This analysis is represented in Fig. 4. As with the previous FAST analysis, an organization may find unneeded functions when they do an internal FAST analysis.

4.3 Function Cost Matrix

The FCM combines the steps from the process flow with the functions from the FAST analysis. In this case, there are 21 functions and 22 process steps. The FCM functions are listed across the top of the matrix. Following the QFD model, the functions are prioritized using the 1 to 5 scale. The process steps are listed down the side of the matrix. The steps are correlated to the functions. The low/medium/high correlations are based on assessing the degree to which completing the step in an excellent manner will directly affect the performance of the function.

When prioritizing the functions, the UN report's assessment of the circular economy "R" principles was used [3, p. 25]. The perceived value is consistent with industry analysis conducted by López Ruiz et al. [16]. They compiled data from 15 studies on circular economy and construction. These studies covered the preceding 15 years and spanned the globe. The UN study placed the highest priority on the complete reuse of the building, but in that case, there would be no CDW. The next highest priority was component reuse, and this study assigned functions that operate at that level the priority rating of "5." These functions were associated with the immediate reuse of components as soon as the component is removed from the construction or deconstruction site. These items are intact and retain their full technical qualities. The other function to receive the highest priority of "5" was the update to the data records. With the widespread adoption of Environmental Performance Declarations (EPDs) in the construction industry, it is essential that correct records of the origin and use of wood construction components are maintained.

The next highest priority from the UN report was material reprocessing [3]. The functions associated with this were given a priority of "4." These were functions directly associated with ensuring the wood components were returned to the construction industry after minor modifications. These would be functions associated with the repair and refurbishment of the recovered item. A rating of "4" was also given to the function, Inspection. This function is needed as support for the repair and refurbishment of items to rate the items correctly and reintroduce them to the supply chain. Finally, the rating of "4" was used with all the functions that selected wood elements in the CDW for some level of circularity, regardless of the process selected. The only selection function not included was the decision to not select a wood item for any type of circular processing and instead just send it to a landfill for decomposition.

The third priority level from the UN report is material recycling [3]. Priority level "3" was used with the functions that transform the wood items recovered from the CDW into another material. This included remanufacturing the items for the construction supply chain and remanufacturing into another type of product that is normally not associated with the construction industry. This latter approach usually includes reprocessing the recovered items into another fiber-based product. This is primarily done by a pulp and paper mill factory. The recovered material is used as stock in those mills. Another function is the use of wood components in the manufacture of new composite materials. Composites rely on a matrix or filler material to provide the overall composite material properties. Generally, CDW wood is less practical than new wood for this application because of the contaminants that are often in the recovered wood items [12].

The lowest two levels in the UN report were energy recovery and disposal. Therefore, energy recovery functions received a "2" rating [3]. With wood items from the CDW, the energy recovery is normally accomplished through incineration. The functions associated with landfills have the priority of "1." Unfortunately, CDW accounts for 36% of all solid waste in Europe, which is an indication of why these functions are so low in priority [16].

The FCM is found in Table 1. The first step in the process, the generation of CDW, is considered a low relationship with all the functions. It does not directly affect any function, but the functions would not be needed if there was no CDW. The next two process steps determine the circularity function to be applied to the CDW. These steps have a high impact on which the "R" function is used. In addition, since they select the function, they also have a low impact on the final result of each function. The "shipping" steps have a low impact on the functions to which they ship the CDW. They must ship the items to the right location, but they do not directly affect the operation of the "R" function. Not surprisingly, the "R" step has a high correlation with its respective "R" function. Finally, the relationship to the documentation function for the "R" steps that return the product to the construction supply chain is high because this function must complete the EPD. The correlation with the other "R" function is medium since all that is documented is the end of the

Table 1 Function cost matrix

	Fun ctions	Component fit for Use	New Component Fabricated	Energy Created	New Wood-fiber product	Composite material	Decomponse	Data records updated	Component restored	Component remanufactured	Component repaired	Incineration	Pulp/paper processing	Composite fabrication	Dispose in landfill	Component undamaged	Slected for repair	Selected for refurbishment	Selected forremanufacture	Selected for incineration	Slected for fpaper product	Selected for composite	No use found	Total

construction life of the wood item. The correlation of the documentation function with the shipping process steps is low since there should not be any modification to the item while being shipped.

The process steps scores are relative scores, not actual cost, or value amounts. They represent the relative value of these steps with respect to each other. The higher the score, the more important that step is to achieve full functional value from the process.

5 Discussion

This analysis is intended to provide a methodology and framework for understanding where value is to be created in the process of recovering and recycling wood from CDW. This framework can be used by those in the market or those intending to enter the market. The result of the analysis is a tool that prioritizes the process steps.

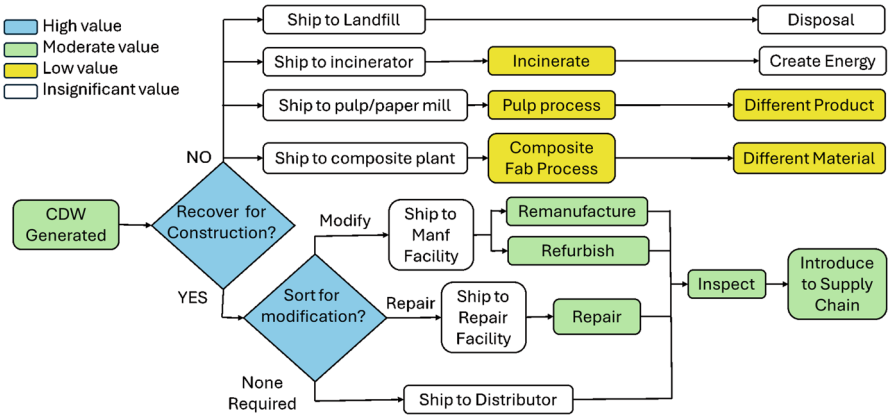

Fig. 5 Prioritized process map for waste recovery and disposition

Organizations can use this tool to identify areas for improvement or new business opportunities. Figure 5 shows the prioritized steps in the process of recovering wood from CDW.

The Function Cost Matrix does not contain any surprises, but it places clear emphasis on several process steps. In this case, the steps that decide what wood items are to be recovered and what "R" process will be used are the steps with the highest scores. This is consistent with the recommendations by López Ruiz et al. on the importance of creating a Site Waste Management Plan and developing collection and segregation techniques [16]. To create maximum value in the context of the circular economy, the two decision steps that determine which wood items can be recovered and identify the best path for circularity must be done in an excellent and efficient manner. That may mean investing in techniques to improve the performance of those steps. Since those steps are early in the process, they are also one of the first points of resistance noted in the UN report [3]. This is understandable. Without clear guidelines and methods for making these decisions, these steps could create delays, added costs, and risk if the wrong decision is made. These two steps should be the focus of further research and development.

The next set of steps with similar moderately high values are the "R" processing steps that create wood products that return to the construction supply chain following inspection. These include the steps of repair, refurbishment, and remanufacture. Equally important to these steps are the inspection capabilities to qualify and accept these items into the supply chain and the corresponding updates to the EPD. Finally, the actual process of introducing and marketing these recovered items is of moderate importance. Each of these process steps is important and adds value to the construction industry. The relative value of each of these steps is very similar. However, if investment in one of these "R" processes results in that process becoming more efficient with lower costs than others, that process will have a distinct value advantage over the other processes.

The low-value steps are the other "R" processes that do not result in the CDW wood item reentering the construction supply chain. Except for disposal in a landfill, these items represent an element of circularity. However, it is not circularity within the construction industry, which is why their score left them with a low rating. Improvements in these areas will be beneficial for a circular economy, but those benefits will not be directly attributable to the construction industry.

Many of the steps in the process are related to shipping. These steps had very low scores because they did not create value within the circular economy. Nevertheless, they can create a great deal of cost. The costs in the shipping process steps should be minimized or, if possible, eliminated. To do this, one or more of the "R" processes would need to be done at or near the site of the building deconstruction. Another possible option to reduce shipping costs would be to create a recovery site where CDW is shipped. That site could do the decision processes of determining which "R" approach to use and have the capability to perform some or all the "R" functions at that facility. This would likely lower the total shipping costs and speed up the process of returning the recovered wood item back into the construction supply chain.

6 Conclusion

The creation and disposition of CDW is currently an issue for the construction industry as it attempts to adopt the principles of a circular economy. Based on value analysis, the most important step in the process of disposing and recovering CDW is the early decision of which "R" path each wood item in the CDW should follow. The highest value paths are those in which the wood item is returned to the construction supply chain. There are four options to achieve this objective, reuse, repair, refurbish, and remanufacture. Investment in the tools or techniques used to improve disposition decision-making or these "R" processing would likely improve the value of the construction wood recovery process. To create maximum value from a circular economy perspective, options for disposing of wood items—such as repurposing, recycling, recovering, or disposing of them in a landfill—should be carefully considered; however, these options may not align with the construction industry's value priorities. Furthermore, any measures to reduce or streamline the shipping costs associated with the disposition and recovery of CDW should be implemented, as these costs do not inherently add value.

This study was conducted as a qualitative analysis of the functional value of each step in a generic process for recovering and disposing of wood items found in CDW. Further research should be done in specific local regions using the actual costs of functions in that region. The access and capability of different "R" function capabilities could change the scores on the process steps.

1 Introduction

The nature of construction activities makes the sector resource intensive [1]. According to Kukah et al. [2], construction and its activities are responsible for a large proportion of carbon emissions. Globally, the construction industry consumes 25% of timber, 16% of water, and 40% of sand, stones, and gravel [3]. Carbon is also released by the construction process due to usage of fuel and electricity [4]. Furthermore, cement is the key component contributing to CO_2 emissions during concrete production [5]. As the world strives towards attaining carbon neutrality and net zero, it is imperative to identify ways in which the construction industry can reduce or totally eliminate its emissions [6, 7].

Schwartz et al. [8] explain lifecycle carbon cycle (LCC) emissions to mean the carbon dioxide that is emitted through the life cycle of buildings via all the processes

the building goes through. LCC has also been explained by Rodrigo et al. [9] and De Wolf et al. [10] to include operational carbon (OC) for ventilation, heating, lighting, cooling as well as embodied carbon (EC) for production, transport, material, construction, and disassembling. Schwartz et al. [8] in their study classified LCC under three groups: (i) EC emissions during extraction of raw material, transporting, construction, maintaining, and refurbishing, (ii) OC emissions cooling, heating, lighting, and (iii) carbon emissions from demolition of building and transporting of the waste generated.

Carbon trading is a market mechanism that seeks to facilitate the reduction of emissions of global greenhouse gases such as carbon dioxide [11]. The principle underlying carbon emissions trading is that entities must not exceed or go beyond the set carbon emission quotas that have been distributed by the government [12]. Firms whose emissions exceed cap would have to purchase emission quotas/allowances in order to emit [13].

According to Ng and Luk [14], the high quantity of emissions arising from the construction industry provides a justification for usage of carbon trading schemes in increasing emission reduction possibilities. The successful implementation of carbon trading in the construction industry is however dependent on the presence of transparent and rigorous standards plus the ability in setting realistic baselines or emission caps [15]. It is, therefore, expedient to have the engagement of all relevant stakeholders involved before carbon trading for the construction industry is implemented [16, 17].

Even though carbon trading has been identified as a panacea for mitigation of greenhouse gases and subsequent decrease in climate change menace, yet current carbon trading systems were originally not developed for the construction industry and carbon trading is a new concept to the construction industry [15, 18–20]. Even though the European Union Emission Trading System (EU ETS) is the largest multinational implemented carbon trading scheme in the world, it covers a number of economic sectors but little on construction [21]. Other typical emission trading schemes also do not have much focus on the construction industry. The aim of this study is therefore to develop a carbon trading emissions system for the construction industry based on systems theory.

2 Literature Review

2.1 Carbon Trading

The concept of carbon trading originates from “emissions trading” proposed by Dales who was an American economist [22]. Emissions trading is a government environmental regulatory policy and market instrument that seems to reduce environmental pollution. In 2002, the Netherlands was the first to launch carbon trading market and was followed by United States in 2005 [22].

Countries around the world have adopted a variety of market mechanisms to internalize environmental externalities, such as the European Union (EU) emissions trading system, the United Kingdom (UK) emissions trading system, the California carbon market in the United States, and the New Zealand carbon emissions trading system [23].

The underlying concept behind carbon emissions trading is to provide incentives for companies/nations to cut down on their carbon emissions so as to have leftover permits they can sell [24]. The wealthier and bigger companies/nations efficiently subsidize the efforts of the poorer and high-polluting companies/nations by purchasing their credits [25]. With time, these wealthier companies/nations are incentivized to also reduce their emissions, so they do not have to purchase as many carbon credits in the market.

2.2 Systems Theory

System refers to the collection of components that are inter-related and work together in attaining a common goal [26]. Systems may be complex and can consist of other smaller systems called sub-systems. Systems do not operate completely in isolation [27]. Systems are contained within environment which contains other systems and external agents. A boundary defines the scope of a system. The constituents outside the boundary are part of the system's environment and everything contained within the boundary also parts of the system itself [28]. System boundary also serves as the interface between the environment and the system [29]. Interface represents the exchanges that take place between the system and other systems or with the environment.

When component of a system is changed, it affects other components within the system or even the whole system [30]. It is possible to predict changes in behavior patterns in the system. For systems that engage in learning and adaptation, the level of growth and degree of adaptation is influenced by how effectively the system engages with the environment and other contexts that influence the organization [31]. Some systems support other systems and maintain the other systems in order to prevent failure. The key aims of systems theory are to model a system's dynamics, conditions, constraints, and relations [32]. Systems theory also makes use of principles such as tools, methods, and measures and applies these principles to other systems [33].

Input of a system encompasses the raw materials that are processed to deliver a particular output [34]. Inputs come in varying forms and are not always physical in nature. Examples of inputs comprise knowledge, data, machinery, personnel, and physical location among others [35]. Process involves the transformation of inputs into outputs [36]. Output of a system is the final outcome or finished product that the system creates. Outputs can take different forms. They can be products, services, information, etc. [37].

3 Carbon Trading System for the Construction Industry

The carbon trading system for the construction industry is modeled based on systems theory. Figure 1 illustrates the high-level model of the carbon trading system. The system comprises of an input, process, and an output. Feedback is from the output to input. Feedback is the element of control in the system. Feedback details out information on performance of the system and helps in adjusting behaviors in the system.

3.1 Inputs of the Carbon Trading System

Input consists of variables that are put in a system. Relating this to carbon trading system for the construction industry, the inputs refer to all the components and constituents that need to be in place for carbon trading to take place. The inputs range from marketplace variables, policies on carbon trading, stakeholders for the trading among others. Since the input for carbon trading is plenty and diverse, a categorization method was deemed expedient to place these various variables under. This study adopts the PROMISE framework for categorizing the system's inputs.

The PROMISE framework is a system thinking approach to sustainability strategy developed by Massachusetts Institute of Technology (MIT) Sloan School of Management researchers John D. Sterman, Jayson Jay, and Roberto Rigobon [38]. It is an acronym representing Personal, Relational, Organizational, Market, Institutional, Social, and Environmental [39]. In this study, it was adopted for categorizing the input variables for the carbon trading system because PROMISE framework is based on systems thinking which belongs to the family of systems theory.

The framework explains how sustainability projects work. Projects that are sustainability-oriented start with people (personal) and the interactions among stakeholders (relational). Firms are involved in these projects (organizational), and they are influenced by market conditions (market). Governments and other stakeholders are involved in these sustainability projects (institutional). A broader group of

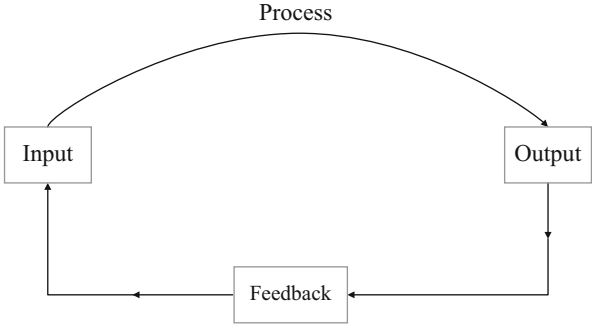

Fig. 1 High-level model of carbon trading system. (Source: Authors' construct (2024))

stakeholders involve the society that is affected by these projects (social). Natural resources further have a role to play in sustainability-related projects (environment). These six factors have an influence on each other [38, 39].

"Personal/relational" category input variables in carbon trading involves both personal and relational aspects of carbon trading in construction. Personal carbon trading underscores the rights and roles of consumers through household use of energy [40]. It operates on the idea that individuals are allocated carbon quota. The quota can be used entirely or partially sold to others [41]. Relational explains the relationship between stakeholders in the carbon trading scheme [42]. Stakeholders for carbon trading in the construction industry include central government, local government, construction firms, individuals, environmental protection departments, non-governmental organizations, and financial institutions [43].

"Organizational" category in carbon trading describes elements that influence the way organizations/firms work and behave. According to Wade et al. [44], organizational factors in carbon trading include corporate culture, environmental attitudes of organization, historical engagement, leadership abilities, innovation adoption, research and development, and technology use.

"Market" category input variables explain where buying and selling takes place. Market category variables encompass economic trends that affect demand and supply. Market category explains the elements in place whereby parties engage in exchange. In carbon trading, market mainly relates to the production and buying and selling of carbon credits [24].

"Institutional" category input variables include the irreplaceable role of government in carbon emissions reduction through carbon trading schemes [45]. Institutional factors include executive orders, laws, penalties, rewards, incentives, and compensations related to carbon trading for construction [46]. Carbon emission targets and policy tools based on these emission targets for the construction industry are encompassed in the input category called institutional [47].

"Social" category input variables are the elements of carbon trading that affect people within a society. Variables in carbon trading under social category include population, urbanization, and social cost. [48]. "Environmental" categorization variables in carbon trading relate to the environmental considerations of carbon trading including emissions of carbon dioxide.

Incorporating these six components in sustainability projects leads to better and successful projects. At each level of the framework, variables can be optimized [39]. The PROMISE framework, however, demonstrates at each level the qualities of a system: interdependencies, uncertainty, and feedback loops [49]. Some recent studies on sustainability have adopted the PROMISE framework for classifying their variables in sustainability-related projects. A notable example is the study by Dumitriu [50]. The study conducted research on sustainability adoption in universities. Figure 2 illustrates the grouping of input variables for the system based on PROMISE framework.

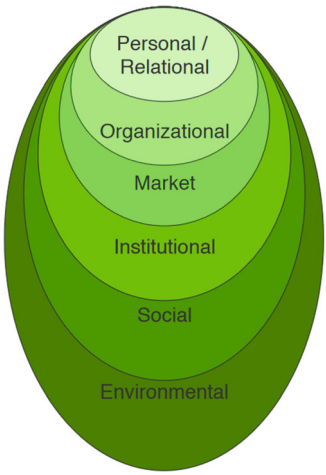

Fig. 2 Classification of grouping for input variables based on PROMISE framework. (Source: [38, 39])

3.2 Process of the Carbon Trading System

Process in systems theory refers to what happens in the system that transforms the inputs into the final output. In carbon trading system, there are multiple processes that transform the input. In this study, the process was based on the interaction and influence among the categorization of input variables using the PROMISE framework. A foremost process in carbon trading is setting of cap. The cap implies the uppermost limit of greenhouse gas that is allowed in the trading scheme. It also represents the total number of allowances that covered entities can have access to. The setting of cap corresponds with the baseline against which emissions must be reduced [51]. In setting the cap, historical emissions are set against a base year or projected future emissions. Governments set cap on the maximum level of permits or allowances under the cap. Emitting firms must therefore obtain and surrender permit for every unit they emit. Permits can be obtained from government or through trading with other firms in the carbon trading market [19]. The allowances from government are either free or auctioned. In Fig. 3, the variables under setting of cap fall under the categories: market, institutional, organizational, and environmental. These variables have interactions among other variables in their categories and other categories. Some of the variables include emission cap, carbon allowance price cap, free quota, carbon intensity reduction rate, CO2 emissions, auction allocation, and level of free allocation of permits [52].

