Lecture Notes in Civil Engineering

Volume 237

Series Editors

Marco di Prisco, Politecnico di Milano, Milano, Italy

Sheng-Hong Chen, School of Water Resources and Hydropower Engineering, Wuhan University, Wuhan, China

Ioannis Vayas, Institute of Steel Structures, National Technical University of Athens, Athens, Greece

Sanjay Kumar Shukla, School of Engineering, Edith Cowan University, Joondalup, Australia

Anuj Sharma, Iowa State University, Ames, USA

Nagesh Kumar, Department of Civil Engineering, Indian Institute of Science Bangalore, Bengaluru, India

Chien Ming Wang, School of Civil Engineering, The University of Queensland, Brisbane, Australia

Zhen-Dong Cui, China University of Mining and Technology, Xuzhou, China

Xinzheng Lu, Department of Civil Engineering, Tsinghua University, Beijing, China

Lecture Notes in Civil Engineering (LNCE) publishes the latest developments in Civil Engineering—quickly, informally and in top quality. Though original research reported in proceedings and post-proceedings represents the core of LNCE, edited volumes of exceptionally high quality and interest may also be considered for publication. Volumes published in LNCE embrace all aspects and subfields of, as well as new challenges in, Civil Engineering. Topics in the series include:

- Construction and Structural Mechanics
- Building Materials
- Concrete, Steel and Timber Structures
- Geotechnical Engineering
- Earthquake Engineering
- Coastal Engineering
- Ocean and Offshore Engineering; Ships and Floating Structures
- Hydraulics, Hydrology and Water Resources Engineering
- Environmental Engineering and Sustainability
- Structural Health and Monitoring
- Surveying and Geographical Information Systems
- Indoor Environments
- Transportation and Traffic
- Risk Analysis
- Safety and Security

Preface

The *1st International Conference on Net-Zero Built Environment: Innovations in Materials, Structures, and Management Practices* was successfully held on June 19–21, 2024, in Oslo, Norway. This conference was part of the *Net-Zero Future* project sponsored by the Research Council of Norway and the Norwegian Directorate for Higher Education and Skills. Through the referenced project, a unique international alliance was formed among Norway, the United States, Germany, South Africa, and India to conduct collaborative research and educational activities toward achieving a net-zero built environment, capitalizing on mutual interests and the diversity of practices. This alliance is in line with sustainable development goals, such as quality education, industry and innovation, sustainable cities, climate action, and partnerships.

The pressing global challenges associated with the degradation of the built environment due to mounting stressors and, on the other hand, the environmental footprint of growth in the built environment serving communities have necessitated a profound transformation in how we design and develop our infrastructure. Civil engineering is the primary field responsible for infrastructural development and is at the forefront of this transformation. The conference series on Net-Zero Built Environment: Innovations in Materials, Structures, and Management Practices has been dedicated to exploring the concept of net-zero within the realm of civil engineering and a variety of relevant domains, emphasizing the critical importance of achieving a net-zero carbon footprint in our built environment.

Net-zero in the built environment refers to the knowledge and practice of delivering, maintaining, and managing civil infrastructures that produce zero net carbon emissions throughout their lifecycle. This ambitious goal requires a holistic effort, encompassing methodological approaches to design, construction, operation, and eventual decommissioning. This motivated us to establish three main themes for this conference series, capturing innovations in materials, structures, and management practices. The first conference of this conference series attracted a large group of participants from the academic, industry, and public sectors, presenting the latest developments in each of the identified main themes.

After a rigorous peer-review process performed by the conference's international scientific committee members and other expert reviewers, 158 full-text papers have been selected to be included in this book. The selected papers represent a diverse group of authors and research groups from around the globe, providing original perspectives and insights into how we can pave the way toward a net-zero built environment. Converging on this ultimate goal, the selected papers offer the latest advances in (i) new materials and manufacturing processes for zero carbon footprint, (ii) robotic construction technologies for minimum formwork and on-site activities, (iii) novel structural designs and details for optimal performance with the least materials, (iv) advanced condition assessment and health monitoring strategies, and (v) innovative life-cycle analyses and civil infrastructure management strategies.