Purchasing of economic carbon credits or carbon offsets is another major process of carbon trading through which buildings in the construction industry can minimize their net environmental impact. These carbon credits come in the form of tradable certificates awarded to firms to lower the content of carbon released in the atmosphere. This can come in the form of carbon capture and sequestration. From the PROMISE framework categorization, majority of the variables for purchasing carbon credits fall under market categorization. However, they have influence on

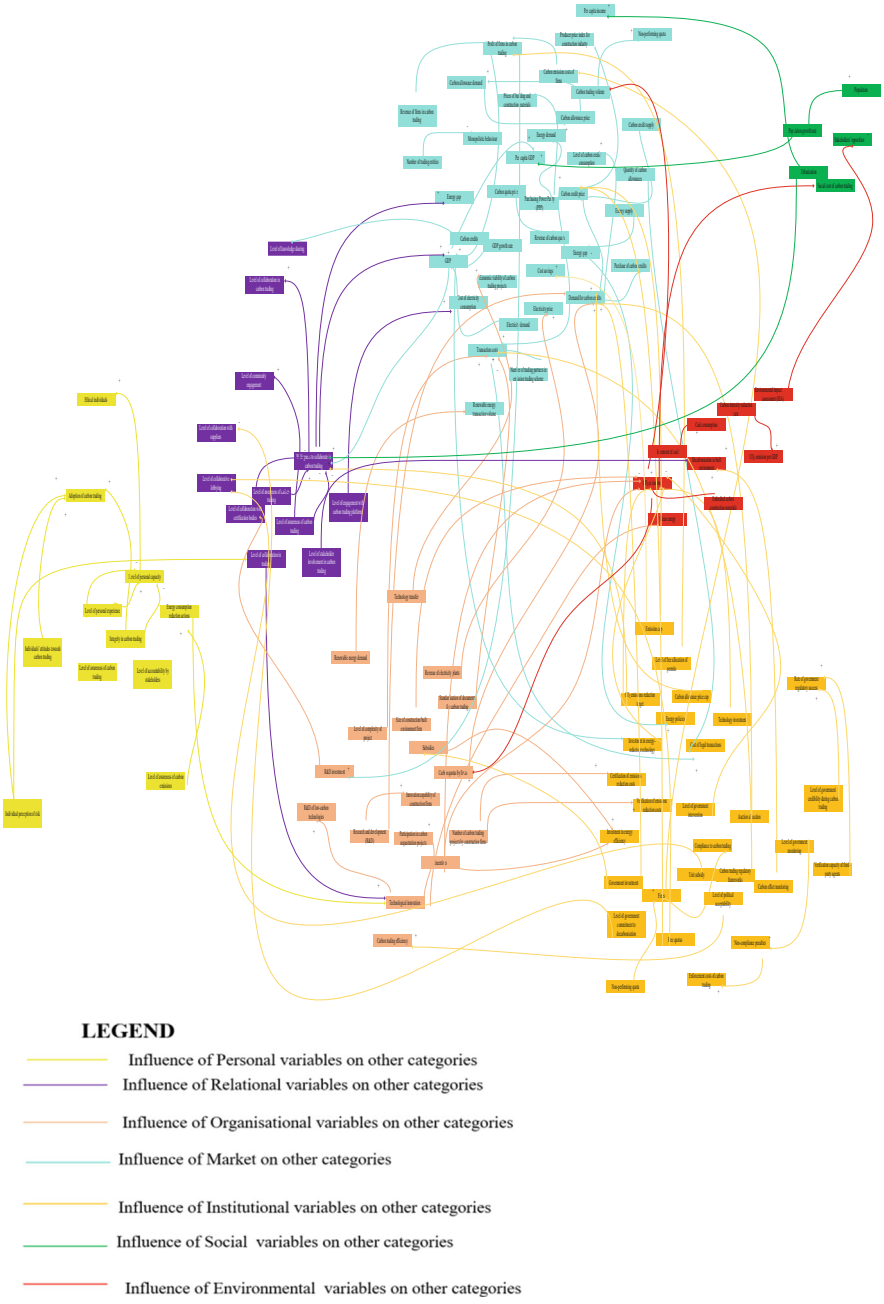

Fig. 3 Process in carbon trading system. (Source: Authors' construct (2024))

other factors in the market categorization and variables in the other categories. Some of these variables include carbon credit price, demand for carbon credits, level of carbon credit consumption, quantity of carbon allowances, profit of firms in carbon trading, carbon trading volume, and transaction costs [21, 22].

A further major process in carbon trading system for the construction industry is Monitoring, Reporting, and Verification (MRV). MRV consists of multiple steps involved in measuring emissions removed by polluting firms and certifying that the removals are truly real, additional, permanent, and verifiable. This is then reported to a third-party agent that is accredited to certify that the removal was completed according to the right MRV protocols. The verification of carbon credits is a rigorous process, and the end goal is to ensure legitimacy of the credits. This verification process starts with the project developers and firms that implement activities that reduce carbon emissions. The developers/firms have to provide evidence of reduction in carbon through the monitoring of data, project reports and other required documents. In Fig. 3, MRV and its associated variables are found in the Institutional category. Some of the variables in the system include verification capacity of third-party agents, verification of emissions reduction costs, certification of emissions reduction costs, and participation in carbon sequestration projects [53].

Figure 3 below shows the process for carbon trading in the construction industry based on the variables in the input categorization using PROMISE.

3.3 Output of the Carbon Trading System

Output in systems theory is the final outcome obtained after running an entire process or a part of the process. In the trading system, the output will be measured by two indicators. These are the efficiency of the trading system and its ability to contribute to mitigation of greenhouse gas emissions. According to Kukah et al. [19], when carbon trading system for the construction industry is operational and running, it is appropriate for the efficiency of the system to be measured in order to ascertain if it is attaining its set goals. Xia et al. [54] also posit that the end goal of a carbon trading system is to contribute to the mitigation of greenhouse gas emissions. The built environment sector contributes 39% of global carbon emissions comprising of both embodied carbon and operational carbon [55]. It is expedient, therefore, to ensure the carbon trading system developed for the construction industry is able to contribute to reduction in these emissions. Figure 4 below shows the output for carbon trading in the construction industry.

Fig. 4 Output in carbon trading system. (Source: Authors' construct (2024))

4 Conclusions

Emissions trading has been identified to be a reasonable panacea for curbing future levels of greenhouse gas emissions. This paper presented a conceptual model of carbon trading system for the construction industry based on systems theory. The system comprises input, transformed through process and having an output. There is feedback from the output to the input in the system. This study has useful practical, empirical, theoretical, and wider implications. Overall, this research makes a unique contribution to climate change mitigation agenda by modeling carbon trading system for the construction industry. This study is relevant to policymakers, industry, and academic researchers since the outcome of the study enhances knowledge and gives sound basis for future works on reduction in greenhouse gas emissions through the application of carbon trading.

1 Introduction

As the planet faces escalating environmental challenges, particularly in the realm of the built environment, the urgency to transition toward zero waste and zero emission strategies is more critical than ever. These strategies are essential to mitigate the profound ecological footprint of human activities, aiming to alleviate the environmental burdens we impose on our planet. Within this pressing context, the circular economy (CE) model emerges as a model of transformation, advocating for the establishment of sustainable, self-sufficient systems that significantly reduce environmental impacts while simultaneously fostering economic resilience. This model, fundamentally, is about creating an economic system dedicated to the elimination of waste and enabling the continual use of resources. It encompasses an extensive array of practices designed to extend the lifecycle of materials, promote efficient recycling and reuse, and decisively reduce the extraction and consumption of resources [1].

Introducing the 'Circulution' concept in this discourse underscores the application of CE principles specifically within the timber and construction sectors. This novel term encapsulates the necessity for both evolutionary and revolutionary approaches in the quest to foster a Net-Zero built environment. 'Circulution' embodies the dual pathways of innovation within the construction sector concerning timber use: evolution, which indicates a gradual, continuous development of sustainable practices and technologies; and resolution, which signals a significant, transformative shift toward groundbreaking innovations. This dual approach underscores the necessity for comprehensive and multifaceted strategies to accelerate the transition to a Net-Zero built environment, blending incremental improvements with radical, systemic changes.

The transition toward a CE necessitates profound shifts not only in our production and consumption patterns but also across the entire value chain. It demands the adaptation of market strategies, the innovation of business models, and a thorough reevaluation of management strategies to align with the diverse visions of stakeholders involved in the circular built environment. However, the concept of circularity is rife with contestation, characterized by diverse interpretations and expectations among stakeholders [2]. This contested nature of circularity highlights the importance of stakeholder expectations and consumer perceptions as pivotal elements that can significantly accelerate the transition process to a robust circular economy but can also hinder it if there are no shared visions and values

[3]. Transitioning to new business models involves redefining value propositions for customers and reconfiguring value chains with partners to create and capture new value, indicating a strategic overhaul of traditional business practices [4, 5]. Achieving a true 'circulution' within the timber building industry necessitates the integration of governance structures, innovative business models, and active policy interaction. It highlights the need for collaboration among a multitude of actors across different sectors and the adoption of collective action. A CE organization cannot operate in isolation across the product or service lifecycle; previous research highlighted that it must engage with its stakeholders and comply with existing regulations, embodying the essence of collective action [6–9]. Observing a CE organization unfolds as an exploration of a collective project, involving regulations, practices, tools, devices, and the amalgamation of diverse values held by stakeholders. This collective endeavor prompts a deeper inquiry into the fundamental reasons behind the existence and emergence of enterprises and, more broadly, into the dynamics of collective action in the circular economy.

The Norwegian SirkTRE project (2022–2025) is at the forefront of pioneering a CE within the timber construction sector, with a clear mission to transform the way timber is utilized, reused, and recycled in the building industry [10]. The SirkTRE is co-funded by the Norwegian Green Platform initiative, which provides funding for enterprises and research institutes engaged in green growth and restructuring driven by research and innovation. SirkTRE was funded to address critical environmental challenges in the construction sector by promoting circular economy principles, particularly focusing on timber, to mitigate the ecological footprint of human activity. There are five focus areas, which are divided into 24 different work packages (Fig. 1). The five focus areas are wood-based plates and connections (SirkRESSURS), solid wood (SirkHELTRE), demonstration projects (SirkREALISERING), digital technology (SirkTEK), and standards (SirkINN). SirkINN envelopes also required coordination, communication, dissemination, and

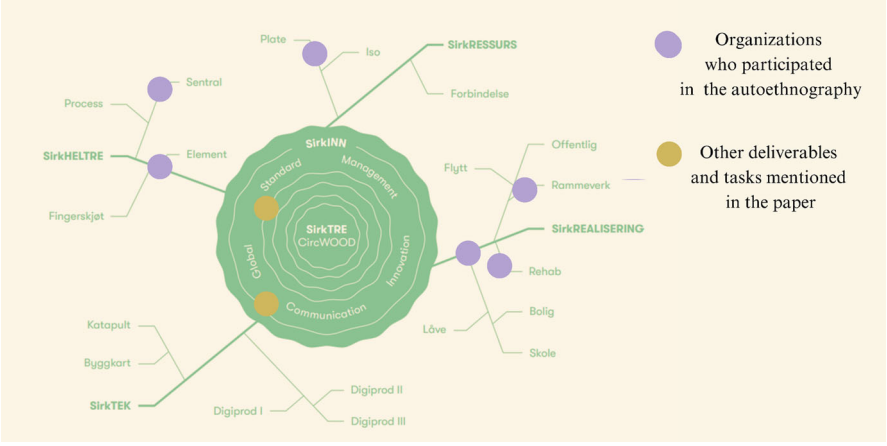

Fig. 1 The structure of SirkTRE, original design by the SirkTRE consortium, adapted by the authors

exploitation activities. The consortium counts almost 30 Norwegian industry partners from across the whole value chain (forestry, wood waste logistics, storage, prefab construction, product manufacturers, and architects), including a cluster organization, which represents more companies. Mostly only one to two partners are allocated to a work package. This means that SirkTRE has overall project objectives, but also envelopes dozens of sub-objectives (linked with the 24 different work packages). Most focus areas are managed by the project manager, Omtre AS, a startup that was founded to address some of the missing roles and responsibilities identified in the proposal writing stage in 2021.

However, this study was inspired by previous research [6–9] highlighting the necessity of stakeholder orchestration and compliance to achieve circularity in the construction sector. Additionally, it was driven by the recognition of the need for a midterm evaluation to assess hypotheses regarding collective learning and coordination, particularly in business model development and upscaling, given the initial structural disconnection of the project. One hypothesis posits that learning by doing addresses these less favorable initial conditions, while another suggests that the absence of companies providing digital enablers may hinder progress. Originally, the project aimed to have another Green Platform project complementing the focus on wood technology and architectural solutions in SirkTRE. Thus, the study serves as a reflective assessment for partners to evaluate necessary actions in the project's final phase, both internally and externally.

Hence, the main objective of this study is to analyze the evolution and resolution pathways within the project, focusing on its endeavor to establish a circular timber value chain for the construction sector and to identify policy recommendations, but also for the ongoing project. This objective will be addressed through the following research questions: How do the evolution pathways pursued by SirkTRE contribute to the transition towards a Net-Zero built environment? What practical strategies and interventions are employed by the SirkTRE consortium to implement circular systemic solutions within the construction sector, particularly concerning timber use? What are the main barriers, success factors, and key learnings derived from the SirkTRE project's implementation so far (in the first two years), and how do they inform future initiatives aiming to scale up circular systemic solutions within the construction industry?

2 Methodology

2.1 Analytical Framework: Evolutionary Lens, Termed 'Circulution'

As aforementioned, we propel our own evolutionary framework, 'circulution'. We build further on other existing evolutionary or economic evolutionary geography frameworks that have been used to analyze the governance of resources in the

transition toward a circular economy in various regions (e.g [12]). Marjanović and Williams [12] explored the uptake of circularity in a Dutch and Finnish region: Evolutionary Governance Theory provides a dynamic lens to understand the evolutionary trajectory of circular systemic solutions, capturing both gradual evolution and transformative shifts akin to the concepts of evolution and resolution highlighted in the title. By emphasizing the continuous interaction among actors, institutions, and discourses, Evolutionary Governance Theory offers insights into how governance structures and strategies evolve over time. However, the lens that [12] uses is based on observations of other phenomena, not on circular economy transitions per se. This conference paper takes a more grounded approach and, through autoethnographic investigation of a specific case (see Sects. 2.2. and 2.3), focuses on economic, political, technological, and strategic factors influencing the scalability and implementation of circular systemic solutions. In this way, we develop our own evolutionary framework, which we term 'circulution', to explore how these varied resources are orchestrated to facilitate the adoption of circular wood solutions in construction.

2.2 Methodological Choice: Collaborative Autoethnography

We opted for a collaborative autoethnographic approach to delve into the multifaceted dynamics of the SirkTRE project. This methodological choice allowed us to blend personal experiences, insights from interviews, and reflections on collective actions within the project context. By engaging with various stakeholders and social scientists involved in the project, we aimed to co-create a rich narrative that captures the complexities, challenges, and successes of SirkTRE's journey towards circular systemic solutions. Through this collaborative endeavor, we sought to provide a holistic understanding of the project's evolution and its implications for sustainable transitions in the timber-built environment. Reflecting on the collaborative autoethnographic approach employed in this study, several strengths and limitations come to light. One notable strength is the rich and nuanced understanding of the research subject derived from the integration of multiple perspectives and experiences. Additionally, the collaborative nature of the approach fosters a sense of ownership and empowerment among participants, enhancing the credibility and relevance of the research findings. However, the approach also presents certain limitations, including the potential for bias or subjectivity inherent in self-reflection and interpretation. One mitigation measure was the omission of solutions developed by Organization G, which was the organization of the first author, which means less representation of, for example, SirkTEK. The focus of this chapter was on external challenges, but there were also hints of internal challenges, for example, lack of entrepreneurship/intrapreneurship in the involved organization and lack of internal resources (financial, competence, capacity, etc.) to scale up inventions to innovations. The investigation of internal challenges might be rather done by researchers in outsider roles. Moreover, coordinating multiple voices and viewpoints in the

analysis process can be complex and time-consuming, requiring careful navigation of interpersonal dynamics and power relations. Due to its autoethnographic approach, his study focused on one consortium but did not compare with other consortia focusing on other products, services and materials, which omits insights about other reasons hindering innovation.

2.3 Data Collection and Validation

This study utilized a multiple-case study approach [11], focusing on interviews with representatives from six partner organizations within the SirkTRE consortium. They are labelled as Organizations A, B, C, D, E and F (see also Fig. 1 for their position in the SirkTRE consortium). The six interviewees are mostly engineers or general managers of architectural firms, manufacturing companies, storage places and environmental consultancy. The first author contacted many contact persons of the SirkTRE consortium for a study on mid-term evaluation of the barriers and key factors for upscaling their solutions., but only these representatives replied to the call. The first author, coming from Organization G, conducted these interviews, transcribed them, and then shared the transcripts with the respective partners for validation and consensus to ensure accuracy and alignment with their perspectives. Based on the insights gained from these validated interviews, the first author crafted an initial draft, capturing the developmental history, and personal reflections on the successes and challenges faced by SirkTRE and its participants. Following the creation of this initial draft, a series of feedback rounds were initiated, involving the interviewees from the partner organizations as well as social scientists who have been closely observing the SirkTRE project. This collaborative review process allowed for a richer, more multifaceted exploration of the themes identified in the interviews, ensuring that the manuscript accurately reflects the collective experiences and insights of those deeply involved in the project. Through this iterative process of drafting, feedback, and revision, the study aims to provide a comprehensive and nuanced understanding of the SirkTRE project's endeavors to foster circular systemic solutions within the construction industry.

3 Results: Diverse Pathways of Circular Systemic Solutions for a Net-Zero Timber-Built Environment for 2021 to 2023

The exploration of circular systemic solutions within the SirkTRE project unveils a rich menu of innovative approaches aimed at achieving a net-zero timber-built environment. Pathways in sustainability and innovation contexts are strategic approaches designed to achieve long-term goals by addressing complex challenges

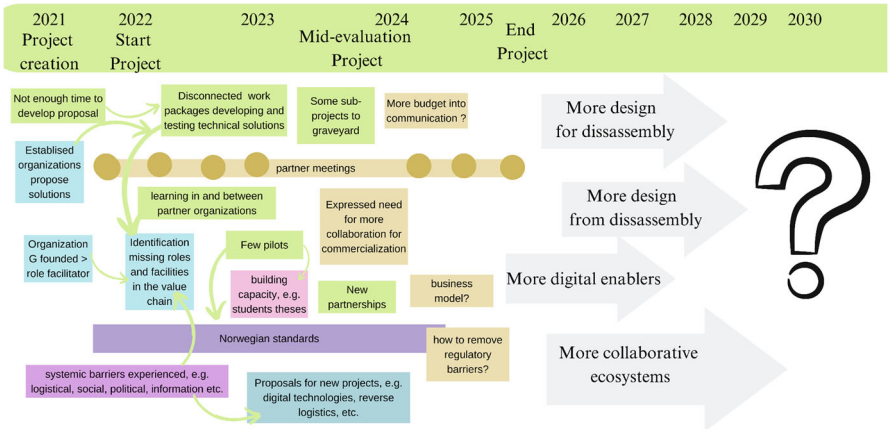

Fig. 2 Timeline of observations in SirkTRE and the possible diverse pathways unfolding for a circular future with net-zero timber built environment

such as climate change or resource scarcity. They are multidimensional, incorporating technological, economic, social, and environmental aspects, and are dynamic, evolving over time to adapt to new challenges and insights. These pathways are systems-oriented, focusing on the interconnectedness of various factors within a system, and are developed through the engagement of diverse stakeholders to ensure inclusivity and broad support. Specifically, in projects aiming for a net-zero timber-built environment, pathways would integrate circular economy principles, innovative construction techniques, and digital tools for material management, emphasizing collaboration across the construction value chain to achieve sustainability objectives efficiently. This section presents an overview of these pathways for SirkTRE (Fig. 2).

3.1 Design for Disassembly and Reuse

The development of modular and reusable interior wall systems represents a significant innovation within the SirkTRE project, particularly highlighted in the work of organizations like D and E. These systems, designed for ease of disassembly and reassembly, stand at the forefront of extending material lifespans and embodying adaptability and flexibility in architectural design. Organization E's approach to this challenge includes the conceptualization and creation of a building model that supports resident participation and transformation over time. Their system is not just about constructing a space but enabling it to evolve according to the needs of its occupants, thereby reducing the need for new materials and minimizing waste. This model is inspired by broader, systemic solutions that consider the entire lifecycle of a building, emphasizing the importance of user interaction and the potential for spaces to adapt and change. Organization D delved into the technical and practical aspects

of implementing circular solutions in the building industry, focusing on the development of a fully reusable interior wall system made from reclaimed timber. Their prototype demonstrates the feasibility of using reclaimed materials in new constructions, offering a tangible solution to the industry's challenge of interior fit-outs that typically have a short lifespan. By designing for disassembly, Organization D's wall system can be easily relocated, reconfigured, or updated, significantly contributing to waste reduction and resource efficiency. Both organizations, through their work, highlight the crucial role of collaboration across the value chain, from material sourcing to construction and beyond. Their projects underscore the potential of modular and reusable systems to not only reduce waste but also to foster innovation in building design and construction. By pushing the boundaries of what is possible with reclaimed timber and modular construction techniques, these initiatives pave the way for a more sustainable, adaptable, and circular building industry.

3.2 Design from Disassembly: Building Models Utilizing Reclaimed Timber

Another pathway is the comprehensive building model that integrates reclaimed timber into its core design. This model not only champions the use of recycled materials but also emphasizes the importance of building systems that can adapt to future needs without requiring extensive modifications. The commitment to using reclaimed timber not only reduces demand for virgin resources but also highlights a valuable shift towards valuing existing materials in the construction sector.

A notable omission within SirkTRE's initial stages was the lack of focused task forces on developing viable business models for these circular solutions. None of the interviewed organizations had any input on business model development for reclaimed timber as it was out of scope for them. This omission was visible after conducting all interviews. This gap has hindered the broader adoption and commercialization of the innovations. However, insights from 2024 suggest a promising shift, with SirkTRE increasingly directing its attention towards overcoming commercial barriers and fostering market readiness for circular construction practices. This evolution marks a crucial step in moving from concept to commercial viability, underscoring the project's role in leading the construction industry towards a more sustainable and circular future.