We recognize that achieving net zero is not merely a development goal but a moral imperative to ensure a sustainable future for all. Reducing carbon emissions can help stabilize temperature patterns, decrease the frequency and severity of extreme weather events, and protect vulnerable ecosystems. All who contributed to this book share the same passion to positively impact the communities around the world. Through the dissemination of the latest findings and innovations, this book's main themes and individual chapters directly contribute to the net-zero domain. By equipping scientists, engineers, policymakers, and the general public with relevant knowledge and expertise, we hope to collectively drive a global transition toward a net-zero future.

Oslo, Norway — Mahdi Kioumarsi
Ames, IA, USA — Behrouz Shafei

Contents of Volume I

An Experimental Study of Consistency and Strength Variation of 3D-Printed Concrete Mixes 1
Dmitry Vysochinskiy, Gunnar Madsen, and Ingrid Lande

Three-Dimensional Printing of Fly Ash-Based Geopolymer Materials 13
Shaurav Alam, Stephen Gordon, Blake Bassett, Kevin Cobb, Brandon Jefferson, Nnamdi Nwoha, Tanvir Manzur, Kelly Crittenden, and John Matthews

Material Stories: Assessing Sustainability of Digital Fabrication with Bio-Based Materials Through LCA 25
Giuliano Galluccio, Martin Tamke, Paul Nicholas, Tom Svilans, Nadja Gaudillière-Jami, and Mette Ramsgaard Thomsen

Increasing the Incorporation of CO_2-Sequestering Materials in Concrete 39
Alexander Mezhov, Bright Asante, and Wolfram Schmidt

Developing Eco-friendly Ultra-High-Performance Concrete by Utilizing Recycled Alternatives 49
Jennifer Wivast, Anette Nyland, Saeed Bozorgmehr Nia, Mahdi Kioumarsi, and Behrouz Shafei

Reducing the CO_2 Footprint of UHPC Through Portland Cement Substitution 59
Ingrid Lande, Andrej A. Sørensen, Martin Hagen, and Rein Terje Thorstensen

Investigation of Lightweight Ultra-High-Performance Concrete for Net-Zero Solutions 71
Amir Ramezani and Behrouz Shafei

Carbonation of Hydrated Blast Furnace Slag Cement Powder: Characterization and Application as a Cement Substitute 81
Hamideh Mehdizadeh, Mohammad Hajmohammadian Baghban, and Tung-Chai Ling

Performance of Metakaolin-Based Alkali-Activated Mortar for Underwater Placement 93
Joud Hwalla, Mariane Saba, Joseph Assaad, and Hilal El-Hassan

Production of CSA Clinker Using Municipal Solid Waste Incineration Fly Ash as a Main Raw Material 105
Carlos Andrés Bedoya-Henao, Oscar Jaime Restrepo-Baena, and Jorge Iván Tobón

Feasibility Study of Precoated Binder-Type Electric Arc Furnace Oxidizing Slags as Aggregates for Cement Mortar 117
Wei-Ting Lin, Andīna Sprince, Marek Hebda, Gábor Mucsi, An Cheng, and Huang-Hsing Pan

Early-Day Effects of Graphene on NA_2CO_3: Activated GGBS Concrete 131
Yongcong Zhao, Meini Su, and Yong Wang

Numerical Modeling of the pH Effect on the Calcium Carbonate Precipitation by *Sporosarcina pasteurii* 141
Shiva Khoshtinat and Claudia Marano

Exploring the Potential Utilization of Silicon Manganese Slag as a Supplementary Cementitious Material for Cement Replacement in Developing Low-Carbon Composite Binders 155
Dileepa Hettiarachchi, S. M. Samindi M. K. Samarakoon, Kjell Tore Fosså, Kidane F. Gebremariam, and Mahmoud Khalifeh

Understanding Carbon-Negative Potential of Hempcrete Using a Life Cycle Assessment Approach 169
Sejal Sanjay Shanbhag and Manish Kumar Dixit

Use of the Fine Fraction from High-Quality Concrete Recycling as an Alternative Cement Substitute 183
Laurena De Brabandere, Vadim Grigorjev, Philip Van den Heede, Hannah Nachtergaele, Krist Degezelle, and Nele De Belie

Discussion of Physical Performance of Hydraulic Lime and Oyster Shell-Based Mortars 195
Poliana Bellei, Inês Flores-Colen, Isabel Torres, and Manuel F. C. Pereira

CO_2 Capturing of Aggregates Extracted from Alkali-Activated GGBS Concrete 205
Syamak Tavasoli and Wolfgang Breit