3.3 Digital Enablers Like Product Passports, Tracing and Tracking Technologies

In the quest for circularity within the SirkTRE project, Organizations A and B have highlighted the pivotal role of digital innovations, particularly emphasizing the potential of digital product passports. Organization A sees digital tools as essential

for tracking the lifecycle of wood products, from production through reuse. Their project focuses on understanding how products can be effectively returned to the manufacturing process or repurposed, with digital tracking systems offering a way to monitor product history and facilitate this circular process. In the journey toward circularity, Organization A encountered significant challenges related to information and data management, which have implications for their product development processes. One of the primary hurdles was the lack of detailed, accessible data on the lifecycle and usage history of wood products. This gap made it difficult for Organization A to accurately assess the potential for reuse and remanufacturing of their existing products and to develop products that could easily be integrated into circular systems. Additionally, the absence of standardized data formats and platforms for sharing information across the construction industry ecosystem further compounded these challenges. As a result, these information and data challenges not only slowed down Organization A's product development but also highlighted the critical need for comprehensive digital solutions, such as the digital product passports discussed, to support the transition to a circular economy in the timber construction sector. Organization B, on the other hand, brings a practical perspective to the implementation of digital passports. They underscore the challenges faced in the current regulatory environment, which often does not favor the reuse of materials due to stringent classification standards. However, they also see digital passports as a solution to these challenges, by providing a transparent and accessible record of material quality, safety, and reuse potential. This could, in turn, influence policy changes and encourage greater acceptance of reused materials in the construction industry. Both organizations underline the necessity of robust, user-friendly digital platforms that can integrate seamlessly with existing industry workflows. The envisioned digital passports would not only store critical material data but also include information on dismantling and reassembly instructions, further supporting the circular economy model. This approach aims to bridge the gap between the potential for material reuse and the current practices dominated by linear consumption. Despite the enthusiasm for digital enablers, there is a gap in SirkTRE's initial focus on these technologies. The early stages of the project did not prioritize the development of digital tools as a central component of circular solutions. However, the evolving insights from Organization A and Organization B suggest a growing recognition of the importance of digitalization in achieving the project's circular goals. This shift points towards a more integrated approach, where digital enablers are seen as critical to the success of circular construction practices, potentially transforming the way materials are managed across their lifecycle.

3.4 Collaborative Ecosystems and Value Chains

Expanding the collaborative ecosystems and innovative value chains within the timber construction industry, SirkTRE exemplifies the transformative potential of cross-sectoral collaboration for advancing circularity. The initiative notably includes

contributions from policy entities like Standards Norway [13] and spans to hands-on industry practitioners, establishing a broad, collaborative network. However, insights from consortium members like Organizations C and D underscore a missed opportunity for more integrated collaborative tasks or work packages that could have fostered deeper synergies across the value chain. They highlight a longing for structured collaborations where partners representing diverse segments of the value chain are intentionally brought together to leverage their unique contributions towards circular solutions. Organization F's experiences further illuminate the challenges of consortium formation, noting the time-intensive nature of assembling a diverse group and the difficulty in identifying and exploiting linkages between partners unfamiliar with each other or who are nascent in their circularity journey. This feedback underscores a critical gap in the consortium's operation, suggesting a need for mechanisms that foster closer collaboration and knowledge exchange among partners. It points to the potential benefits of incorporating collaborative tasks explicitly designed to bridge different areas of expertise, encouraging innovation through shared knowledge and co-creation. The initiative's focus on establishing supportive standards and advocating for policy adjustments further showcases its dedication to overcoming regulatory hurdles and fostering an industry-wide shift towards circular solutions. While the journey reveals areas for improvement, particularly in enhancing partner collaboration and integration, SirkTRE's comprehensive approach continues to drive the timber construction industry closer to achieving a net-zero, circularly built environment, demonstrating the critical role of partnerships in achieving systemic change.

4 Major Challenges and Key Success Factors So Far

The SirkTRE project, with its diverse consortium and ambitious goals, has fostered the development of multiple circular solutions within the construction sector, addressing the urgent need for sustainable practices. A more grounded lens, with the aim to propose a circulation framework, provides a comprehensive understanding of both the evolution and revolution of the outcomes, challenges, and the path forward for these solutions. The different pathways within SirkTRE illustrate not only the successes but also the challenges, including how economic, political, technological, and strategic decisions can impact the scaling up/out or ending.

4.1 Technical–Economic Dimension

A recurring theme across the experiences of the SirkTRE partners is the balancing act between technical feasibility and economic viability. Innovations like modular and reusable interior wall systems and comprehensive building models utilizing reclaimed timber exemplify technical successes with significant environmental

benefits. Technologically, the SirkTRE project showcases an array of innovations aimed at enhancing circularity in construction. The progression from conceptual stages to real-world prototypes in some projects illustrates a successful translation of innovative ideas into practical applications. However, technological limitations are also apparent, particularly in scaling up these solutions for broader market adoption. The economic acceptability of these solutions often hinges on overcoming market inertia, regulatory barriers, and the upfront costs associated with adopting new technologies. One of the key challenges, remarked by several interviewees, facing the reuse of reclaimed timber is the cost competitiveness relative to virgin materials. The collaboration with stakeholders such as Standards Norway indicates a movement towards establishing supportive policies and standards, yet the pathway to economic viability remains a challenge, underlined by concerns over the scalability of solutions within current market structures. Challenges related to the integration of digital enablers, such as digital product passports, and the need for more advanced technological solutions to streamline the reuse of materials are underscored. Moreover, the disparity in Technology Readiness Levels among different solutions indicates varying degrees of maturity and market readiness, which could impact the project's overall success.

4.2 Ethical–Political Dimension

The ethical–political dimension highlights the project's alignment with broader societal, economic, and environmental goals. SirkTRE partners reveal a collective ambition to contribute significantly to Norway's CO_2 reduction targets and to foster a more sustainable construction industry. A strong emphasis on environmental sustainability as a primary motivation behind the circular solutions is evident. Projects ranging from reusable interior wall systems to comprehensive building models utilizing reclaimed timber exemplify a commitment to reducing waste and carbon emissions. However, environmental challenges such as the classification and standardization of reclaimed materials, as well as the need for broader life cycle assessments, are highlighted. The difficulty in measuring the direct environmental impact of the SirkTRE project on the broader value chain and sector points to a gap in comprehensive environmental reporting and assessment methodologies within circular construction practices. In addition, the realization of these goals is contingent upon navigating political landscapes, securing governmental support, and influencing policy changes to favor circular practices. The CO_2 accounting system remains a work in progress with significant political dimensions, as major corporations lobby intensively to shape a system that prioritizes their interests. As [14] illustrated, the current policy landscape in Norway does not view construction material circularity as a policy objective at any governance level and lacks economic, capacity building and regulatory tools to advance wood circularity in construction under-utilizing the influence of top-down mechanisms. The engagement with policymakers and standard-setting bodies marks steps towards these ends, but the pace of political and regulatory support is a noted barrier.

4.3 Developmental Dimension

SirkTRE's impact is also measured through its developmental growth, encompassing geographical expansion, stakeholder engagement, and performance metrics. While the project has successfully fostered a collaborative ecosystem, expanding its influence beyond initial boundaries remains challenging. The diversity of stakeholders from various sectors enhances the project's richness but also complicates coordination efforts. These observations in SirkTRE are aligned with other observations in other ecosystems and projects and previous research highlighting stakeholder coordination as an enabler of CE in the construction sector [6–9]. Growth in terms of legal status changes, sales evolution, or geographical presence is indirectly influenced by the project's ability to navigate and adapt to the evolving landscape of the timber construction industry. Concerning the geographical dimension, the Norwegian ecosystem has path dependencies (e.g. forestry infrastructures, and incineration plants competing for wood waste resources) that can hinder the uptake. In addition, spatial capacity building and planning for a circular built environment are not present in Norwegian circular economy discourse and actualization, while these are required policy instruments [15, 16]. Litleskare and Wuyts [16] addressed findings from qualitative interviews and focus groups with architects, stakeholders in the wood industry and inhabitants of urban timber buildings. They found that the choice of using wood efficiently and adapting circular construction goals in the wood industry is partially guided by values, ideas and convictions of implementing practices that benefit society. The governance aspect within SirkTRE reveals a complex interplay of regulatory frameworks, industry standards, and collaborative dynamics. The project's goal to create new value chains and influence policy through the development of new standards and practices is commendable. Yet, the interviews disclose a notable barrier in the form of existing regulations that do not fully accommodate or incentivize circular solutions, thereby hindering wider adoption. Furthermore, the interviews reflect a need for enhanced governance mechanisms within the SirkTRE consortium itself. A more integrated approach, facilitating better cooperation and knowledge exchange among partners, is essential for overcoming silos and leveraging the collective expertise toward achieving the project's ambitious goals.

4.4 Inventiveness and Regulationist Dimension

The project's capacity for innovation and the establishment of new rules and coordination mechanisms is critical. The development of digital enablers like product passports and the exploration of novel construction models demonstrate a high degree of inventiveness. Yet, the formation of collective action and the implementation of new practices are impeded by existing regulatory frameworks and industry

standards. Efforts to negotiate and coordinate within the consortium and with external entities reveal the complexities of aligning diverse interests and visions for a circular future.

5 Conclusion, Implications and Recommendations

The findings offer valuable insights into the governance of circular systemic solutions in the timber-built environment. SirkTRE's journey can be aptly described as a 'Circulution', a term that encapsulates its evolutionary path towards fostering circular systemic solutions within the construction industry. This progression is characterized by the project's ambitious aim to integrate circular economy principles into the timber construction sector, navigating through a complex landscape of technological, economic, ethical–political, and developmental dimensions. SirkTRE has successfully sparked innovation by developing modular and reusable interior wall systems and comprehensive building models utilizing reclaimed timber and leveraging digital enablers like product passports. However, the solutions are still at a low technology readiness level (TRL), and some solutions score lower at the market readiness level (MRL).

These inventions not only showcase the project's technical and economic achievements but also its commitment to ethical and political values, emphasizing sustainability and resource efficiency. Participants got access to knowledge on diverse topics from wood technology to circular business models, training programs, educational initiatives, and networking opportunities in promoting awareness and understanding of circular economy principles and practices. However, the circulution of SirkTRE is not without its challenges. The project has encountered obstacles in fully realizing its goals, stemming from a need for more robust collaborative ecosystems and value chains. Various partners shared a desire for more integrated efforts and knowledge sharing among partners, highlighting the importance of collaboration in overcoming barriers to circularity. Moreover, there's a recognized need for addressing the scale-up challenges, particularly in terms of business models and regulatory support, which were less emphasized in the project's early stages. The SirkTRE partners underscore the importance of supportive policy frameworks in facilitating the adoption of circular practices in timber construction. They highlighted the need for clearer regulations on material reuse, standardized guidelines for sustainable timber sourcing, and streamlined permitting processes to incentivize circularity. To advance the adoption of circular systemic solutions in the construction sector, policymakers and the science-policy interface are advised to refine regulations and standards to better support circular practices, foster public-private partnerships for co-creating circular economy models and introduce financial incentives for circular solutions. Additionally, bridging the gap between science and policy involves disseminating SirkTRE's innovations and sustainable construction practices widely, establishing collaborative platforms for stakeholder engagement across the construction value chain, and promoting education and training focused

on circular economy principles and sustainable building techniques. Several key implications emerge, shedding light on the challenges and opportunities for advancing circularity in the sector. The recommendations for the final phase of SirkTRE focus on enhancing these collaborative efforts, suggesting the formation of task forces or work packages that foster inter-partner collaboration, thus ensuring a more cohesive approach to circularity. Additionally, the project is encouraged to deepen its engagement with policymakers and the science-policy interface to facilitate the broader adoption of circular systemic solutions. In conclusion, SirkTRE's successes and challenges alike offer valuable lessons for future endeavors in this field, underscoring the need for continued innovation, policy support, and, most critically, collaborative action. This study demonstrates a way for practitioners to evaluate their project-based collective learning and innovation and the diverse pathways to reach their bigger and smaller goals. As SirkTRE enters its final phase, the focus on overcoming existing barriers and leveraging the project's achievements can further propel the construction industry toward a more sustainable and circular future. Strategic emphasis on cross-project collaboration, stakeholder engagement, scalability, and digital innovation is essential. It is recommended that the consortium intensify efforts to foster cross-work package synergies through regular interdisciplinary workshops, complemented by a unified communication strategy for disseminating project achievements. Active engagement with policymakers, industry partners, and end-users is crucial to demonstrate the practical applicability and benefits of circular solutions, thereby facilitating policy support and market adoption. Developing sustainable business models and conducting market analyses will be key to assessing commercial viability and ensuring the long-term impact of innovations. Additionally, documenting lessons learned and investing in training and educational initiatives can enhance knowledge transfer within the construction sector. Leveraging digital tools, such as product passports and material databases, will further support the optimization of resource use throughout the construction lifecycle. Focused efforts in these areas can significantly contribute to achieving SirkTRE's vision for a sustainable, circular timber-built environment, setting a precedent for future construction practices.

Acknowledgements This conference paper is funded by the Norwegian Research Council, Innovation Norway and Siva under the two sister projects CircWood (project No. 328698) and SirkTRE (project No. 328731) and by the European Union under the DRASTIC project (grant agreement No 101123330). We want to thank Ola Rostad and Marjan Marjanović for providing comments on earlier drafts.

1 Introduction

The construction industry is intricately connected to economic growth, employing approximately 7% of the global workforce and contributing to 13% of the gross domestic product (GDP) [1]. This sector consumes vast amounts of raw materials annually. Worldwide statistics show that construction produces 30–40% of all solid waste, with an average of 35% ending up in landfills. Consequently, this situation presents a substantial environmental challenge for the construction sector worldwide [1]. Therefore, the industry must move from its linear economy (Take-Make-Waste) to the circular economy. The circular economy encompasses concepts like industrial ecosystems and symbioses, the 3R principle (reduce, reuse, recycle), circular material flows, zero emissions, and more [2]. In the realm of construction, the impact of cutting-edge digital tools and methodologies is becoming increasingly evident [3].

Industry 4.0 technologies play a pivotal role in the journey toward Circular Economy (CE) [4]. By redefining waste management practices, the convergence of Industry 4.0 and CE holds immense promise for environmental, health, and societal gains. The European Commission [5] has pinpointed three key areas where Industry 4.0 decision support systems can bolster CE efforts: (1) facilitating circular production through resource flow tracking, (2) enhancing the resilience and adaptability of built assets in alignment with CE principles via robust material information management, and (3) driving innovation in data spaces and establishing the architecture and governance framework for intelligent applications. Simultaneously, as a new technological era unfolds, digital advancements are revolutionising national and global economies by expediting decision-making and enhancing core business processes [6]. The recent surge in novel technologies propels the built environment into a contemporary data-driven landscape characterised by five distinct phases: data acquisition, mobile data highways, data security, data analysis, and data realisation [7–9].

This chapter focuses on the design science research (DSR) strategy to develop a conceptual framework for a digital information management system (DIMS) to facilitate construction and demolition waste management.

2 Research Philosophy for Information Systems Through Design Science Research

Research and its conclusions may be deceptive or meaningless if philosophy is not given enough thought or comprehension [10]. This is supported by Dawood & Underwood [11], who state that the failure of a great deal of research arises from the researcher needing first to understand their own philosophical assumptions. On the other hand, understanding philosophical questions can help Information Systems (IS) researchers ensure that their work is insightful and comprehensive. It can also improve the quality of the real work [12]. Ontology, epistemology, and axiology are the philosophical groundings of design science in research [13, 14]. Ontology pertains to underlying beliefs concerning the fundamental nature of reality. Ontological assumptions aid the researcher in moulding the perspective through which research objects are seen and examined [15]. After gaining an understanding of the fundamental concept of reality (ontology), the researcher can then delve into exploring its nature (i.e. epistemology) [16]. Epistemology, as a foundational component of research philosophy, delves into the essence of knowledge. It is defined as 'the theory of knowledge' and places its emphasis on the procedure involved in constructing, understanding, and advancing knowledge [15]. According to Mardiana [17], there are three paradigms within the philosophy of IS research: positivism, interpretivism, and pragmatism.

Positivism and DSR in IS share a focus on research rigour and relevance [18, 19]. While positivist research emphasises hypothesis testing and quantitative methods, DSR incorporates interpretive and critical perspectives, allowing for a

comprehensive understanding [19]. Therefore, interpretivism emerged in response to positivism's limitations, emphasising contextual variables and human experiences [20]. In DSR within IS, interpretivism complements positivism by emphasising the subjective experiences of individuals, acknowledging the complexity of human sense-making and the importance of context in studying IS [21]. However, pragmatism is also recognised as a paradigm for DSR in IS, emphasising practical solutions to real-world problems [22, 23]. Pragmatism supports the creation and evaluation of I.T. artefacts, aligning with DSR's goal to address organisational challenges and contribute to both theoretical knowledge and practical value [21, 24]. Pragmatism emerged as the preferred research philosophy for this study. This decision was based on its ability to blend elements of various philosophies, including qualitative and quantitative approaches, and its strong alignment with applied research and practical problem-solving. Given the goal of developing a DIMS that serves the RECONMATIC consortium and contributes to knowledge, pragmatism offers the flexibility to use a mix of methods, consider multiple stakeholder perspectives, and prioritise practical outcomes.

3 Design Science Research for Information Systems

DSR within the field of IS represents a research paradigm focused on developing and evaluating innovative I.T. artefacts designed to address practical, real-world issues. The foundational principle is that knowledge and comprehension of a problem domain and its solution are acquired through the construction and application of the designed artefact. [22].

Several authors, including Hevner and Chatterjee [22], Vaishnavi and William Jr Kuechler [13], and March and Smith [25], have collaborated to outline common approaches in DSR within IS. Their collective work focuses on the step-by-step process of DSR, covering problem identification, artefact design, artefact evaluation, and knowledge contribution Fig. 1. Moreover, they unanimously agree on the key outcomes of DSR. They emphasise the creation of practical elements like constructs, models, methods, and real-world applications, along with the continuous improvement of overarching theories. This shared perspective underscores a widespread consensus in academia regarding the importance of tangible contributions through constructs, models, methods, real-world applications, and refined theoretical frameworks within the realm of DSR.

Holmstrom et al. [26] assert that the initial stage in design science involves pinpointing the problem through 'diagnosing the primary research problem'. Johannesson [27] suggests that the foremost consideration for a design science researcher should be the realisation that 'something is not quite right with the world, and it has to be changed'. The output of this phase is a proposal, formal or informal, for a new research effort [13]. Furthermore, the second step, according to Voordijk [28] and Hevner et al. [22], is to create the 'technological rule' (artefact) that will solve the real-world issue. Designing and creating this artefact, according to

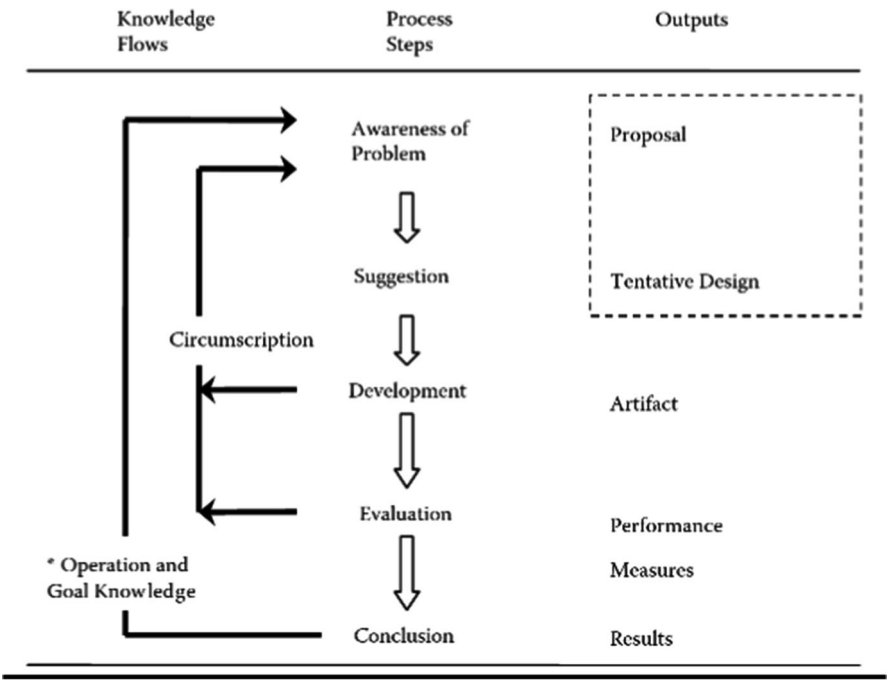

Fig. 1 The general methodology of design science research [13]

Hevner et al. [22], is the process of creating a solution concept (method or system) for a specific goal. This stage comes right after the proposal and is closely connected to it through the tentative design that is expanded upon and put into practice during the development stage [13]. Kehily and Underwood [29] state that the process of creating the artefact needs to be transparent for the solution to be meaningful from an academic perspective. This calls for an explanation of the choices made during the artefact's evolution and the development process. According to Hevner et al. [22], a design artefact's utility, quality and efficacy must be thoroughly demonstrated through well evaluation techniques. This is supported by Peffers et al. [30], who mentioned that these techniques are such as observation, analysis, experimentation, or testing, whereas Arthur [31] divided the evaluation into two components based on his belief that design science researchers have a greater chance of producing high-quality research outcomes if they employ a high-quality research process. The two components are (1) evaluating the quality of the process used and (2) evaluating the quality of the outcomes Fig. 2.

The evaluation results should provide evidence of the artefact's utility, quality, and efficacy. DSR in IS should also contribute to theoretical and practical knowledge of the problem and solution domains [30].

Finally, the last phase of DSR is the conclusion. As stated by Vaishnavi and William Jr Kuechler [13], this phase marks the culmination of a distinct research endeavour, typically resulting from satisficing, wherein discrepancies in the

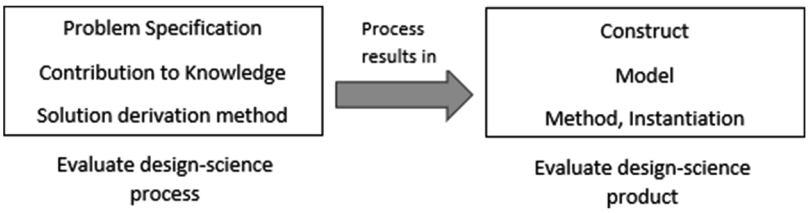

Fig. 2 Evaluating quality of DSR [31]

artefact's behaviour from the (repeatedly) revised hypothetical predictions are considered 'satisfactory'. Furthermore, Hevner et al. [22] emphasise the importance of presenting DSR effectively to both technology-oriented and management-oriented audiences.