Application of Iron Mine Waste Rock as an Innovative Cement Replacement Material in Mortar 219
Bruna Figueiredo Cezar, Margareth da Silva Magalhães, and André Rocha Pimenta

Feasibility of Utilizing Treated Domestic Wastewater (TDW) for the Production of Concrete 231
Hans Beushausen, Zaid Manuel, Joanitta Ndawula, and Dyllon Randall

Compressive Characteristics of Perforated Re-entrant Auxetic Steel Honeycomb–Mortar Composite 245
Emmanuel Owoichoechi Momoh, Mohammad Hajsadeghi, Amila Jayasinghe, Raffaele Vinai, Prakash Kripakaran, John Orr, and Ken E. Evans

An Experimental Investigation on Using Seawater in Sustainable Mortar Mixtures 259
Shekhar Saxena, Harald Justnes, and Mohammad Hajmohammadian Baghban

Effect of Recycled Aggregate Utilization on Strength Properties of Lightweight Concrete Facade Having a Self-Cleaning Characteristic 269
Hatice Gizem Şahin, Hatice Elif Beytekin, and Ali Mardani

The Use of Recycled Construction and Demolition Waste in Low-Strength Concrete Brick and Block Production: A South African Perspective 279
Jaziitha Simon, Hans Beushausen, and Mark Alexander

Scaling Effect on Mechanical Property of Calcium Silicate Hydrate in Cement Using Reactive Molecular Dynamics 293
Jie Cao, Chao Wang, Jaime Gonzalez-Libreros, Yongming Tu, Lennart Elfgren, and Gabriel Sas

Exploring the Impact of Silica-Rich Calcined Clay as Portland Cement Additive to Reduce Carbon Dioxide Emissions 303
Mohammed Seddik Meddah and Ola Najjar

Enhancing Strength and CO_2 Uptake into Mortar Through Supercritical CO_2 Treatment 315
Gregor Kravanja and Željko Knez

Effects of Superabsorbent Polymers and Natural Zeolite in the Properties and Pore Structure of Ultra-High-Performance Concretes 327
Yuxiang Tan, Weizhuo Shi, Bo Li, and Yung-Tsang Chen

Performance Evaluation of the Quantification of Cement Microphases Using Energy Dispersive X-ray Spectroscopy Imaging 341
Anuradha Silva, Shanaka Baduge, and Priyan Mendis

Effect of Discarded Rubber Tire Crumbs and Tile Ceramic Waste Powder on Workability and Strength Properties of Geopolymer Concrete 353
Iman Faridmehr, Ghasan Fahim Huseien, Mohammad Hajmohammadian Baghban, and Håvard Lund

Advancing Toward Net Zero: The Role of Fibers in Sustainable Concrete Construction 367
Raymond Pepera and Behrouz Shafei

Environmental Assessment of Fiber-Reinforced Self-Compacting Concrete Containing Class-F Fly Ash 377
Behnoosh Khataei, Masoud Ahmadi, and Mahdi Kioumarsi

Strengthening Brick Masonry Structures with Natural Fiber Elements for Enhancing Earthquake Resistance 389
Manisha Kushwaha, Kusum Saini, and Vasant Matsagar

Mechanical Reinforcement of Building Materials with Microfibers Produced by Electrospinning 403
Habtom Daniel, Omar Mohamed Omar, Mahdi Kioumarsi, Shima Pilehvar, and Rafael Borrajo-Pelaez

Affordable Phase Change Materials in Lightweight Concrete Walls for Superior Hygrothermal Performance 415
Saeed B. Nia, Raymond Pepera, and Behrouz Shafei

Effects of Low-Carbon Binders on the Mechanical and Thermal Properties of Biobased Insulation Materials 425
Houssam Affan, Badreddine El Haddaji, and Fouzia Khadraoui

The Effect of Phase Change Materials (PCM) on the Thermophysical Properties of Cement Mortar 437
Iman Asadi, Guomin Ji, Gerald Steiner, and Mohammad Hajmohammadian Baghban

Thermal Performance Characterization of Recycled Textile-Based Materials for Building Insulation 449
Alessandro Dama, Esra Abdelhalim Mohamed Khalfallaand, Andrea Alongi, and Adriana Angelotti

Temperature-Dependent Dual-Operation Mode for Energy Tunnel Integrated with Phase-Change Materials in Geothermal Environment 461
Qiling Wang, Jiaolong Zhang, Peng Xiao, Xi Chen, Eddie Koenders, and Yong Yuan