4 DSR to Develop DIMS for CDWM

To address the challenges in CDWM, a comprehensive DIMS is being developed using the DSR method. Following DSR Fig. 3., the first phase is awareness of problem, the journey began with a critical review of the existing literature and the latest studies in CDWM, exploring the barriers and drivers in CDWM, the application of Industry 4.0 in CDWM, and the role of IS in the field to understand the problem. Through this critical examination, a noticeable gap emerged, concerning the integration of Industry 4.0 technologies to support the waste management, waste quantification, auditing and waste diversion in the C&D sector [31–33]. Specifically, this gap revolves around the absence of a comprehensive digital information management system that encompasses the entire project lifecycle, extending from inception to demolition or deconstruction phases. Furthermore, there is a notable lack of clarity regarding the roles and engagement of various stakeholders within these systems. Most of the information management systems reviewed in the existing literature, while promising in their potential, have exhibited shortcomings. One significant limitation is the absence of a secure and robust database infrastructure for effectively handling the vast datasets inherent in the integration of technologies like BIM and IoT or real-time data collection in BIM and Blockchain integration. Moreover, many systems have faltered in achieving real-time data collection, a critical feature to ensure the timely and accurate tracking of waste and materials in construction and demolition processes which will help analysing the material flow. In response to this gap, a proposal was formulated, suggesting the integration of BIM, IoT, and BC to enhance material flow analysis throughout the lifecycle of the project.

Looking towards the future, implementing the proposed solution will undergo a rigorous evaluation as part of the DSR process outlined by Arthur [34]. This process begins with a preliminary study to verify the identified problem's existence and

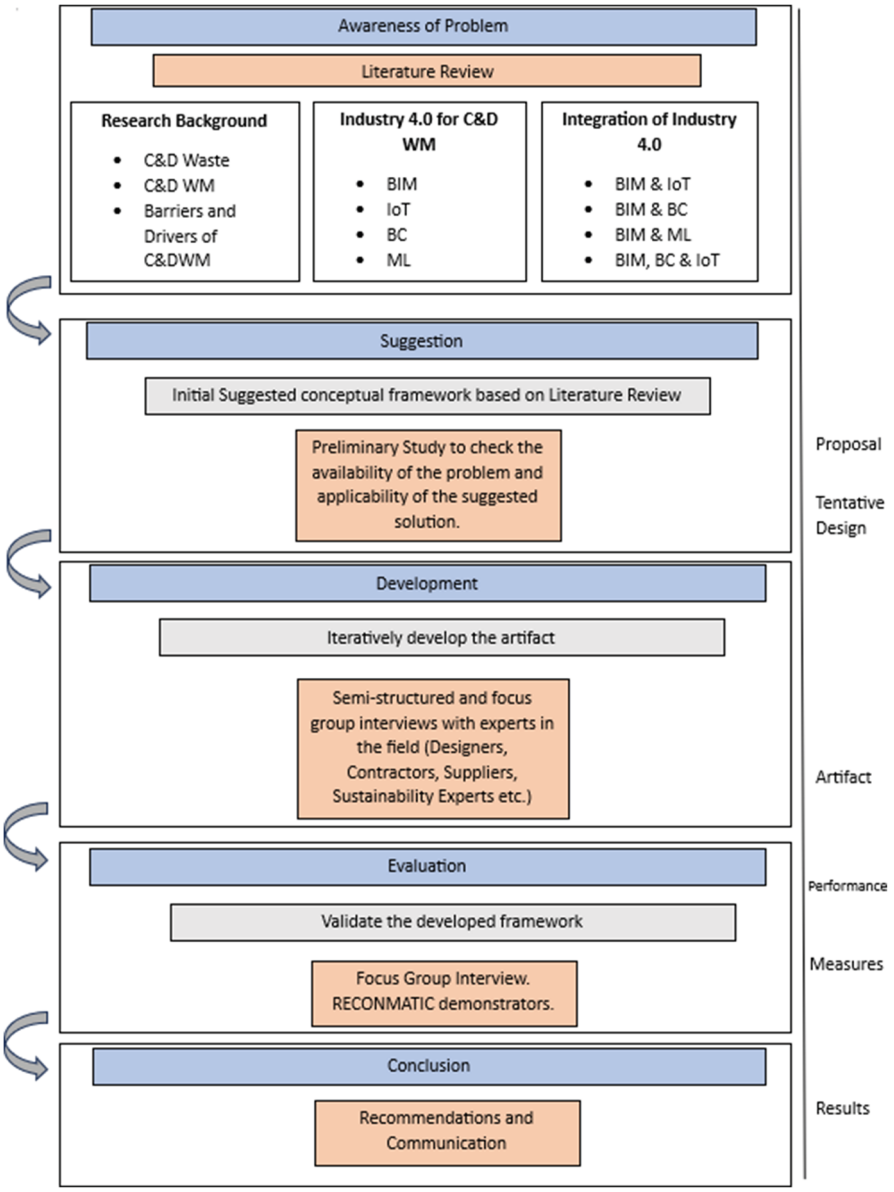

Fig. 3 Design science research process flow

assess the proposed solution's applicability. Two distinct groups will be targeted for this study through a questionnaire survey. RECONMATIC partners will be engaged to examine the problem's existence, the solution's applicability, and its support for RECONMATIC DEMONSTRATORS [35], and the wider industry's perspective will also be considered to check the problem's existence and the solution's

applicability. Following data collection, the results from the preliminary study will undergo statistical analysis using SPSS to analyse the data and assess its reliability. Subsequently, the artefact will develop as a co-creation between the industry experts, involving semi-structured interviews with RECONMATIC partners and a focus group in a workshop with the wider industry. The framework will undergo iterative refinement by thematically analysing the qualitative data collected and then will be evaluated in the RECONMATIC annual meeting workshop, incorporating insights from RECONMATIC case studies. This will be done by following the Framework for Evaluation in DSR developed by Venable et al. (2016), by defining the explicit goals, choosing evaluation strategies determining properties that will be evaluated and designing the individual evaluation episodes [36]. Following this, the framework will progress to implementation, culminating in the development of the system architecture. This will be done by following the Togaf standard [37]. The outcomes and results of this endeavour will be disseminated through various channels, including journal papers, conferences, and the RECONMATIC website, solidifying its contribution to the field of CDWM, CE and Digital Technologies.

5 Conclusion

In conclusion, the aim of this research is to develop a comprehensive conceptual framework for a DIMS that incorporates Industry 4.0 technologies to enhance CDWM, encompassing the entire project lifecycle. This approach aligns seamlessly with the principles of DSR, where the central focus is on designing and exploring the use of an artifact to address a specific problem within a given context [38]. In DSR, researchers propose and develop an artifact to engage with a problem context, ultimately aiming to enhance elements within that context [38, 39]. This chapter has delved into the steps followed within the DSR strategy to develop this system as part of the Horizon Europe Project RECONMATIC.

Moreover, developing the DIMS presents challenges that blend academic standards with human interactions. Engaging stakeholders through interviews requires balancing diverse needs and opinions, often requiring negotiation to reach consensus. Whereas the development of the framework will be a co-creation between RECONMATIC Partners and the wider industry, this could also be a challenge since the RECONMATIC Partners would give their insights based on RECONMATIC project only. This potentially limits the scope of perspectives and experiences considered in the development process, posing a challenge in ensuring the inclusivity and comprehensiveness of the DIMS framework.

Thus far, the researcher has completed the problem detection phase, identifying key issues, including the lack of integration of Industry 4.0 covering the entire project lifecycle, a lack of understanding of stakeholder roles within these systems, and the absence of systems supporting material flow analysis. The researcher has proposed a framework that integrates BIM, IoT, and BC specifically to strategically manage information across the whole lifecycle of the project, supporting material

flow analysis. This proposed solution will be followed by an evaluation of the identified problem and the suggested framework with RECONMATIC partners and the wider industry. Subsequently, the research will move on to the development of the artifact and, finally, its evaluation.

Funding This research was funded by Horizon Europe (grant agreement number 101058580, 2022) and by Innovate UK as part of the UK Guarantee programme for UK Horizon Europe participation (project number 10038579). 1 Introduction

The concept of a circular economy strives for an efficient use of materials and a reduction of waste [1]. A difficulty in making progress toward the goal of circularity is that there has often been confusion concerning key principles that should be followed [2]. In fact, the definition and measurement of a circular economy and its impact often lack scientific and research rigor [3]. Within this context, the construction industry is a major contributor to waste and pollution [4]. In their study, the EU Commission expressed concern that the construction industry has not fully embraced the principles of circularity. The study included a model of the ecosystem and identified areas of concern, in particular, the slow uptake of circularity in construction.

The report by the European Commission found the construction industry is "currently responsible for over one-third of total waste generation in the EU" [4: 3]. This study noted that the industry has been relying on voluntary targets and measures to reduce waste and pollution, but these have been ineffective. The construction industry in Europe represents 9.6% of the total economic activity and employs 24.9 million people [4: 3]. However, the industry is highly fragmented and distributed with thousands of contractors and construction material providers.

To transform, the industry needs to change from linear thinking to systems thinking [4]. The traditional mindset of those in the construction industry has not been consistent with a circular economy [5]. Systems thinking approaches the industry as a network of many elements, where the actions of one element influence the actions of others [6]. These interactions can be modeled with a causal loop diagram (CLD). This leads to this study's research objectives. The first is to create a model of the construction industry when applying circularity. The second is to analyze the model to identify control loops and potential dysfunctional behavior. The third is to assess the likely impact of adopting the recommendations identified by the European Commission [4].

2 Background

The concept of a circular economy is not new. Civilizations such as ancient Egypt, India, Peru, and the Byzantine Empire had programs for recycling and reuse [7]. At its core, the modern circular economy mindset is concerned with sustainability [1]. Despite the interest in the circular economy, progress is still needed to develop viable business models that achieve high performance and are grounded in the circular economy [8].

Galle et al. note that the classic chicken and egg dilemma exists in the construction industry [5]. There is little demand for circular construction solutions, so there are few product offerings. Since there are few products, customer awareness is low, resulting in little demand. The technical and social challenges facing the construction industry as it transforms into a circular economy are well documented [3]. These challenges are throughout the industry and point to the need for a holistic change [9]. One of the challenges is the fragmentation throughout the industry. Most builders or suppliers do not recognize the impacts their actions can have on the entire industry ecosystem [10]. Fragmentation also exists on the regulatory front. There are many policymakers with many policies and standards being developed [11]. For instance, there is little harmonization of standards and processes with regard to construction and demolition waste disposal [12]. In addition, past decisions made by architects and builders when a building was built are the cause of high levels of current construction waste. However, there is no current accountability for future demolition problems [4, 13]. This is to be expected since most construction design decisions are made based on short-term cost/benefit tradeoffs [5]. Buyers and financial institutions seldom include circular economy criteria in their

decision-making. Osei-Tutu et al. [14] addressed this in their scientometric analysis of available literature concerning the barriers to the construction industry's adoption of circularity. The six categories of barriers they identified were social, cultural, economic, technical, environmental, and technological.

Several studies have approached the construction industry from a systems perspective. Ghufran et al. analyzed the construction industry supply chain using systems analysis [13]. This study found 12 enablers of circularity for the construction industry. The study found that the reinforcing action of system loops was slow-acting. In addition, a strong fast-acting balancing loop keeps the industry in a steady-state condition. Ding et al. considered the forward and reverse logistics cycles as a system and identified the similarities and differences between the two flows [15]. The process steps identified by Ding et al. closely mirror the nine process steps identified in the EU report [4].

Many circular economy business models are built on linear thinking [16]. System thinking incorporates feedback loops and multiple interaction effects. A system model consists of elements and their interactions. System elements are events, processes, states, or objects [17]. The critical characteristic of system elements is the interaction between elements [6: 14]. Systems thinking often uses visualizations to provide stakeholders with insight into how to transition an industry to a circular economy [18]. In a CLD, the interactions are shown with arrows indicating the interaction between elements. These arrows are depicted with a plus sign to show a positive correlation or a minus sign indicating a negative correlation. An element can be connected to many elements, causing all of them to be impacted simultaneously. Similarly, one element may be impacted by multiple elements and the actual effect will be a balance between those elements.

Feedback loops occur in a CLD when two or more elements are connected in a chain that doubles back on itself. When all the arrows in the chain have the same sign, the loop is a reinforcing loop. Interactions in this loop will continue until they exceed a system constraint or until an element is consumed. When there are both positive and negative signs, the loop is likely to be a balancing loop. A balancing loop tends to hold the elements at a specified level or steady-state condition. Meadows [6] identifies several system performance challenges and issues. One of these, layers of limits, occurs when the performance of an element is based on multiple interactions that must work in concert. Another challenge is ubiquitous delays, where the impact of a relationship within a system is slow-acting, resulting in feedback loops that may be ineffective at influencing the behavior of the system. Another performance issue is the tragedy of the commons. It is associated with an element of the system that is consumed by other elements. Success to the successful problem occurs when a reinforcing feedback loop grows one aspect of the system to a dominant position and changes the structure of the system. One additional problem is seeking the wrong goal. It is associated with establishing goals for system elements that are not aligned with the overall system goal.

3 Methodology

3.1 System Elements

As noted earlier, system elements are events, processes, states, or objects. An example of this is the implementation of a new industry regulation. An example of this process is the demolition of a building. A state example is the end-of-life condition of construction materials. Object examples are recovered construction materials. The CLD uses elements from the EU report [4]. That report identified nine phases in a construction lifecycle [4; 12–13]. Each of those phases is a process element in the CLD.

- Concept—Initial ideas, goals, and constraints are identified.
- Procurement—Acquisition of goods and services for construction is conducted.
- Design—Detailed plans and schematics of the construction (and deconstruction, when applicable) are created.
- Manufacture—Fabrication of construction materials, including the refurbishment of previously used materials.
- Demolition—Dismantling an existing construction asset to make room for new construction. This is the first step in a renovation, rather than a deconstruction.
- Construction—Assembly and erection of the designed structure.
- Handover for Use—User/occupant takes possession of the constructed asset and uses it for their purpose.
- Refurbishment, reuse, renovation, repair—Modification and replacement of elements in the constructed asset.
- Deconstruction and end-of-life—Dismantle and dispose of materials from the constructed asset.

A critical element of circularity in the construction industry is the disassembly and reuse of construction materials. This area required more detail in the CLD. The study conducted by López Ruiz et al. identified five stages related to the deconstruction and end-of-life of buildings [12]. These stages are added as process elements to the CLD to enhance the overall process of demolition, as listed in the EU report [4].

- Preconstruction—Designing to minimize waste and simplify disassembly and deconstruction. Within the CLD, this is synonymous with the design element.
- Construction and Renovation—Creating and implementing site waste management plans. Within the CLD, this is considered to be the construction element.
- Collection and Distribution—Techniques and controls for collecting and segregating all demolition materials and optimizing the transportation of those materials.
- End-of-Life—Techniques and procedures to determine whether materials are at end-of-life or if they can be reused, refurbished, repaired, or recycled.
- Material Recovery and Production—Establishing processes for the reuse and recycling of demolition materials and the restoration of the site.

The CLD also required more detail in the supply chain. The literature review identified a study by Ghufran et al., that included a CLD for the construction industry supply chain [13]. That diagram used 12 elements that included processes and a number of organizational or cultural states. These were merged into the CLD being developed using causal relationships identified by Ghufran et al.

- Agility—The ability to quickly pivot to new products or processes.
- Adaptability—The level of difficulty in changing systems and processes.
- Collaboration—The willingness and capacity to work with other organizations.
- Compatibility—The ability of physical products, digital systems, and personnel resources to integrate with other organizations.
- Information Sharing—The willingness and capability to release product and project information to other interfacing organizations.
- Just in Time—A management and scheduling approach for materials and components that ensures the materials are available when needed, not early and not late.
- Strategic Risk Planning—Proactive risk management to identify organizational threats and opportunities within the design, construction, and renovation processes.
- Leadership—The ability to influence the actions of others to achieve a goal.
- Top Management Support—The level of interest and engagement by senior managers with respect to an initiative or goal.
- Corporate Social Responsibility—The degree to which corporate decision-making includes social and environmental issues as major considerations.
- Flexible Structure—The ability of the organization to reallocate and deploy resources based on current needs and issues.
- Visibility—The extent to which the current status of a project or process is made known to various levels of decision-makers in an organization.

Additional elements used to enhance the CLD were based on the inherent industry barriers identified by Osei-Tutu et al. [14]. Their research identified six barrier categories that create challenges for the construction industry's transition to circularity.

Cultural Barriers—The cultural barriers included the perception that reclaimed/refurbished materials were of poor quality and an unwillingness to collaborate within the value chain. This latter barrier is a long-standing characteristic of the industry.

- Economic Barriers—The economic barriers addressed profitability. First, reclaimed materials are often more expensive than new materials. Second, developing new circular designs adds costs for existing builders with old designs. Finally, in many areas, the landfill costs for construction materials are low.
- Technical Barriers—These barriers were related to the lack of design standards and codes. This creates uncertainty and delays for both architects and builders.
- Social Barriers—These barriers are due to the lack of demand for construction projects that embrace the principles of a circular economy. The study found a lack of knowledge about the construction impacts on the environment. In addition,

builders are unaware of construction practices that align with circular economy principles.
- Environmental Barriers—The environmental barriers were also two-fold. There is widespread ignorance of environmental impacts with respect to construction waste. In addition, there are few incentives to encourage the adoption of construction practices that minimize negative environmental impacts.
- Technological Barriers—These barriers are associated with recovery, reuse, recycling, and refurbishment technologies. There is limited availability of reliable technologies and little incentive for producers to adopt or improve these technologies.

3.2 Element Interactions

In a CLD, every interaction is represented with an arrow that indicates the nature of the correlation. The ecosystem relationships represented in this diagram are based on the relationships identified in the literature. The goal of this system analysis is the adoption of circular economy principles in construction. Therefore, the positive relationships are those that promote circularity, and the negative ones inhibit circularity.

Many of the high-level lifecycle process steps have multiple predecessor arrows, some positive and some negative. When the influence of the positive causes is greater than the negative causes, that element aligns with circular economy principles. For instance, at the design element, when the positive causal predecessors are stronger than the negative predecessors, the building designer(s) will likely incorporate circular economy design features. If the negative predecessors predominate, the designs will continue with conventional construction designs and processes.

3.3 Causal Loop Diagram

The construction industry CLD contains 30 elements representing the lifecycle flow of a construction project (see Fig. 1). This CLD includes causal effects that encourage the development of buildings relying on circularity concepts and barriers or challenges that limit the adoption of circularity principles.

A quick assessment of the CLD shows that the design element is the most connected with six successor relationships and four predecessor relationships. Next is visibility with nine relationships, followed closely by construction with eight and both collection and deconstruction with seven. Only six elements follow the classic linear thinking approach of a single predecessor and successor. None of those are part of the construction industry lifecycle. The complexity of this CLD indicates the construction ecosystem cannot be successfully managed with linear thinking; it must be managed as a system.

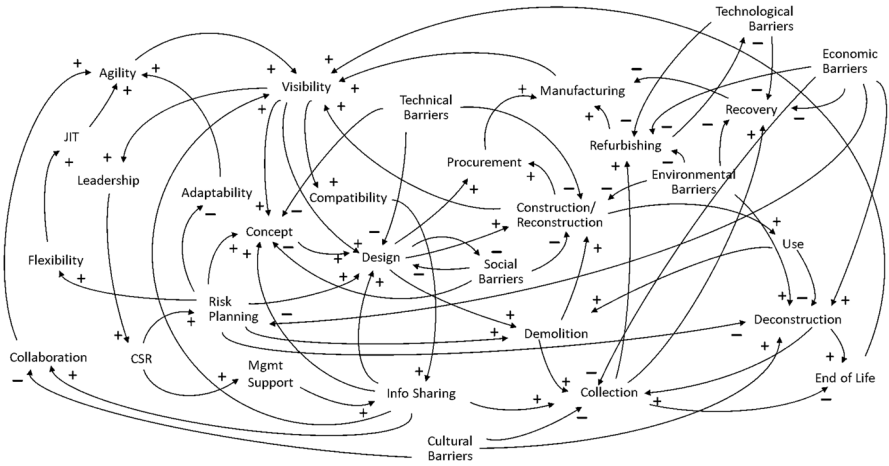

Fig. 1 Construction Industry Causal Loop Diagram

4 Analysis

4.1 Loops

One method of analyzing a CLD is to identify the balancing and reinforcing loops. Based on the level of complexity of this diagram, there are many loops. For the purposes of this study, the focus will be on loops that include the primary elements of the construction lifecycle. Ten reinforcing loops were identified.

- Concept to Design to Construction to Visibility to Concept—This loop illustrates that publicizing buildings that incorporate the circular economy principle should lead to more buildings that follow that approach. However, the technical barriers due to standards are suppressing activity in concept, design, and construction. In addition, social barriers limit the demand for circular concepts, designs, and construction.
- Concept to Design to Demolition to Construction to Visibility to Concept—This variation on the previous loop includes demolition. As buildings are renovated or retrofitted with circular designs, that trend is amplified. However, the technical barriers due to standards and social barriers that limit demand are suppressing activity in concept, design, and construction.
- Concept to Design to Procurement to Manufacturing to Visibility to Concept—This loop is a variation on the first loop. The difference is a shift from the contractors doing the building to suppliers who provide materials that are fabricated using circular economy principles. However, the technical barriers due to standards are suppressing activity in concept and design. In addition, social barriers are limiting the demand for concepts and designs that embrace circular economy principles.

- Concept to Design to Demolition to Collecting to Refurbishing to Manufacturing to Visibility to Concept—This loop is based on taking reclaimed construction materials from the demolition process and remanufacturing or refurbishing them to be reintroduced into the supply chain. However, technical and social barriers are again limiting the demand for concepts and designs. Collecting is constrained by economic and cultural barriers. Refurbishing is constrained by technological and economic barriers.
- Concept to Design to Construction to Visibility to Leadership to CSR to Risk Planning to Concept—This loop steps away from the building lifecycle after a building is constructed to use the visibility to spur on leadership to set new goals and objectives. However, technical barriers and social barriers are still limiting the demand for concepts, designs, and construction that embrace circular economy principles.
- Concept to Design to Procurement to Manufacturing to Visibility to Leadership to CSR to Risk Planning to Concept—This loop is like the previous loop only the emphasis now is on the suppliers and manufacturers of building components instead of the builder/contractors. Once again, the technical and social barriers are limiting the demand for concepts and designs that embrace circular economy principles.
- Design to Social Barriers to Design—This is a short loop with negative signs on both arrows. This means the more circular designs are completed, the lower the social barriers, in particular the lack of customer demand, and when social barriers are lowered and demand increases, more circular designs will be created.
- Construction to Use to Demolition to Construction—This loop is focused on the renovation aspect of construction. The building user removes (demolishes) items in the existing building and replaces them with items that are. However, the technical barriers due to standards are suppressing circular economy construction. In addition, social barriers limit the demand for construction that embraces circular economy principles.
- Collection to Refurbishing to Manufacturing to Visibility to Compatibility to Info Sharing with Collection—This loop is focused on the growth of refurbished or remanufactured recovered materials. As the availability of remanufactured materials increases, their visibility leads to greater demand for those materials, identifying even more candidates for refurbishment. However, the collecting function is suppressed by economic and cultural barriers that create difficulties in sorting the construction materials.
- Refurbishing to Technological Barriers to Refurbishing—This is another short reinforcing loop with negative relationships. The more refurbishing, the lower the technological barriers for refurbishing, which will further increase the amount of refurbishing.

The element visibility was found in seven of the ten reinforcing loops. The greater the visibility of actual building projects and actual refurbishment of construction materials, the more momentum there is for the entire circular economy movement. The design element was also found in seven reinforcing loops. This highlights the

need for design tools, techniques, and templates to encourage architects and designers to use circular economy approaches. In contrast, eight of the loops are impacted by social barriers, which are typically constraining the demand for design, concepts, and construction. In addition, the technical barriers impacted seven loops. The technical barriers create friction in the system, making it difficult for architects, engineers, and contractors to shift to circular economy construction approaches.

Four balancing loops were identified. These tend to hold elements of the system at a steady-state level. Balancing loops are advantageous if the loop in the system is meeting its desired goal or objective. They are detrimental if they prevent desired change. Again, only loops that affect primary processes in the construction lifecycle are included.

- Concept to Design to Demolition to Collection to Recovery to Manufacturing to Visibility to Concept—The negative correlation is between recovery and manufacturing. The more materials that are recovered, the less demand for new or refurbished materials. This loop assumes a constant overall demand for construction materials. While this loop dampens manufacturing, it does not reduce the shift to circular economy construction since the reuse of recovered material is often better from an environmental perspective. However, social barriers limit the demand for this concept, regardless of material origin. The key to this loop is to set the goal for the desired amount of recovered material, not manufactured material. The technical barriers constrain the concept and design elements of this loop.
- Construction to Use to Deconstruction to End-of-Life to Visibility to Concept to Design to Construction—The negative correlation relationship in this loop is between building use and deconstruction. Buildings that stay in use do not require deconstruction. The steady-state stabilization of this loop is based on the need for buildings. This loop becomes interesting when a building's use changes. If a building were designed for disassembly, instead of the balancing loop that goes through deconstruction and end-of-life, the reinforcing loop that goes through demolition and renovation would be activated. While the system goal is in the building use element, the place to break or suppress this loop is in the design element. The technical barriers limit the efficacy of the concept, design, and construction elements. In addition, social barriers constrain the demand for this type of construction. Finally, the cultural and economic barriers impact the deconstruction element.
- Demolition to Construction to Use to Deconstruction to End-of-Life to Visibility to Leadership to CSR to Risk Planning to Demolition—The negative correlation relationship in this loop is between building use and deconstruction. The steady-state stabilization of this loop again happens in that relationship. However, this loop does not go through design; it goes through leadership, CSR, and risk planning. This loop is susceptible to economic barriers that impact risk planning and social and technical barriers that constrain construction. The stabilization goals that are the focus of this loop will occur at the use and deconstruction elements.

- Deconstruction to End-of-Life to Visibility to Leadership to CSR to Risk Planning to Deconstruction—The negative relationship is between risk planning and deconstruction. When circular economy risk planning is low deconstruction will be high. However, risk planning often leads to the consideration of alternatives to deconstruction. The steady-state level of deconstruction is based on cultural and economic barriers that tend to increase deconstruction. In addition, economic barriers suppress risk planning.

4.2 System Performance and Archetypes

The system is subject to performance problems associated with its design and behaviors. One of these problems is layers of limits on many elements. For instance, the design element is based on interactions between six elements. At any given time, one of these will be the primary limit on the creation of circular designs. Improvement in that interaction just shifts the focus to the next one. Changes must be made in all areas simultaneously to see significant changes in the nature of building designs.

Ubiquitous delays are inherent in any manual system. In this system, the delays are magnified because many of the steps in the construction lifecycle take months or years. This effect is further amplified by the fragmented nature of the industry. Even if one builder or architect adopts circularity, there are still thousands of others who do not.

The archetype known as the tragedy of the commons occurs when a key system resource is consumed by multiple system actors with no one actor taking responsibility. This archetype is at the core of circularity. Civilization is consuming non-renewable resources with no way to replenish them. The reuse and refurbishment of construction materials reduce this effect. Education and communication are needed to overcome this archetype. This highlights the importance of the visibility element of the system.

The archetype of success refers to elements of the system that grow and squeeze out other elements. When the growth is with elements that adopt circularity, this is not a problem. However, as mentioned earlier, this industry has thousands of actors and those who do not adopt circular principles could find themselves shut out of a portion of the industry, reducing their employment. This will likely increase the cultural or social barriers, which would depress some of the reinforcing loops.

The final archetype is seeking the wrong goal. The EU report identifies several goals for the construction industry as it adopts circular economy principles [4]. These include a significant reduction in construction waste, a reduction in CO_2 emissions, economic growth through job creation, and targets for renovation. Each of these goals is beneficial. Therefore, they must be kept in balance. If any one goal rises to ascendancy, it will likely cause the system to be unable to achieve the other goals.

4.3 Loops

The EU report recommended the introduction of metrics that show the level of adoption of circularity [4]. Publicly tracking these metrics would strengthen the visibility element, which is prominent in many of the feedback loops. The EU report listed the recommended measures in Table 8 [4: 58–64]. These recommendations have been summarized in Table 1, which also identifies the system elements and loops impacted. The nature of the leverage point for improvement that the metrics address is also identified.

Nine of the 11 recommendations impact the design elements of the system. In fact, the most significant impact of the EU recommendations from a systems perspective is the enhancement of the design element. The next most significant system impact from these recommendations will be the establishment of a system goal. The danger is that if there are too many goals, one or more of the reinforcing loops will lock onto one goal and drive the system to a state of suboptimization.

5 Conclusion

The construction industry's transitional adoption of circular economy principles can be modeled using systems thinking. The CLD shows a complex system with many interactions that invalidate a linear approach to this ecosystem. The reinforcing loops in the system are susceptible to ubiquitous delays and are relatively weak because of barriers. The balancing loops are also weak. However, they could assist in moving the industry forward with visible measurable goals, particularly with respect to waste and reuse. The EU is recommending the adoption of many new measures to stimulate the transition. These will increase visibility, which will likely improve system performance, but there is a danger of seeking the wrong goal if the set of measurements does not stay balanced.

The most significant leverage point from a systems perspective is to enhance the design element in the system. It is the most connected element, and the EU metrics prominently focus on design measures. The barriers constraining that element are technical barriers, primarily standards, and social barriers, primarily customer demand.

This study was conducted as a qualitative review of literature that was then used to create the CLD. Further research should include a quantitative analysis to establish the strength of the interaction relationships. In addition, this study represents a broad industry overview. Local region analyses should be done to identify regional differences.

Table 1 EU Recommendations and Systems Impact

Recommendation	Element affected	System loop impact	Leverage point
Product as service, new business models	Concept, Risk Planning, Flexibility, Economic Barriers	Concept impacts 7 loops, risk planning impacts 4 loops, and Economic Barriers impact 4 loops	Restructure the system with a new business model
Designing for future disassembly and reuse	Design	Design impacts 8 loops	Improve the most strategic element
Designing for flexibility and adaptability	Design, Refurbishing	Design impacts 8 loops Refurbishing impact 3 loops	Improve the most strategic element
Improving material characteristics of materials used	Design	Design impacts 8 loops	Improve the most strategic element
Improving durability, lifespan, and repairability of construction works	Concept, Design, Construction, Demolition, Use, Refurbishing	Concept impacts 7 loops, Design impacts 8 loops, Construction impacts 6 loops, Demolition impacts 4 loops, Use impacts 3 loops, Refurbishing impacts 3 loops	Improve the reinforcing loops that emphasize renovation and refurbishing
Increasing recycled and secondary content of construction materials	Design, End-of-Life, Collection, Recovery	Design impacts 8 loops, End-of-Life impacts 3 loops, Collection impacts 2 loops, Recovery impacts 1 loop	Expand recovery and improve those reinforcing loops
Increasing direct reuse of products and materials	Concept, Design, Demolition, Collection, Recovery, Refurbishing	Concept impacts 7 loops, Design impacts 8 loops, Demolition impacts 4 loops, Collection impacts 2 loops, Recovery impacts 1 loop, Refurbishing impacts 3 loops	Improve reinforcing loops that emphasize renovation and refurbishment over deconstruction
Increasing reuse/recycling of waste from construction works	Design, Construction, Recovery, Refurbishing, Technical Barriers	Design impact 8 loops, Construction impacts 6 loops, Recovery impacts 1 loop, Refurbishing impacts 3 loops, Technical Barriers impact 9 loops	The focus is on the construction process, not the demolition
Increasing reuse/recycling of waste from demolition works	Design, Demolition, Collection, Recovery, Refurbishing, End-of-Life	Design impacts 8 loops, Demolition impacts 4 loops, Collection impacts 2 loops, Recovery impacts 1loop, Refurbishing impacts 3 loops	The focus is on demolition, not construction

(continued)

Table 1 (continued)

Recommendation	Element affected	System loop impact	Leverage point
Reducing waste/ wastage rates/ waste generation from construction activities	Concept, Construction, Demolition, Deconstruction, End-of-Life	Concept impact 7 loops, Construction impacts 6 loops, Demolition impacts 4 loops, Deconstruction impacts 3 loops, End-of-Life impacts 3 loops	Use of measures to set waste goals at critical steps/elements
Lifetime extension e.g., through retaining and refurbishing	Concept, Design, Construction, Demolition, Recovery, Refurbishment, End-of-Life	Concept impacts 7 loops, Design impacts 8 loops, Construction impacts 6 loops, Demolition impacts 4 loops, Recovery impacts 1 loop, Refurbishing impacts 3 loops, End-of-Life impacts 3 loops	A new set of lifetime measurements for materials and wastes will change design goals

1 Introduction

The materials used in construction are responsible for approximately 10% of total global carbon emissions per year and are the industry with the largest consumption of raw materials and the highest amount of waste generated [1, 2]. In Norway, the construction industry is only 2.5% circular and consumes upwards of 43 million tons of materials each year as construction material recycling and reuse schemes are nascent and underdeveloped [3, 4]. The overall material footprint of the construction industry urgently needs to be reduced to reduce the overall ecological footprint, which is estimated to be over one million tons of CO_2 annually from road construction in Norway alone [5]. Simultaneously, the existing built environment presents an

opportunity for the construction industry as a large reservoir of materials within the built environment is available for future use. The quantities are potentially enormous, as the total estimated material stock of roads in Norway is more than 420 gigatons [6].

The Norwegian national statistics organization reports that more than 2.1 million tons of construction waste are generated each year, with less than 954,000 tons being sent to recycling, 447,000 tons sent to landfills, and 537,000 tons sent to incineration [7]. Indeed, there is a large potential benefit for reusing and recycling construction materials for use again, and collecting and using these materials represents a first step in a circular construction industry [8, 9]. The challenge for construction actors is both planning for circularity within smarter design and developing systems for collecting, sorting, and recovering materials from existing building stocks on construction (or de-construction) sites.

The pilot project, known as GoGreen, is an attempt to further develop material recovery from existing building stocks slated for demolition and to allow for further reuse and recycling of these materials. The GoGreen pilot is part of a larger road construction project where several existing structures were demolished and the waste was collected, sorted, and sent for recycling and reuse instead of being sent directly to landfill or incineration. The purpose of this chapter is to understand the environmental benefits of implementing thorough material recovery and recycling processes as part of a greater push towards circularity in the construction industry.

2 Methods

This study is an LCA study that is based on the GoGreen tent activities. LCA methods are used in combination with data from the Betna-Hestnes site.

2.1 LCA Methodology

This study follows LCA methods in ISO14040 (2006), which have four main phases: goal and scope, inventory analysis, life cycle impact assessment, and interpretation [10] (Fig. 1).

The goal of this study is to evaluate the environmental impacts of the GoGreen tent, which was in operation from November 2022 to December 2023, and sort materials collected within this time period. Thus, the functional unit of the study is 13 months of operation of the GoGreen tent, or alternatively, the entire waste collection and sorting of demolition materials in the Betna-Hestnes road project. The scope of this study is based on a case study of the GoGreen pilot located in Betna, Norway. The system boundaries are shown in Fig. 2.

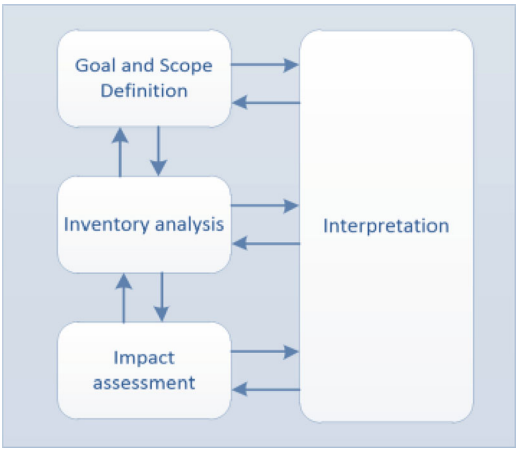

Fig. 1 Four steps within an LCA study

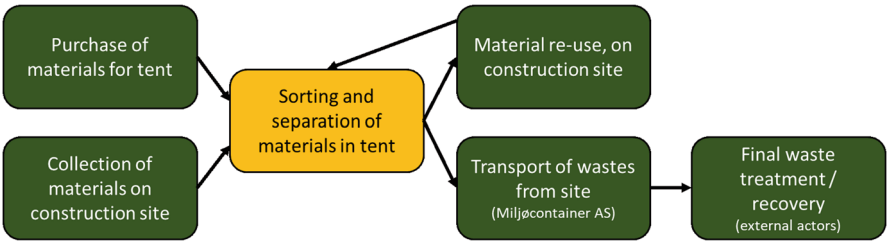

Fig. 2 System boundaries of the GoGreen LCA study

The purchase of materials pertains to the materials used for waste sorting, primarily plastic bags, used on-site. The collection of materials from demolished structures happens on the construction site with machinery, and the materials are transported further for sorting and separation in the tent. The sorting process is done manually and is not considered to have an environmental impact. Some of the materials on site are reused on the construction site, primarily wood used in formwork, before being taken back to the tent and resorted. The transport of the waste to the waste treatment facility is done by the company Miljøcontainer AS, which collects and delivers the waste to additional sorting and processing approximately 150 km away in the city of Trondheim. This waste is then further transported for recycling, while some are also incinerated according to local laws on processing contaminated materials.

The study was carried out using SimaPro version 9.5.0.1 with EcoInvent database version 3.9.1. The global impact assessment method ReCiPe 2016 Midpoint (Hierarchical) was used for this study. This study is intended to be a consequential LCA study, where avoided impacts from production are explicitly included in the model where material recycling and reuse are included. Several assumptions were made to

include avoided impacts based on European and Norwegian market average processes contained within the EcoInvent databases.

2.2 Case Study

The GoGreen pilot is part of a larger Betna-Hestnes road construction project on the Europavei 39 (E39) in Trøndelag County, Norway. This 12.8 km highway project is managed by construction firm Bertelsen and Garpestad (B&G) and began construction in 2022. As part of reducing the environmental impacts of the overall construction process, several circular and "green" innovations were implemented by B&G. The focus of this paper is the GoGreen pilot, which was developed by B&G to recover materials from existing structures slated for demolition for the new road. The pilot project is designed to be easily implemented in other projects, flexible, and effective at recovering materials, with a stated goal of recovering 100% of materials from the demolished structures to be sent for further recycling and reuse.

The GoGreen pilot consists of a 300 m^2 portable tent structure, which acts as a facility for dismantling, sorting, and warehousing recovered materials. Two workers at a time sort and separate the materials by hand before placing them in containers, which are sent for further processing. Although not a part of the scope of this paper, the workers are hired in collaboration with the Norwegian social services, as part of an integration process for individuals who have struggled to find work. The GoGreen pilot also works with these employees to offer on-the-job training for further advancement in B&G as part of the social sustainability measures. The workers use hand tools and electric tools to aid in the separation of materials and sorting materials based on material type. In 2022 and 2023, the workers sorted through 354 tons of material collected from three demolished houses, one shed, one garage, one small barn, one cabin, and several other smaller constructions. Figure 3 shows the GoGreen tent in use, including the sorted materials, material collection bins, and overall structure and design. The GoGreen system is designed to be simple to implement for B&G in future projects, and they would also like to push the construction industry towards greater material recovery and sorting.

The GoGreen pilot intends to test the efficacy of the material collection and sorting process, which is intended to be further implemented in future construction projects. This paper is an evaluation of the environmental impacts and potential benefits of the GoGreen system seen in the context of the larger Betna-Hestnes construction project.

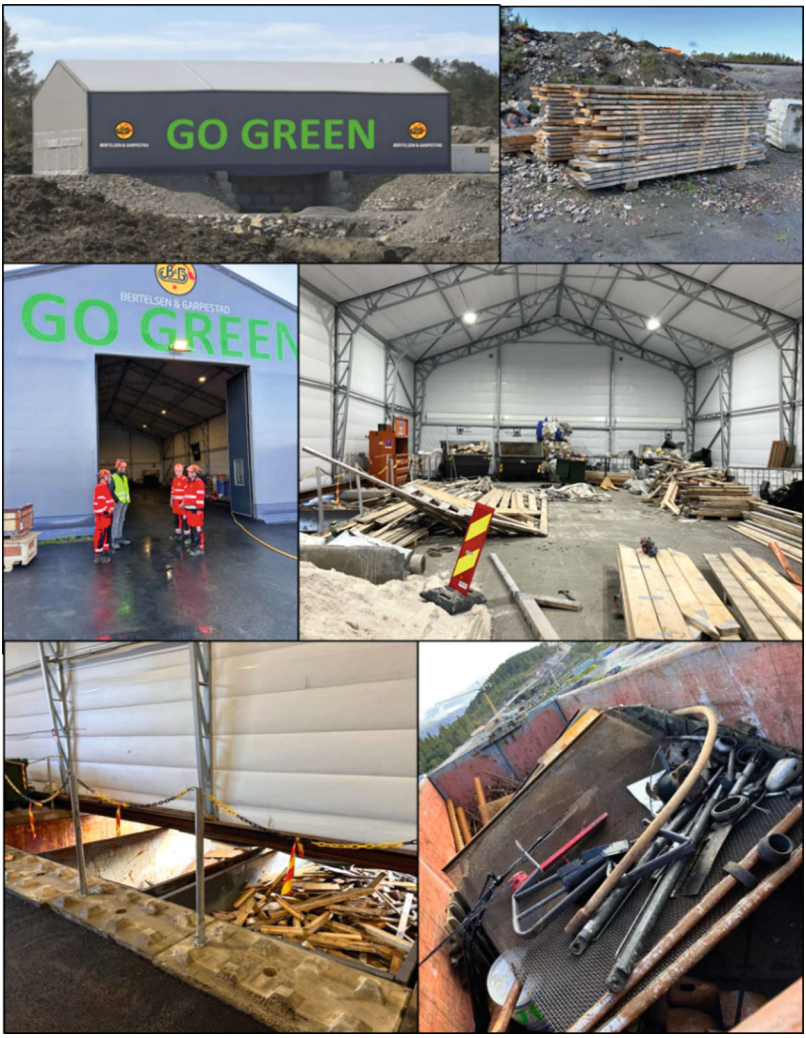

Fig. 3 Visual overview of the GoGreen tent activities

2.3 Data Collection

The data for this study was collected from the operators of the GoGreen tent, the Betna-Hestnes project manager, and the waste collection company Miljø Container AS. The waste quantities are based on data from Miljø Container AS received from the Betna-Hestnes site. Miljø Container AS weighed containers of sorted waste to form the basis of the life cycle inventory. The waste collected is transported 154 km by truck to the waste processing facility in the city of Trondheim. Additional information on how the waste is treated comes from the manager of Miljø Container

AS based on his communication with the waste processing facility in Trondheim where the waste is delivered.