Effect of LightweightMasonry on Life Cycle Energy: A Case Study of Residential Buildings in India 475
Pradip Sarkar and Nikhil P. Zade

Seasonal Waste Heat Storage in Energy-Efficient Finnish Apartment Buildings 489
Janne Hirvonen, Santeri Sirén, and Piia Sormunen

Optimization of Nativo Wood Fibre Insulation Board Through LCA Analysis 499
Angela Daniela La Rosa, Gaute Thomassen, and Petter Erlandsen

Dynamic Characterization of Indian Pond Ash Through Cyclic Simple Shear Tests 511
Ghanta Naga Sireesha and Prishati Raychowdhury

Analysis of the Mechanical Behavior of Rammed Earth Mixes Using Soft Computing Methods with an Emphasis on Sustainability 525
Aryan Baibordy, Mohammad Yekrangnia, and Fatemeh Khodabakhshian

Towards Circular and Sustainable Insulation Solutions: Resolving Uncertainty in the Thermal Conductivity of Mycelium-Based Composites (MBCs) 539
Joni Wildman, Andrew Shea, Daniel Henk, Martin Naido, and Pete Walker

A Comparative Life Cycle Assessment of Ordinary Portland Cement, Limestone Calcined Clay Cement and Mining Waste Marl Cement 551
Yasmine Rhaouti, Yassine Taha, and Mostafa Benzaazoua

R^3 Reactivity Test on Biochar from Pyrolyzed Green Waste, Wood Waste, and Screen Overflow 563
Maximilian Mayer, Neven Ukrainczyk, and Eduardus Koenders

Low Carbon-Oriented Concrete Mix Optimization Using Ensemble Learning and NSGA-II 575
Lin DENG and Xueqing Zhang

Preliminary Environmental Assessment of Ultra-High-Performance Concrete Mixtures 589
Leila Farahzadi, Saeed Bozorgmehr Nia, Behrouz Shafei, and Mahdi Kioumarsi

Compressive Strength Gain of Glass Powder–Portlandite: An Investigation Toward Maximizing the Use of Waste Glass as Cement Replacement in Concrete 599
Gaurav Chand, Mithila Achintha, and Yong Wang

Impact of High-Strength Low-Alloy Steel in Reducing the Embodied Water of Buildings: A Case Study 611
Manish Dixit, Pranav Pradeep Kumar, and Sarbajit Banerjee

Environmental Impact of Timber Concrete Composites: An Overview 623
Alemayehu Darge Dalbiso and Mohammad Haj Mohammadian Baghban

Influence of Spatial Coarsening of Pore Space in Porous Asphalt on Simulated Infiltration for Enhanced Stormwater Management 635
Rebecca Allen

Controllable Generation of Porous Microstructures Through Generative Adversarial Networks 647
Jakob Torben and Kai Bao

Marine-Based Photocatalytic Protection of Building Envelopes on Behalf of Climate Change 659
Jéssica Deise Bersch, Ana Paula Soares Dias, Denise Dal Molin, Angela Borges Masuero, and Inês Flores-Colen

Importance of Optimally Combining Binder Types and Rebar Cover in Reducing Lifetime CO_2 Emissions in RC Structures 673
Sakib Hasnat and Tanvir Manzur

Corrosion Risk Assessment of Bridges in Oslo, Norway, Based on Visual Inspection 687
Amirhosein Shabani, Wahid Amin, and Sven Kirschhausen

Reducing the Carbon Footprint of New Reinforced Concrete Structures in Aggressive Environments: From Real Experience to Future Applications 697
Juan Daniel Cassiani Hernandez and Sylvia Keßler

Misconceptions Around Strength Requirements for Concrete Repair Materials and Related Sustainability Issues 707
Nicholas Jarratt and Hans Beushausen

The Use of Electrodeposition Technology to Promote Self-Repairing of Cracks in Concrete: A Mini Review 719
Mohammed H. Alzard and Hilal El-Hassan

Predicting Dry Shrinkage Using Machine Learning Methods 731
Peyman Khodabandeh, Fazel Azarhomayun, Mohammad Shekarchi, and Mahdi Kioumarsi

Reducing Carbon Footprint of RC Structure in Saline Exposure: Bangladesh Perspective 739
Nazmus Sakib Pallab, Mahin Sultana, Saadman Sakib, Amrita Barua,, and Tanvir Manzur