3 Results

3.1 Life Cycle Inventory Results

Table 1 shows an overview of the waste materials collected on the Betna-Hestnes site as delivered to the waste collection process as well as their assumed final product

Table 1 Life cycle inventory of materials collected at the GoGreen tent

Waste type	kg	Treatment process	Final product	Notes
Mixed timber wastes	245,030	Material recycling	Wood chips	Assumed 5% loss
Mixed metals	20,960	Material recycling	Reinforcing steel	Assumed 5% loss
Metals (unclassified)	18,340	Material recycling	Reinforcing steel	Assumed 5% loss
Asbestos	14,760	Landfilling	Inert waste	
Insulation/mineral wool	11,270	Material recycling	New insulation	Assumed 20% in new insulation
CCA-impregnated timber	10,400	Energy recovery	District heat	Assumed net 14,4 MJ per kg
Hard plastic	7880	Material recycling	Plastic bags	
Cardboard and paperboard	7560	Material recycling	Recycled paper	Assumed 5% loss
Tractor and truck tires	7300	Material recycling	Rubber granulate	Assumed 75% loss of quality
Other tires	3200	Material recycling	Rubber granulate	Assumed 75% loss of quality
Mixed hard plastics/plastic waste	2200	Material recycling	Plastic bags	
Cables and wires	1500	Unknown	Unknown	Transport included
Plastic wrapping	1300	Material recycling	Plastic bags	
Window glass, not laminated	540	Material recycling	Glass cullet	
Floor sealer	359	Energy recovery	District heat	
Mixed electronic wastes	350	Unknown	Unknown	Transport included
Remaining materials	1581	Unknown	Unknown	Transport included
In total, all materials	**354,530**	–	–	All transport included

once treated. The largest quantity of materials was mixed timber wastes from structural elements of the dismantled buildings (walls, roofs, etc.). This material would typically be incinerated, but the waste treatment company sends these materials to be chipped and made into new oriented strand boards and particle boards. Mixed metals and unclassified metals can be a variety of metal materials but are mostly steel, which is then melted down and reused as reinforcing steel. Hard plastics and mixed plastic wastes are turned into plastic bags, while truck and tractor tires used on site are recycled into rubber granulate, which can be used for flooring and on artificial sports fields. Some materials are not able to be recycled, primarily asbestos, which is banned for use and is landfilled. Other materials that are not suitable for recycling are incinerated with heat being produced. CCA-impregnated wood is bound by regulations to be incinerated. The treatment of some wastes was not known at the time of the study, so it is assumed they have been landfilled, with transport included in these processes. Assumptions have also been made in the model regarding system efficiency, quality loss, and energy content in combustion.

3.2 *Impact Assessment Results*

The life cycle impact assessment (LCIA) results show impacts from the three main GoGreen processes that are included in this model (Fig. 4). The "*material reuse*" process, shown in green, shows the impact of the materials being reused on site, which is the reuse of concrete formwork for bridge construction. The assumption was that formwork was reused five times for each of the identical bridge designs on the Betna-Hestnes project. The orange represents the impacts of "*purchased*

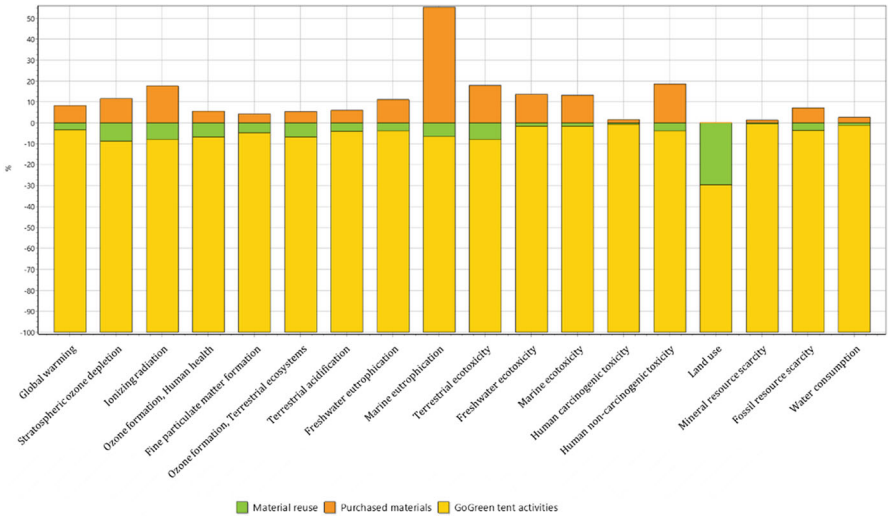

Fig. 4 Normalized LCIA results, by the GoGreen process

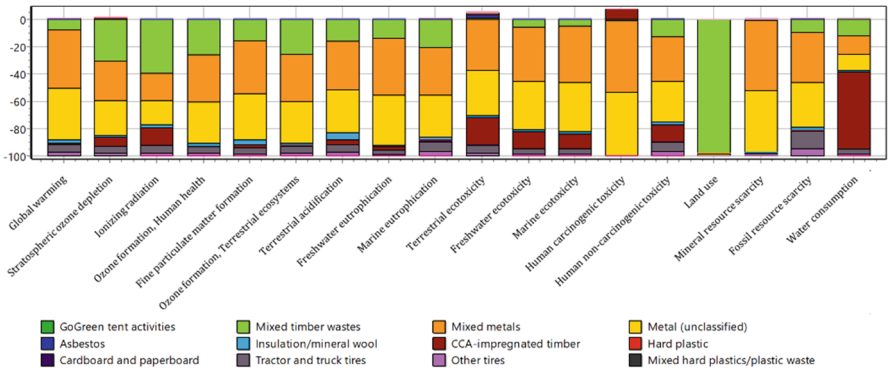

Fig. 5 Normalized LCIA results, by material type

materials" required for the GoGreen tent, which are primarily plastic bags and energy for heating and lighting of the tent. The yellow refers to the "*GoGreen tent activities,*" which are the sorting processes and the environmental benefit of avoided impacts. The overall results show a mix of both environmental impacts and environmental benefits based on the consequential modelling of avoided impacts. The results in Fig. 4 show that in all impact categories, there was an environmental benefit to recycling and reusing materials, respectively, while there was an environmental impact from the use of virgin materials and energy. Using avoided impacts in the assessment showed that the overall impact of implementing the GoGreen pilot led to a net environmental benefit (i.e. negative emissions vs the standard use of new materials). While the model makes some estimates on the efficiency of the recycling process and the loss of product quality, the overall results show that the GoGreen pilot has environmental benefits versus using newly produced raw materials.

Figure 5 shows the normalized LCIA results based on each material type. The scale of the figure shows that the environmental impacts are negative (i.e. environmental benefits) for most materials within most impact categories. The only processes with notable environmental impacts are the CCA-impregnated timber, which is due to emissions from combustion. Most other materials have impacts that are negative.

The materials with the largest environmental benefit are mixed metals and metals (unclassified), where the production of new materials is the greatest, with more than 39 tons of production for reinforcing steel assumed to be avoided. The second most environmentally beneficial product is from mixed timber wastes, which had the highest total mass of materials that were collected and sorted in the GoGreen tent.

Figure 6 shows the overall global warming potential (GWP) for all GoGreen processes on the Betna-Hestnes site, while Fig. 7 shows the GWP for all the materials processed in the GoGreen tent. The largest environmental benefit comes from the avoided impact of new material production due to material recycling. Reuse of formwork also has a small but relevant environmental benefit, while the purchase of materials (plastic bags and heating and lighting of the tent) and transport of

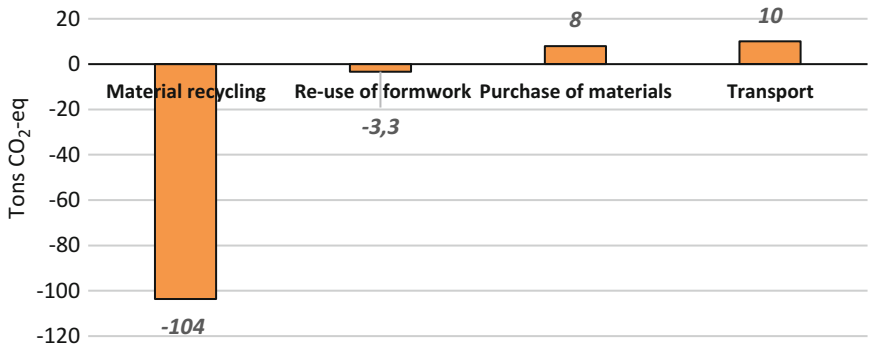

Fig. 6 GWP in tons CO_2-eq, by GoGreen process

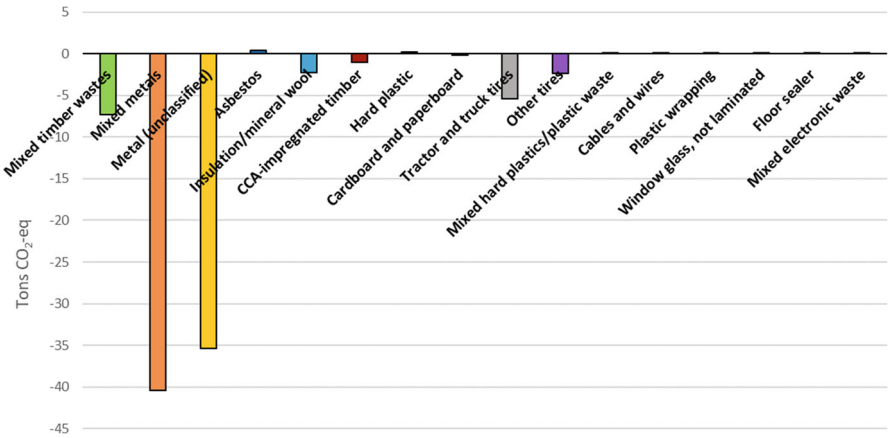

Fig. 7 GWP in tons CO_2-eq, by material type

products to the waste treatment facility had an environmental impact. The net overall global warming potential benefit for the GoGreen pilot, including material recycling, reuse of concrete formwork, purchase of materials, and transport, was −88.9 tons of CO_2-equivalents based on a sorting and final waste treatment (landfilling, incineration, and recycling) of 354 tons of materials collected in the GoGreen tent.

Figure 7 shows the GWP for the material from the collection, sorting, and recycling with avoided impacts of new material production included. This figure shows the dominance of the avoided impacts from metals in the overall result. The mixed timber wastes and tires also have a noticeable environmental benefit.

4 Discussion

The overall result of this study shows that there is an environmental benefit to collecting and sorting materials on the construction site as long as these materials are sent for further processing and recycling and can avoid the impacts of new material production. The GoGreen pilot also facilitated the reuse of materials on site, such as concrete formwork, which would not have been possible without a sorting facility. The GoGreen pilot reported a sorting of 100% of all waste materials with a small fraction of materials lost, sent to landfills, or incinerated. The materials that were lost for recycling were lost primarily due to regulations on waste for the treatment of toxic materials (i.e. asbestos and CCA-impregnated timber). This GoGreen pilot project shows that it is possible to implement effective sorting and collection of materials in the demolition phase of infrastructure and drastically reduce the amount of construction waste that is sent to landfills.

The environmental benefits and impacts of collecting and sorting waste are relatively simple to determine when the fate of the waste is known and if there is a protocol for documenting waste collected. This study has made several assumptions on how the waste is treated, which materials avoid impacts, and on system efficiency and loss in material quality. These assumptions have not accounted for any market expansion due to lower prices leading to increased material demand (i.e. price effect), which may not actually lead to reduced consumption of new materials due to positive feedback loops [11, 12]. This study is intended to only evaluate the GoGreen pilot, but an LCA study of upscaling of this method should include market dynamics as an additional model parameter.

The choice of using avoided impacts implies a value judgement that the entirety of the environmental benefits of the GoGreen pilot is allocated to the construction firm B&G. This allocation method may be unfair, as B&G does not actually carry out the recycling process [9, 13]. B&G were chosen as the beneficiaries of this assessment as they are responsible for recovering the materials and choose not to send them to landfills or incineration. The use of the EcoInvent database for modelling generic processes for avoided impacts also adds to the uncertainty of the results. EcoInvent is only a representation of the waste treatment and avoided production processes, not necessarily the most accurate measurement of real-world activities. The generic processes chosen for avoided impacts were region-specific, and processes were modified to account for Norwegian conditions (primarily changing energy mixes and transport distances) when information was available. Future work should involve carrying out additional studies on the waste treatment of collected materials and a better understanding of the final fate of the collected materials.

The scale of the GoGreen pilot project is not particularly large, as this project is primarily a road construction project in which existing structures that were dismantled had a relatively small building stock (354 tons total vs 2.1 million tons of construction waste generated in Norway annually). This sorting method, while useful on the GoGreen project, should be further expanded to be implemented on

buildings with larger stocks that are slated for demolition and have more complex structures, like concrete and steel buildings. Thus, the environmental benefit of this single pilot study is positive; the overall effects of a more thorough dismantling and sorting system will be more effective when scaled up for the entire construction industry.

The environmental savings from the GoGreen pilot are also relatively small compared to the overall estimated environmental impact of the entire Betna-Hestnes project, which was estimated to produce more than 10,500 tons of CO_2 (in 2022 and 2023 combined) from diesel fuel consumption in construction machinery alone. This implies that B&G still has more to do to reduce its environmental impact further. B&G has implemented additional innovative methods for reducing environmental impacts from construction on the Betna-Hestnes site, such as reusing construction masses, reducing the area footprint of the construction site, using electric machines when possible, and avoiding construction on boglands, which are outside of the scope of this study but can potentially have large environmental benefits within a circular economy framework. The GoGreen pilot also contributes to creating new jobs within the circular industry and training the future workforce to work towards sustainability. Additional metrics for measuring circularity in road construction projects that go beyond the traditional life cycle assessment framework are needed to fully understand the impact and benefits of circular activities [4, 14].

5 Conclusion

This study used life cycle assessment to quantify the environmental impacts and benefits of implementing dismantling, collection, and sorting procedures on a road construction project in Norway. The results show that there is an environmental benefit to implementing better sorting procedures so that more materials may be sent to recycling. The scale of the GoGreen pilot is relatively small but can have potentially large benefits for reducing material consumption and emissions if implemented on a larger scale. Further work should focus on evaluating emissions from additional circular economy strategies in road construction and defining better metrics for measuring circularity in road construction projects.

Carbon footprint, 40, 41, 45, 50, 72, 76–77, 141, 169–171, 173, 180, 205, 281, 284, 288, 289, 304, 311, 342, 354, 367, 368, 372–375, 378, 379, 386, 476, 526, 535, 589, 595, 624, 625, 674, 683, 697–705, 739–748, 765, 766, 776, 858, 862, 870, 875, 890, 899, 930, 941, 1061, 1077–1080, 1084, 1085, 1156, 1157, 1166, 1186, 1239, 1244–1247, 1251, 1262, 1290, 1301, 1320, 1363, 1368, 1369, 1438, 1448, 1464, 1529, 1537, 1581, 1597, 1604, 1618, 1654, 1689, 1696, 1733, 1741, 1746, 1747, 1806, 1808
Carbon footprint reduction, 40, 41, 45, 50, 170, 284, 289, 304, 311, 354, 368, 375, 476, 674, 683, 697–705, 739–748, 776, 858, 875, 890, 899, 930, 1061, 1156, 1186, 1262, 1320, 1368, 1369, 1448, 1597, 1604, 1618, 1696
Carbon negativity, 172, 175, 180
Carbon trading, 41, 1869–1877
Case study, 26, 451, 475–485, 491, 615, 616, 680, 688–689, 698–705, 834, 899–910, 941–953, 956, 957, 987, 993–997, 1008–1010, 1015–1024, 1031, 1052, 1054–1059, 1065, 1067, 1068, 1070, 1071, 1083, 1084, 1100, 1104, 1112, 1113, 1128–1130, 1133, 1137–1147, 1149–1157, 1160, 1188, 1189, 1192, 1227, 1245, 1302, 1336–1338, 1342, 1343, 1426, 1429, 1431, 1491–1498, 1530, 1564–1567, 1588, 1606, 1627, 1630, 1636–1638, 1640, 1642, 1643, 1653, 1676, 1677, 1680, 1691–1693, 1697, 1703, 1711–1723, 1727–1732, 1741, 1743, 1744, 1774, 1833–1834, 1836–1838, 1859, 1903, 1921–1931
Causal loop diagram (CLD), 1908
Cellular network signals, 1673
Cellulose acetate (CA), 405, 406, 408, 409, 412, 413, 576
Cement, 4, 14, 39, 50, 59, 72, 81, 93, 111, 118, 132, 141, 156, 171, 183, 195, 205, 220, 232, 248, 260, 270, 280, 293, 304, 315, 328, 341, 354, 367, 378, 404, 417, 426, 438, 462, 475, 526, 551, 563, 575, 589, 599, 611, 625, 703, 708, 719, 740, 767, 781, 801, 813, 821, 855, 867, 891, 913, 1079, 1093, 1097, 1262, 1362, 1464, 1611, 1692, 1700, 1745, 1869
Cement contents, 49, 50, 75, 76, 224, 286, 368, 379, 438, 531, 708–712, 715–717, 734, 792, 864, 874
Cement mortar, 62, 118–127, 200, 260, 261, 263, 266, 267, 308, 317, 319, 320, 325, 370, 437–446, 834
Cement paste, 4, 42, 43, 73, 82–84, 88–90, 111–113, 184, 206, 220, 236, 262, 286, 288, 304, 332, 342, 344, 348, 350, 351, 360, 361, 412, 438, 441, 566, 814, 816, 817, 819
Cement replacement, 42–44, 88, 90, 155–167, 184, 186, 190, 193, 219–226, 599–608, 682, 683
Cementitious composites, 220, 369, 405, 1290
Chemical and chloride attack, 232, 327, 370, 861
Chloride-induced corrosion, 674, 677, 699, 740, 743, 868, 871, 874, 1545
Chloride ingress, 742, 868, 870–876, 1545
Circular construction, 625, 1040, 1888, 1889, 1891, 1892, 1908, 1922
Circular economy (CE), 41, 106, 169, 170, 280, 282, 289, 426, 540, 660, 705, 709, 828, 844, 847, 942, 944, 947, 958, 1039–1042, 1046, 1047, 1076, 1231, 1232, 1239, 1278, 1302, 1304, 1310, 1317, 1488, 1573–1582, 1585, 1586, 1597–1606, 1707, 1743, 1843, 1846, 1847, 1850, 1855–1857, 1862, 1865, 1866, 1882, 1883, 1885, 1887, 1889, 1892–1894, 1897, 1898, 1903, 1921–1931
Circular infrastructure, 1574
Circularity, 106, 188, 281, 856, 857, 955–963, 1045, 1046, 1275, 1302, 1303, 1581, 1585, 1589–1593, 1598, 1600, 1602–1604, 1606, 1841, 1842, 1846–1849, 1855, 1882, 1884, 1885, 1888–1891, 1893, 1894, 1907–1912, 1916, 1917, 1922, 1931
Circularity index, 956–962, 1849
Circular road infrastructure, 1573–1582
Circular timber building industry, 1883
Citizen engagement, 1678, 1726–1728, 1732, 1735, 1793
Citizen participation, 1139, 1675–1684, 1726, 1735

Civil engineering, 118, 285, 350, 698, 707, 748, 766, 769, 832, 1090, 1323, 1474
Classification, 321, 515, 522, 576, 698, 700, 733, 735, 822, 846, 931–933, 996, 1033, 1036, 1065, 1140, 1278, 1587, 1654, 1657, 1874, 1889, 1891
Clay, 93, 94, 283, 288, 303–312, 415, 417, 479, 484, 515, 531, 551–554, 557, 558, 831, 835, 900, 901, 904, 908, 910, 913–923, 1078, 1103, 1234, 1237, 1239, 1289, 1591, 1700, 1702, 1706, 1848
Clay brick, 283–285, 304, 389, 476, 480–482, 485, 884, 1098, 1767, 1768, 1771
Climate, 43, 199, 269, 417, 422, 478, 491, 497, 504, 739, 950, 968, 975, 991–1000, 1004, 1009, 1010, 1012, 1015–1024, 1053, 1055, 1058, 1064, 1065, 1067, 1125, 1156, 1160, 1191–1193, 1243–1253, 1289, 1306, 1329, 1348–1358, 1361, 1362, 1487–1498, 1540, 1543, 1545, 1549–1551, 1554, 1559, 1650, 1652, 1765, 1773–1783, 1810
Climate change, 40, 46, 155, 156, 171, 310, 367, 378, 425, 426, 500, 504–508, 554, 557, 563, 593–595, 659–666, 867, 899, 942, 967, 969, 972, 974, 975, 981, 992, 993, 996, 998, 999, 1008, 1064, 1065, 1076, 1126–1128, 1131, 1132, 1134, 1138, 1146, 1149, 1159, 1174, 1191, 1192, 1245, 1248, 1249, 1251, 1301, 1348, 1438, 1487, 1540–1545, 1618, 1649, 1650, 1701, 1733, 1743, 1762, 1796, 1803, 1810, 1816, 1841, 1870, 1877, 1887
Climate mitigation, 660, 969
Climate resilience, 171, 991–1000, 1627
Co-creation, 1161, 1166, 1725–1736, 1788–1795, 1797, 1890, 1903
CO_2 emissions, 28, 33, 34, 39, 41, 50, 72, 76, 77, 81, 82, 90, 105, 155, 156, 171, 183, 205, 206, 280, 304, 312, 315, 368, 372–375, 382, 415, 425, 504, 506, 551, 554, 563, 575, 590, 595, 624, 629, 673–683, 703, 704, 740, 741, 744, 746, 748, 780, 784, 792, 797, 798, 822, 827, 844, 846, 848, 851, 867–870, 874–876, 913, 942, 946, 949, 951–952, 1079–1082, 1118, 1157, 1251, 1253, 1363–1365, 1371, 1438, 1650, 1655, 1701, 1739, 1740, 1745, 1773, 1805, 1869, 1874, 1916
Collaborative project delivery, 1111–1113
Collapse risk, 1395–1406
Compressive strength, 5, 14, 49, 60, 72, 82, 94, 120, 132, 159, 179, 184, 207, 223, 232, 245, 261, 270, 284, 304, 319, 327, 343, 354, 370, 382, 404, 426, 438, 526, 553, 575, 589, 600, 675, 707, 719, 770, 780, 795, 802, 814, 822, 832, 858, 869, 892, 901, 914, 1259, 1266, 1324, 1338, 1412, 1427, 1492, 1542, 1743
Concepts, 283, 316, 462–463, 697–699, 705, 720, 736, 739, 856, 864, 914, 942–947, 958, 968, 969, 971, 973, 974, 987, 991, 992, 1006, 1015, 1029, 1034, 1035, 1040, 1055, 1091, 1116, 1118, 1139, 1160, 1161, 1168, 1174, 1186, 1189–1192, 1194, 1221, 1226, 1276, 1302, 1314, 1428, 1437, 1474, 1487–1498, 1551–1554, 1586, 1590, 1593, 1597–1599, 1626, 1635, 1637, 1639, 1641, 1650, 1652, 1653, 1656, 1657, 1678, 1691, 1726, 1727, 1731, 1733, 1739–1747, 1750–1753, 1775, 1776, 1787, 1788, 1790, 1793, 1794, 1796, 1807, 1822, 1870, 1871, 1882, 1885, 1888, 1897, 1898, 1900, 1907, 1908, 1910, 1912–1915, 1918, 1919
Concrete, 1, 14, 39, 49, 59, 71, 81, 93, 118, 132, 141, 156, 171, 183, 200, 207, 220, 232, 246, 259, 269, 281, 299, 303, 316, 332, 341, 354, 367, 377, 391, 415, 426, 438, 462, 475, 528, 553, 564, 575, 589, 599, 611, 623, 673, 687, 697, 707, 719, 740, 751, 765, 780, 791, 801, 813, 821, 832, 848, 856, 867, 883, 890, 900, 914, 931, 968, 1082, 1089, 1100, 1119, 1226, 1258, 1265, 1290, 1302, 1313, 1325, 1347, 1361, 1371, 1383, 1409, 1424, 1464, 1488, 1540, 1549, 1573, 1591, 1611, 1691, 1701, 1735, 1744, 1779, 1847, 1927
Concrete bricks and blocks, 281, 284, 286, 288, 884
Concrete consistency, 1–10
Concrete cover, 555, 674, 677–680, 682, 683, 698, 700, 701, 705, 723, 744, 869, 874, 907, 1426, 1492
Concrete from waste, 82, 283, 285, 288, 801, 1591
Concrete infrastructures, 707, 867–876
Concrete mix, 42, 44, 56, 133, 135, 184, 186, 187, 209, 210, 214, 238, 240–242, 259, 284, 356, 357, 359, 367–369, 375,

378, 379, 381, 382, 384, 385, 575–585, 600, 675, 676, 683, 691, 697, 698, 700–705, 708, 710, 740–742, 748, 822, 825, 826, 858–860, 1091, 1094, 1262, 1363, 1745
Concrete production, 14, 40, 41, 45, 61, 82, 157, 183, 206, 209, 232, 234, 236, 260, 280–282, 286, 287, 289, 354, 378, 379, 382, 575, 592, 595, 703, 802, 824, 827, 858, 861, 1100, 1105, 1119, 1707, 1745, 1869
Concrete recycling, 183–193
Construction, 13, 26, 39, 49, 71, 90, 93, 105, 131, 142, 156, 169, 196, 205, 220, 232, 245, 259, 270, 279, 294, 303, 316, 327, 354, 367, 378, 390, 404, 416, 426, 462, 475, 502, 512, 526, 540, 572, 575, 589, 599, 611, 624, 635, 660, 674, 688, 699, 707, 719, 740, 751, 765, 779, 801, 813, 821, 833, 843, 856, 867, 889, 899, 914, 941, 955, 967, 981, 1010, 1017, 1028, 1039, 1052, 1078, 1097, 1111, 1142, 1163, 1173, 1192, 1213, 1226, 1231, 1244, 1257, 1276, 1289, 1301, 1313, 1323, 1335, 1357, 1362, 1371, 1381, 1440, 1497, 1502, 1529, 1550, 1573, 1586, 1597, 1611, 1650, 1687, 1700, 1711, 1733, 1740, 1762, 1774, 1802, 1816, 1829, 1841, 1856, 1869, 1882, 1897, 1907, 1921
Construction and demolition waste (CDW), 206, 279–289, 879, 880, 882–886, 945, 963, 1084, 1290, 1855–1858, 1860–1866, 1897–1904, 1908
Construction and demolition waste management (CDWM), 1598, 1898, 1901–1903
Construction industry, 26, 41, 45, 49, 71, 72, 82, 90, 105, 106, 131, 156, 169–171, 180, 232, 236, 269, 282, 284, 285, 289, 303, 304, 311, 315, 316, 325, 341, 367, 369, 371–375, 378, 380, 386, 425, 426, 475, 476, 526, 589, 611–613, 624, 625, 673, 683, 726, 728, 737, 828, 843–845, 847, 856, 864, 879–886, 889, 896, 914, 930, 931, 959, 960, 962, 963, 1010, 1027, 1039–1047, 1054, 1149, 1231, 1232, 1257, 1258, 1301, 1302, 1310, 1323, 1347, 1362, 1369, 1529, 1573–1575, 1581, 1586, 1588, 1597–1600, 1604, 1613, 1620, 1621, 1687, 1700, 1703, 1708, 1709, 1802, 1807, 1810–1812, 1818, 1841, 1848, 1855, 1856, 1862, 1863, 1865, 1866, 1869–1877, 1884, 1886, 1888–1894, 1897, 1907–1913, 1916, 1917, 1921, 1922, 1924, 1931
Construction logistics, 1620
Construction transport, 1687
Continuous conditional GAN (CCGAN), 648, 649, 651, 657
Contractor evaluation
CO_2 reduction, 43, 791–798, 859, 862, 946, 952, 1891
Corrosion, 53, 232, 266, 369, 554, 559, 613, 687–694, 697, 698, 700, 713, 720, 722–724, 727, 740, 742, 743, 745, 814, 844, 861, 869, 871, 874, 1224, 1361, 1362, 1368, 1409–1420, 1540, 1545
CO_2 sequestration, 40–45, 81, 315, 1076, 1085
Costs, 16, 50, 118, 132, 172, 183, 220, 245, 282, 311, 351, 354, 369, 378, 390, 437, 497, 511, 526, 540, 575, 596, 614, 636, 647, 674, 688, 698, 719, 740, 780, 797, 831, 844, 858, 881, 943, 974, 982, 1008, 1027, 1052, 1076, 1098, 1114, 1145, 1150, 1165, 1187, 1200, 1208, 1232, 1244, 1258, 1278, 1309, 1323, 1362, 1405, 1425, 1444, 1474, 1488, 1539, 1551, 1565, 1577, 1589, 1599, 1612, 1626, 1650, 1662, 1688, 1700, 1725, 1740, 1749, 1775, 1803, 1823, 1831, 1842, 1856, 1873, 1891, 1908
Crack repair, 719–728
Cracks, 3, 75, 118, 135–137, 297, 347, 349, 368–370, 383, 389, 396, 416, 421, 635, 674, 677–679, 681, 682, 714–717, 719–728, 740, 745, 795, 796, 798, 817, 836, 1224, 1226, 1227, 1269, 1270, 1272, 1278, 1279, 1290–1293, 1296, 1305, 1307, 1317, 1318, 1362, 1365, 1424, 1425, 1429, 1502, 1509, 1545, 1564, 1707
Cross-laminated timber (CLT), 171, 627, 628, 631, 1017, 1018, 1054, 1233, 1235–1237, 1302, 1303, 1305, 1307, 1310, 1313–1320, 1372
Crowdsourcing, 1065
Crumbed rubber, 353–363, 890–892, 895
CSA cements, 105, 106, 110, 114
CT scanner, 438, 443, 1280
Cultural heritage assets, 1336, 1342
Cyclic simple shear test, 511–522

D
Damage detection, 1222, 1226
Damping ratio, 519, 522, 1291, 1336
Data-driven decision-making, 1567, 1662, 1673
Data-driven modelling, 1276, 1279
Decarbonization, 41, 856, 864, 969, 1005, 1076–1086, 1138, 1146, 1190, 1244, 1362, 1364, 1650, 1651
Deconstruction, 631, 857, 1040–1042, 1586, 1588–1591, 1598, 1601, 1606, 1842, 1843, 1845, 1860, 1862, 1866, 1901, 1910, 1912, 1915, 1916, 1918, 1919
Deep foundations, 900, 909
Deep learning (DL), 350, 527, 531, 648, 649, 651, 1531, 1626
Deflection, 16, 20, 254, 395, 792, 794–796, 798, 1259, 1283, 1284, 1316–1318, 1324, 1372, 1375, 1378, 1379, 1425, 1427, 1428, 1430–1433, 1617
Degradation index, 520–521
Demand response (DR), 1163, 1164, 1727–1730, 1732–1735
Design for disassembly (DfD), 1232, 1586–1590, 1592, 1593, 1599, 1600, 1602, 1604, 1606, 1844, 1845, 1887–1888
Design science research (DSR), 1897–1904
Design workflow, 1027–1036
Digital, 27, 249, 452, 636, 761, 794, 900, 956, 967–973, 975, 1028, 1030, 1033, 1045, 1089, 1091, 1092, 1115, 1116, 1162, 1164, 1190, 1222, 1286, 1336, 1338, 1339, 1343, 1456, 1497, 1630, 1675–1684, 1725, 1730, 1743, 1884, 1887–1889, 1891–1894, 1898, 1911
Digital fabrication (DF), 25–35, 1600
Digital information management system (DIMS), 1897–1904
Digital twins, 1221–1228, 1336, 1342, 1451–1460, 1603, 1604, 1673
Direct shear test, 512, 516, 832, 833, 838
Drying shrinkage, 132, 186, 192, 328, 331–332, 334, 338, 339, 342, 368, 420–421, 710, 716, 722, 731, 732, 737
Dual trenches, 1464–1471
Durability, 2, 20, 45, 49, 50, 53, 55, 56, 59, 65, 66, 72, 75, 76, 90, 94, 106, 141, 162, 184, 186–187, 191–193, 196, 202, 212, 260, 265–267, 270, 283, 284, 286–288, 304, 307–309, 311, 327, 341, 368–372, 375, 378, 379, 390, 408, 416, 421, 552–555, 559, 560, 564, 589–592, 596, 647, 648, 674, 697, 698, 708, 719, 720, 724, 726, 727, 731, 732, 740, 745, 747, 761, 779, 780, 783, 785–789, 802, 813–819, 834, 839, 845, 848–850, 861, 868, 871, 876, 890, 896, 914, 915, 923, 937, 1040, 1103, 1232, 1235, 1239, 1257, 1289, 1291, 1304, 1305, 1310, 1314–1317, 1319, 1324, 1348, 1361, 1362, 1368, 1451, 1452, 1457, 1458, 1501, 1550, 1591, 1700, 1705, 1706, 1708, 1918
Dynamic analysis, 390, 1178, 1397, 1410
Dynamic shear modulus, 519, 520, 522

E
Early contractor involvement (ECI), 1112, 1119, 1120
Earthen construction, 913–923
Earthquake-resistant, 1382
Eco-materials, 105, 765–776
Economic impact, 780, 783, 785, 788, 1077, 1099, 1105, 1107, 1594
Educational building, 1016, 1017, 1024, 1052
Electrodeposition, 719–728
Electrospinning, 404–413
Embodied carbon (EC), 41, 43, 44, 613, 614, 616–619, 624, 625, 715, 744, 855–861, 863, 864, 899–910, 927–938, 1262, 1263, 1301, 1554, 1559, 1591, 1593, 1650, 1651, 1870, 1876
Embodied carbon assessment, 927–938
Embodied energy, 141, 179, 284, 378, 383, 385, 476–483, 485, 613, 614, 616–619, 624, 630, 673, 682, 856, 857, 933, 1084, 1347, 1600, 1606, 1706, 1846
Embodied water (EW), 611–619
Energy community (EC), 1040, 1138–1147, 1163, 1194, 1495, 1496, 1729
Energy conservation building code (ECBC), 1762–1771
Energy efficiency, 71, 156, 172, 173, 270, 373, 378, 416, 419, 625, 899, 969, 973, 974, 981–988, 993, 1005, 1016, 1018–1024, 1051, 1059, 1061, 1116, 1140, 1150–1152, 1155–1157, 1160, 1165, 1166, 1168, 1191, 1199, 1201, 1203–1205, 1208, 1247, 1306, 1313, 1323, 1348, 1362, 1536, 1603, 1606, 1649–1651, 1653, 1746, 1749, 1762–1764, 1771, 1782, 1787, 1820, 1825
Energy efficiency challenges, 981–988
Energy efficiency solutions, 981–988

Energy modelling, 1139, 1766
Energy monitoring system (EMS), 1149–1157
Energy savings, 416, 437, 482, 987, 997, 1000, 1004, 1023, 1051, 1151, 1152, 1155, 1156, 1163, 1165, 1167, 1200, 1208–1210, 1213, 1218, 1650, 1731, 1763
Energy tunnel, 462–473
Ensemble learning, 575–585, 733
Environmental assessment, 26, 179, 589–596, 698, 699, 701, 930
Environmental impact reduction, 1611–1621
Environmental impacts, 26, 30, 31, 50, 71, 72, 105, 169–175, 179, 183, 193, 289, 311, 328, 367, 368, 371–375, 378–382, 386, 426, 450, 475–477, 485, 500, 522, 539, 552, 555, 556, 558–560, 585, 590–596, 623–632, 662, 683, 699, 701, 751, 765, 780, 784–785, 787–789, 822, 843, 848, 858, 862, 867, 889, 896, 900, 928, 929, 931–933, 935–938, 956, 981, 987, 1051, 1052, 1076, 1079, 1089–1095, 1098–1100, 1102, 1104, 1106, 1108, 1126, 1143, 1151, 1157, 1231, 1237–1239, 1244, 1247, 1290, 1298, 1302, 1306, 1362–1365, 1369, 1448, 1550, 1552, 1563, 1568, 1576, 1579, 1586, 1591, 1604, 1611–1621, 1626, 1629, 1650, 1651, 1653, 1687, 1709, 1740, 1741, 1743–1746, 1749, 1751, 1752, 1776, 1803, 1820, 1830, 1831, 1874, 1882, 1891, 1922–1924, 1928, 1929, 1931
Environmental product declaration (EPD), 28, 32, 60, 500, 503, 596, 628, 703, 857, 863, 867, 869, 930–933, 936, 1244, 1247, 1494, 1568, 1743, 1744, 1747, 1768, 1834, 1863, 1865
eQUEST, 1766
ETABS, 391, 1529, 1531–1533
Evaluation, 20, 31, 41, 212, 233, 261, 338, 355, 374, 381, 409, 479, 553, 571, 579, 583, 590, 591, 626, 662–663, 689, 690, 698, 699, 725, 732, 733, 735, 741, 757, 783, 801–810, 837, 893, 928, 932, 933, 936, 949, 956, 973, 992, 1009, 1015–1024, 1090, 1093, 1162, 1165–1166, 1173–1182, 1187, 1212–1213, 1216, 1222, 1271–1273, 1279, 1286, 1289–1298, 1303, 1307, 1327, 1355, 1388, 1391, 1413, 1442, 1451–1460, 1474, 1483, 1502, 1509, 1510, 1567, 1586, 1587, 1589, 1592, 1593, 1626, 1630, 1631, 1639, 1644, 1650, 1655, 1662, 1663, 1679, 1681, 1683, 1751, 1752, 1758, 1815–1825, 1832, 1842, 1884, 1886, 1899–1901, 1903, 1904, 1924
Evolutionary approach, 1882
Excavation waste, 914, 916, 917, 920, 922, 923
Experimental modal analysis (EMA), 1291, 1292, 1296
Experimental tests, 223, 1268, 1324, 1350, 1352, 1365, 1432, 1588, 1591

F

Façade, 269–276, 419, 659, 661, 666, 848, 851, 984, 985, 1190, 1234, 1235, 1243–1253, 1323–1332, 1347–1358, 1766
Fault detection, 1199–1205
Fiber-reinforced concrete (FRC), 368–370, 1329, 1502
Fiber-reinforced polymer (FRP), 390–400, 844, 845, 848, 849, 1362, 1363, 1502, 1503, 1506
Finite element analysis (FEA), 1341, 1353, 1355, 1614, 1615, 1619, 1715–1716
Finite element model (FEM), 400, 466–467, 472, 832, 834, 1335–1343, 1350–1352, 1358, 1372
Finite element modeling, 1222, 1266–1269
Flexural strength, 5, 7–9, 14, 62, 63, 65, 67, 261, 263–264, 266, 270, 272, 275, 276, 305, 307–309, 311, 317–320, 327, 355, 357, 358, 361–363, 369, 370, 390, 783, 795, 849, 1258, 1266, 1373, 1425, 1530, 1531
Flexure, 246, 254, 362, 1258, 1410, 1423, 1424
Flipped classroom, 1089, 1090, 1092, 1094
Floating offshore wind turbine (FOWT), 1739–1747
Flood hazard, 1540–1545
Floor system, 1371–1379, 1491, 1495, 1497, 1498
Fly ash, 4, 13–23, 40, 60, 93, 98, 100, 101, 111–113, 118, 119, 121, 123–126, 131, 156, 221, 304, 341, 342, 344, 346, 350, 354, 377–386, 476, 511, 512, 522, 551, 564, 576, 577, 584, 585, 590, 591, 596, 599, 716, 740, 741, 743–748, 779, 780, 782, 787, 801–810, 814, 860, 861, 868, 872, 874, 875, 890–892, 1102, 1107, 1108, 1262, 1702, 1745
Free vibration, 1521, 1525

Fresh properties, 72, 77, 82, 233, 305–307, 358–360
FRP sheet, 1502
Full-scale testing, 792, 798
Functionally graded materials (FGM), 1515–1526
Fungal Mycelium, 540, 543, 1235–1237, 1239

G
Generative adversarial networks (GANs), 647–649, 651, 657, 934
Genetic algorithm (GA), 582, 1614, 1616
Geopolymer, 13–23, 93–102, 106, 220, 342, 354–356, 358, 360, 361, 363, 379, 526, 779, 781, 801, 821–828, 889–896, 914–916, 920, 921, 923
Geopolymer concrete (GPC), 14, 157, 353–363, 801–810, 822–825, 827, 828
Geothermal environment, 462–473
GFRP reinforcement, 1368, 1369
Glass, 56, 59, 76, 77, 186, 368, 369, 371, 373, 390, 400, 481, 551, 599–608, 663, 832, 844, 848, 849, 950, 1055, 1238, 1246, 1262, 1347, 1349, 1362, 1363, 1367, 1368, 1768, 1833, 1926
Glass fiber-reinforced concrete, 371, 1324
Global warming potential (GWP), 29–34, 44, 170, 172–180, 193, 382, 385, 386, 504, 506–508, 557, 559, 560, 590, 592–596, 628, 703, 704, 780, 782–785, 788, 826, 827, 848, 857, 859, 860, 863, 868–871, 875, 876, 1100, 1105, 1106, 1108, 1237, 1243–1253, 1550, 1555, 1556, 1560, 1740, 1741, 1743–1747, 1752, 1757, 1834, 1928, 1929
Glulam, 31, 32, 627, 1302, 1303, 1305, 1307, 1310, 1314, 1324, 1348–1358, 1372–1374, 1379
Graphene, 132–139, 342, 724, 1291
Greenhouse gas emissions (GESs), 40, 81, 131, 156, 169, 170, 180, 220, 287, 354, 378, 425, 500, 563, 595, 679, 780, 844, 857, 862, 867–871, 875, 928, 968, 981, 1051, 1052, 1082, 1090, 1094, 1126, 1160, 1301, 1362, 1363, 1487, 1488, 1490, 1497, 1498, 1549, 1592, 1650, 1653, 1654, 1762, 1788, 1876, 1877
Ground granulated blast furnace slag (GGBS), 60, 63–65, 67, 68, 82, 83, 118, 119, 121, 122, 124–126, 131–139, 205–215, 342, 344, 599, 780, 792, 802, 803, 813–819, 860, 890–892, 913–915, 922, 923
Grouting, 1291–1293, 1295, 1296

H
Hamilton's principle, 1519
Harmonic loading, 1465
Healthcare design, 1815–1825
Heating, ventilation, and air conditioning (HVAC), 982, 994, 997, 998, 1000, 1051–1053, 1055, 1166, 1200, 1656, 1657, 1733, 1762, 1763, 1765, 1768, 1770
Heat pump, 463, 489–494, 496, 497, 987, 1018, 1055, 1153, 1190, 1806, 1810
Hemp, 170–180, 390, 426, 427, 430–434, 540, 541, 845, 849, 1232
Hempcrete, 170–175, 177–180
High-pressure carbonation, 317–320, 322, 325
Historical Villages (HVs), 1137–1147
Hot disk method, 451, 542, 546
HSLA steel, 613, 615–619
Hybrid, 172, 173, 354, 576, 585, 845, 864, 903, 988, 991–1000, 1010, 1100, 1202, 1243–1253, 1323, 1324, 1347–1358, 1371–1379, 1628
Hybrid energy systems, 986
Hybrid unitized façade (HUF), 1244–1247, 1249–1253
Hybrid ventilation, 991–1000
Hydrated blast furnace slag cement, 81–90
Hygrothermal performance, 415–423, 1246

I
Image processing, 318, 350, 636, 1281, 1456
Imperfect beams, 1524, 1525
Incineration ashes, 114, 1102, 1107
Infiltration, 100, 635–645, 831, 993, 1767
Information system (IS), 392, 1030, 1078, 1898, 1900
Innovation in urban design, 1627, 1628, 1631
Integrated technical building installations (ITB), 1052–1059, 1061
Intensity measures (IM), 1399, 1539
Interactive diagrams, 1150

International Performance Measurement and Verification Protocol (IPMVP), 1208, 1210
Internet of Things (IoT), 968, 1028, 1034
Iron mine waste rock, 219–226
Iron waste, 219–226

L
Lab-performance design, 698, 705
Leadership, 982, 987, 1114, 1336, 1787–1797, 1873, 1911, 1914–1916
Legislation, 449, 880, 884–886, 944, 958, 1031, 1141, 1146, 1187, 1777, 1847, 1849, 1850
Levelized cost of energy, 1749–1758
Life cycle assessment (LCA), 25–32, 34, 35, 59, 90, 156, 169–180, 193, 205, 375, 378, 380, 382, 477, 478, 499–509, 539, 551–560, 590, 591, 594–596, 619, 624–631, 662, 666, 699, 703, 726, 822, 824, 826–828, 857, 867, 869–871, 875, 927–938, 952, 1031, 1076, 1077, 1079, 1080, 1085, 1099, 1100, 1232, 1237, 1239, 1244, 1245, 1247, 1248, 1250–1253, 1550–1557, 1613, 1653, 1688, 1693, 1740–1747, 1750–1753, 1830–1836, 1838, 1891, 1922–1924, 1930, 1931
Life-cycle cost assessment (LCCA), 1364, 1368
Life cycle cost/costing (LCC), 596, 674, 699, 740, 743, 745–747, 850, 982, 984, 993, 1031, 1084, 1116, 1239, 1368, 1602, 1614, 1618, 1806, 1830–1835, 1837, 1838, 1850
Life cycle energy (LCE), 475–485
Lifetime CO_2 emissions, 673–683
Lightweight composites, 848
Lightweight concrete, 269–276, 415–423, 813–819, 849
Lightweight ultra-high-performance concrete (LUHPC), 71–77
Lime-based, 170, 196
Linear regression (LR), 349, 548, 802, 804, 806, 809, 1211, 1415, 1417–1419, 1477, 1480
Liquefaction potential, 512, 519–520
Long-term monitoring, 1365–1367
Low-carbon cement, 559
Low-carbon concrete, 156, 166, 858, 859, 868–870, 875
Low-carbon impact binders, 425–434
Low-strength concrete, 284, 286–289

M
Machine learning (ML), 526, 530–536, 576, 579, 581, 585, 615, 617, 731–737, 801–810, 927–938, 1082, 1204, 1221, 1222, 1410, 1415–1419, 1437–1449, 1473, 1474, 1478, 1626, 1628, 1709
Maintenance and rehabilitation, 688, 1563, 1565, 1566
Marine, 94, 189, 200, 558, 593, 660, 662, 663, 665, 674, 683, 722, 727, 740, 743–746, 748, 847, 868, 872, 875, 1118, 1363, 1364, 1711, 1779
Masonry structures, 389–400, 974, 1290–1298, 1396, 1399–1401, 1405
Masonry tower, 1342
Masonry units, 287, 392, 485, 890, 892–896, 1338
Material efficiency, 1611–1621, 1849
Material flow analysis (MFA), 1076, 1098–1100, 1102–1103, 1108, 1901, 1903, 1904
Measurement and Verification (M&V), 1207–1218
Mechanical performance, 72, 77, 90, 132, 139, 328, 338, 381, 526, 595, 752, 755, 1349
Mechanical properties, 14, 41, 42, 72, 76, 82, 84, 94, 100, 131, 132, 172, 224–225, 247, 261, 270, 271, 286, 293, 294, 297–299, 304, 316, 350, 362, 368–371, 375, 404, 412, 413, 426, 428, 429, 433, 438, 526, 528, 530–535, 589, 591, 595, 613, 698, 726, 758, 760, 776, 783, 785, 828, 844, 846, 849, 890, 1100, 1103, 1269, 1276–1279, 1283, 1286, 1304, 1306, 1316, 1324, 1325, 1331, 1332, 1348, 1362, 1365, 1367, 1368, 1410, 1412, 1419, 1429, 1503, 1506, 1857
Megaprojects, 1118, 1122
Metakaolin (MK), 18, 93, 131, 156, 221, 304, 317, 319–322, 324, 325, 814, 860, 915
Meta-modules, 1030
Microfibers, 368, 373, 404–413
Microstructure, 55, 82–86, 90, 94, 106, 125, 126, 132, 133, 135, 136, 139, 165, 166, 265, 266, 283, 341–343, 347–349, 438, 602, 605, 607, 647–657, 682, 725, 732, 740, 847, 872, 1455, 1460
Mixed-mode, 991–1000
Mobile factory, 1687–1693, 1696, 1697
Mobility transition, 1635–1644
Modular buildings, 1585–1594
Moisture carbonation, 82, 85–88, 90
Molecular dynamics, 293–295, 297, 299, 727

Monte Carlo simulation (MCS), 179, 674, 678, 1619, 1754, 1756
Mortar, 1, 14, 51, 61, 94, 118, 186, 195, 206, 220, 248, 260, 272, 281, 305, 317, 331, 344, 370, 389, 438, 485, 564, 707, 724, 839, 883, 917, 1103, 1262, 1289, 1848
MSWI fly ash, 1102, 1104
Multi-level governance networks, 1185–1195
Multi-objective optimization (MOO), 576, 582, 585, 586, 1614, 1617

Planning, 232, 688, 752, 754, 864, 867, 880, 883, 946, 956, 968, 973, 982, 984, 986, 988, 1027, 1028, 1052, 1053, 1055, 1059, 1064, 1072, 1086, 1117, 1119, 1143, 1145, 1147, 1162, 1186–1190, 1192–1195, 1199, 1208, 1238, 1306, 1405, 1540, 1577, 1600, 1606, 1627, 1636, 1638, 1642–1644, 1663, 1671, 1675, 1676, 1678–1680, 1682–1684, 1730, 1774, 1775, 1777–1782, 1787–1789, 1793, 1794, 1797, 1807, 1820, 1823, 1824, 1892, 1915, 1916, 1922
Planning process, 1082, 1186, 1188, 1192–1194, 1204, 1636, 1676, 1678, 1679, 1683, 1774, 1777–1779, 1782
Plasterboards, 846, 1234, 1237–1239, 1763, 1766, 1768, 1770, 1771
Policy, 26, 170, 180, 288, 740, 844, 930, 1007, 1008, 1010–1012, 1042, 1085, 1139, 1141, 1150, 1186, 1187, 1191, 1193, 1565, 1578, 1581, 1582, 1586, 1635, 1640, 1654, 1668, 1673, 1726, 1775, 1790, 1803, 1804, 1810, 1815, 1846, 1848, 1850, 1870, 1873, 1883, 1884, 1889–1894
Policy framework, 1008–1010, 1893
Polymer composites, 400, 843–851, 1234
Pond ash, 511–522
Pore structure, 55, 265, 322, 327–339, 421, 441, 446, 514, 647, 649
Porosity distribution rate, 1515–1526
Porous asphalt (PA), 635–645, 649, 1140
Porous structure, 42, 75, 274, 540, 648, 649, 651
Positive energy districts (PEDs), 1159–1168, 1185–1195, 1774, 1787–1797
Post-occupancy evaluation (POE), 1024, 1052, 1816
Power distribution network, 1128, 1130, 1134
Pozzolanic reaction, 121, 122, 308, 309, 383, 564, 567, 569, 745, 914, 923
Pozzolanic reactivity R^3 test, 918
Precast concrete (PC), 330, 1258, 1324, 1446, 1448, 1702, 1706–1709
Precast industry (PI), 1702–1704, 1706–1709
Precoated binders, 118–127
Predictive performance, 1473–1475, 1483
Prefabricated vertical drains (PVDs), 1711, 1712, 1714–1716, 1718–1723
Primary care facilities, 1817
Printable concrete, 1–10
Probabilistic analysis, 674, 679–681, 1754–1757
Project-based collective action, 1894
Pumice, 270–276
Pushover analysis, 1266, 1273
Pyrolysis, 40–42, 563–565, 572

Q
Quantitative analysis, 108, 932, 1917

R
Railway embankment, 1711–1723
Railway projects, 1119
Rammed Earth, 525–536, 914
Random forest (RF), 531, 578–580, 584, 733, 735, 737, 809, 931, 932, 1415, 1417–1420
RC beam, 849, 1423–1428, 1432–1434, 1491, 1493
RC buildings, 478, 1382, 1392
RC elements, 485, 746
Reactivity, 73, 88, 90, 113, 184, 186, 189, 191, 193, 213, 226, 335, 564, 567–570, 572, 914–916, 918–923
Reclaimed timber, 1275–1286, 1303, 1307, 1309, 1888, 1890, 1891, 1893
Recycled aggregates (RAs), 118, 183, 184, 191–193, 206, 207, 210, 211, 213, 215, 269–276, 281–289, 884, 1591
Recycled concrete, 184–190, 316, 325
Recycled concrete aggregates (RCAs), 206, 207, 270–274, 276, 283, 284, 286–289, 831–840
Recycling, 26, 82, 118, 169, 183, 189, 193, 206, 207, 280–283, 288, 353–355, 373, 378, 426, 449, 450, 459, 508, 599, 612, 626, 628, 705, 831, 844, 856, 860, 862, 880, 881, 883–886, 889, 890, 895, 896, 942, 943, 946, 952, 960, 962, 1080, 1097–1108, 1241, 1348, 1555, 1557, 1560, 1577, 1578, 1580, 1585, 1586, 1591, 1592, 1597, 1598, 1600, 1601, 1606, 1702, 1746, 1767, 1809, 1829, 1843, 1844, 1846, 1855, 1857, 1858, 1863, 1864, 1882, 1908, 1910, 1912, 1918, 1921–1924, 1926–1931
Re-entrant honeycombs, 246–249, 252, 253
Reference values, 704, 1017, 1020, 1316, 1367
Regression modeling, 1483
Regulations, 171, 183, 282, 288, 354, 416, 417, 490, 504, 552, 691, 740, 752, 823, 827,

831, 886, 947, 952, 974, 987, 1008, 1011, 1030, 1040, 1044, 1046, 1052, 1057, 1058, 1080, 1103, 1139, 1141, 1145, 1162, 1187, 1193, 1236, 1239, 1244, 1248, 1302–1306, 1309, 1458, 1459, 1574, 1578, 1580, 1582, 1598, 1762, 1763, 1777, 1803, 1804, 1807, 1809, 1811, 1812, 1846, 1849, 1883, 1892, 1893, 1910, 1927, 1930
Reinforced concrete bridge, 1368, 1540, 1545
Reinforced concrete corbel, 1502, 1503, 1507
Repair, 94, 368, 673, 674, 679, 682, 683, 688, 697, 701, 704, 707–717, 723–727, 740, 743–745, 766, 770, 776, 857, 871, 1291, 1362, 1368, 1444, 1586, 1702, 1706, 1830, 1831, 1856, 1860, 1861, 1863, 1865, 1866
Research-based design, 1113, 1188–1191, 1680
Resource management, 328, 941–953, 1100, 1600, 1603, 1612
Retrofit strategies, 1251, 1650–1654, 1656, 1657
Reuse, 26, 31, 118, 124, 280, 378, 449, 450, 560, 626, 631, 856, 880, 881, 883, 886, 890, 914, 923, 941–953, 959, 960, 962, 1042, 1043, 1045, 1115, 1138, 1231, 1233, 1276, 1286, 1291, 1292, 1298, 1302, 1303, 1305–1307, 1309, 1310, 1348, 1349, 1585, 1586, 1590–1593, 1598, 1599, 1601, 1606, 1702, 1706, 1745, 1773, 1803, 1804, 1808–1811, 1829–1831, 1833, 1837, 1838, 1841–1850, 1855–1857, 1861, 1862, 1866, 1882, 1887–1889, 1891, 1893, 1897, 1908, 1910, 1912, 1915–1918, 1921–1924, 1927–1930
Reusing building elements, 941, 942
Reusing mapping, 942–944
Review, 2, 27, 72, 170–173, 450, 508, 531, 552, 624, 627, 631, 660, 717, 722, 843–851, 856, 880, 969–975, 982, 992, 993, 1003–1012, 1030, 1040, 1041, 1058, 1083, 1085, 1090, 1092, 1093, 1095, 1111, 1116, 1161, 1190, 1201, 1204, 1205, 1222, 1258, 1266, 1302, 1303, 1307, 1309, 1310, 1372, 1396–1397, 1473–1475, 1550, 1587, 1588, 1590, 1593, 1600, 1602, 1613–1614, 1627, 1628, 1630, 1631, 1637–1639, 1643, 1652, 1727–1732, 1747, 1776, 1788, 1793–1796, 1805, 1817, 1819, 1821, 1830–1833, 1845, 1870–1871, 1886, 1901, 1911, 1917
Rheology, 43
Risk assessment, 687–694, 1125–1134, 1200, 1399, 1545
Risk-based structural design, 1488, 1494–1495
Risk management, 946, 947, 1117, 1119, 1199–1205, 1911
Risk-targeted response spectrum (RTRS), 1396, 1398, 1399, 1401–1405
Road construction, 281, 282, 832, 868, 884, 1102, 1921–1931
Road infrastructure (RI), 868, 1563, 1566, 1567, 1573–1582

Sustainability, 25, 40, 49, 76, 106, 156, 170, 183, 206, 225, 232, 260, 269, 289, 304, 338, 342, 367, 378, 423, 475, 525, 589, 619, 660, 698, 728, 743, 831, 858, 867, 890, 899, 928, 942, 956, 987, 991, 1011, 1015, 1028, 1041, 1059, 1061, 1075, 1090, 1100, 1111, 1150, 1160, 1191, 1205, 1232, 1245, 1265, 1290, 1301, 1313, 1347, 1363, 1405, 1444, 1498, 1530, 1550, 1568, 1574, 1586, 1599, 1612, 1626, 1635, 1655, 1662, 1675, 1703, 1726, 1740, 1751, 1762, 1777, 1781, 1788, 1801, 1816, 1829, 1846, 1872, 1887, 1908, 1924, 1931
Sustainability transition (ST), 1159, 1167
Sustainable, 15, 27, 50, 71, 102, 105, 156, 169, 183, 220, 289, 328, 354, 378, 390, 415, 426, 449, 475, 526, 548, 596, 698, 726, 765, 801, 839, 845, 858, 889, 929, 942, 962, 987, 992, 1006, 1031, 1044, 1052, 1065, 1085, 1098, 1112, 1139, 1157, 1167, 1173, 1185, 1200, 1208, 1239, 1244, 1290, 1302, 1313, 1363, 1371, 1382, 1463–1471, 1487, 1529, 1546, 1550, 1573, 1586, 1597, 1612, 1625, 1640, 1650, 1662, 1675, 1712, 1727, 1746, 1763, 1775, 1802, 1816, 1846, 1882
Sustainable building materials, 45, 535
Sustainable built environment, 386, 851, 1199, 1488, 1498, 1585–1594, 1731
Sustainable construction, 42, 45, 71, 72, 77, 170, 171, 178, 368, 372–375, 380, 416, 476, 526, 860, 929, 930, 932, 1537, 1598, 1603, 1612, 1763, 1771, 1807, 1891, 1893
Sustainable construction materials, 49, 368, 380, 889–896, 1371
Sustainable construction solutions, 141
Sustainable development, 27, 71, 105, 171, 475, 499, 525, 527, 726, 814, 819, 845, 928, 941, 1000, 1003, 1005, 1011, 1015,

1061, 1146, 1166, 1185, 1186, 1529, 1536, 1573, 1589, 1728, 1733, 1739, 1767, 1802, 1804, 1807, 1810
Sustainable plus energy neighbourhoods (SPENs), 1188–1195
Sustainable strategies, 551
Sustainable transition, 552, 1725, 1885
Sustainable urban planning, 1625–1631, 1776
Synthetic fibers, 368, 369, 372, 374, 375
Systems theory, 1869–1877
System thinking, 1872, 1909

T
Tactical urbanism, 1635–1640, 1642–1644
Thermal conductivity, 269, 418, 420, 422, 426–429, 432, 433, 438–443, 446, 450–459, 465–467, 539–548, 846, 1237, 1323–1325, 1329, 1330
Thermal expansion, 393, 716, 1327, 1330–1332
Thermal properties, 179, 418, 421, 425–434, 438, 462, 465, 468, 473, 540, 545, 890, 1767
Thermogravimetric analysis (TGA), 84, 108, 306, 567, 568, 570, 662, 917, 918, 921
Thermo-mechanical behavior, 1330
3D printed concrete, 1–10
3D printing, 1–6, 8, 13–23, 27, 29, 170, 172, 177, 178, 180, 847, 1708
3DXRCT scanning, 636–637
Tile ceramic, 353–363
Timber, 30, 31, 170, 502, 506, 528, 529, 535, 536, 623–632, 751–762, 899–910, 1233–1238, 1243–1253, 1262, 1275–1286, 1301–1310, 1320, 1323–1332, 1347, 1371–1379, 1550–1552, 1554, 1557, 1558, 1591, 1855–1866, 1869, 1887–1888, 1926–1930
Timber bridges, 1550–1552, 1554, 1558, 1559
Timber concrete composites (TCCs), 623–632, 1372, 1591
Timber recovery, 1855–1866
Timber structure fatigue life, 1348, 1349
Train, 579, 649, 804, 806, 1173–1182, 1480
Treated domestic water, 232
Tropical climates, 1003–1012

U
Ultra-high performance concrete (UHPC), 49–56, 59–68, 72, 75, 327–339, 341, 342, 350, 589–596, 732, 1257–1263, 1265–1267, 1269–1273, 1324
Uncertainty, 33, 34, 179, 180, 281, 289, 456, 500, 507, 535, 539–548, 571, 699, 827, 828, 875, 934, 947, 957, 962, 993, 1010, 1111–1113, 1115–1117, 1119–1121, 1126, 1128, 1141, 1165, 1178, 1187, 1195, 1200, 1205, 1210, 1212, 1237, 1239, 1276, 1285, 1286, 1330, 1348, 1361, 1396, 1398, 1444, 1453, 1491, 1495, 1619, 1752–1755, 1758, 1782, 1783, 1795, 1796, 1816, 1834, 1843, 1850, 1873, 1911, 1930
Underwater placing, 96
Undulated substrata, 1721, 1723
Uniform hazard spectrum (UHS), 1395, 1396, 1401–1404
Unmanned aerial vehicles (UAVs), 688, 1221, 1222, 1564
Urban heat islands (UHIs), 1064–1072, 1075, 1085, 1086
Urban-industrial metabolism, 1097, 1099, 1100, 1108
Urban metabolism, 1076–1078
Urban mobility, 1637, 1661–1673, 1773
Urban planning, 991, 1000, 1064, 1065, 1072, 1086, 1163, 1191, 1625–1629, 1631, 1650, 1653, 1673, 1676, 1683, 1726, 1727, 1775, 1779, 1781, 1787
Urban weather observations, 1060–1072
URM infill, 1381–1392
Utsira Nord & Sørlige Nordsjø 2, 1741

V
Value co-creation, 1160, 1162, 1164, 1167, 1168, 1726
Value engineering, 1855–1866
Vibration screening, 1463–1471
Virtual cement and concrete testing laboratory (VCCTL), 343, 346, 348–351
Visual inspection, 687–694, 1307, 1319

W
Wall panel, 848, 1232–1235, 1239, 1258, 1259, 1261, 1323, 1324, 1705, 1706, 1709
Wall systems, 623, 848, 1257–1263, 1887, 1888, 1890, 1891, 1893
Waste heat recovery, 491–492, 496
Waste management, 105, 106, 282, 289, 354, 508, 880–886, 889, 945, 952, 1040, 1078, 1085, 1107, 1557, 1588, 1600,

1606, 1626, 1803, 1808, 1897–1904, 1910
Waste steel fiber, 813–819
Water management, 232, 613
Wave excitation, 1182
Windborne debris impact, 1258, 1259, 1263
Wood-geopolymer composites, 890, 892
Workability, 14, 42, 54, 56, 63, 72–75, 88, 159, 184, 209, 223, 238, 243, 274, 284, 286, 304, 353–363, 379–381, 438, 439, 441, 741, 766, 769, 793, 861, 890, 892, 895, 896, 914

X
XGBoost, 531, 578–580, 583, 584, 802, 806, 807, 809, 1415, 1417, 1418, 1420
X-ray, 84, 86, 208, 438, 443–445, 513, 565, 600, 606, 608, 917–918, 1276, 1278, 1279, 1286, 1455, 1456

Y
Yield stress, 94, 98, 907, 1427, 1429, 1432, 1506

Z
Zero-emission, 1015–1024, 1051–1061, 1065, 1776, 1782, 1807
Zero-emission building (ZEB), 1017, 1022, 1051–1061
Zero-emission neighbourhoods (ZENs), 1774, 1782, 1783