Upcycling of Single-Use Pallet Wood to Cross-Laminated Timber 751
Niels H. Vonk, Jan Niederwestberg, Ron W. A. Oorschot, and Jan de Jong

Designing Eco-Friendly Materials Intended for Repairing Reinforced Concrete Structures 765
Karim Belmokretar, Kada Ayed, Nordine Leklou, Djamel El Ddine Kerdal, Mohammed Mouli, and Meftah Allal

Multicriteria Performance Index Analysis of Geopolymeric and Cementitious Screed Flooring Materials 779
Joud Hwalla, Hilal El-Hassan, Joseph Assaad, and Tamer El-Maaddawy

CO_2 Reductions Utilising Self-Stressing Steel Fibre Reinforced Concrete 791
Martins Suta, Liga Gaile, and Rolands Cepuritis

Evaluation of the Compressive Strength of Fly Ash- Based Geopolymer Concrete Using Machine Learning 801
Maryam Bypour, Mohammad Yekrangnia, and Mahdi Kioumarsi

Sustainable Enhancement of Lightweight Concrete: A Comprehensive Investigation into GGBS and Waste Steel Fiber Incorporation for Improved Strength and Durability 813
Babak Behforouz, Davoud Tavakoli, Behrouz Naderi, and Mohammad Hajmohammadian Baghban

Life Cycle Assessment of Geopolymer Concrete Made with Tailings from Ilmenite Mining 821
Simon Brekke and Reyn O'Born

Performance Evaluation of Recycled Concrete Aggregates as Drainage Material in Combination with Geosynthetics for Landfill Cover Systems 831
Sayeeda Syed and Anumita Mishra

Bio-Based Polymer Composites Used in the Building Industry: A Review 843
Chinyere O. Nwankwo and Jeffrey Mahachi

Decarbonizing Conventional Building Materials for Net-Zero Emissions: A Feasibility Study in Canada 855
Chi Dara

Greenhouse Gas Emissions and Service Life of Concrete Infrastructures 867
Gro Markeset

Review of South African Waste Management Practices and Their Integration into the Construction Industry 879
Areej Gamieldien, Hans Beushausen, and Mark Alexander

1 Introduction

Concrete three-dimensional (3D) printing is an innovative technology that allows for building three-dimensional objects layer by layer. Although the process is traditionally called concrete 3D printing, most of the mixes used have a maximum particle size of 2–3 mm, and, thus, calling the process mortar 3D printing would be more technically correct. In this chapter, the terms "3D-printed mortar" and "3D-printed concrete" are used interchangeably. Typical concrete 3D printing involves extrusion of a mortar filament through a nozzle with a diameter ranging from 6 to 50 mm [1]. The printing head is mounted on a gantry or robotic arm that positions the material to form the printed structure layer by layer. The advantages of concrete 3D printing include the absence of the need for formwork and shape flexibility, whereas the challenges include difficulties in applying reinforcement to 3D-printed structures and the lack of standards for the structural use of 3D-printed parts. A substantial

portion of the research on 3D-printed concrete is dedicated to the properties of the fresh concrete and mix design, ensuring the pumpability, extrudability and buildability of the mix. Interested readers are referred to reviews by Zhang et al. [2] and Chen et al. [3] for more details on mix design and characterization methods. When it comes to the strength and durability of hardened 3D-printed concrete, researchers are mainly concerned with the anisotropy and influence of the layer-interface properties on the overall performance of the structure as reported by e.g. Nerella et al. [4] and Rahul et al. [5]. When a mortar mix is tested in a laboratory, the water-to-binder-ratio (*w/b*) is usually known and fixed, whereas in the case of an industrial printing process, the concrete printer operator specifies not *w/b* but the amount of water in litres per hour and routinely adjusts this amount based on a feel of good consistency. Thus, the behaviour of the same mix in the laboratory and at the printing site might vary due to a fluctuating *w/b*. In this chapter, we present an approach that allows quantifying this variation, which has not yet received enough attention in the literature.

2 Materials and Methods

2.1 3D Printers and Materials

The main piece of equipment is a robot arm-based 1K system concrete printer from Hyperion Robotics™, as shown in Fig. 1. This printer consists of a silo with dry mix, a mortar mixing pump and a robot arm that performs the printing. The printing

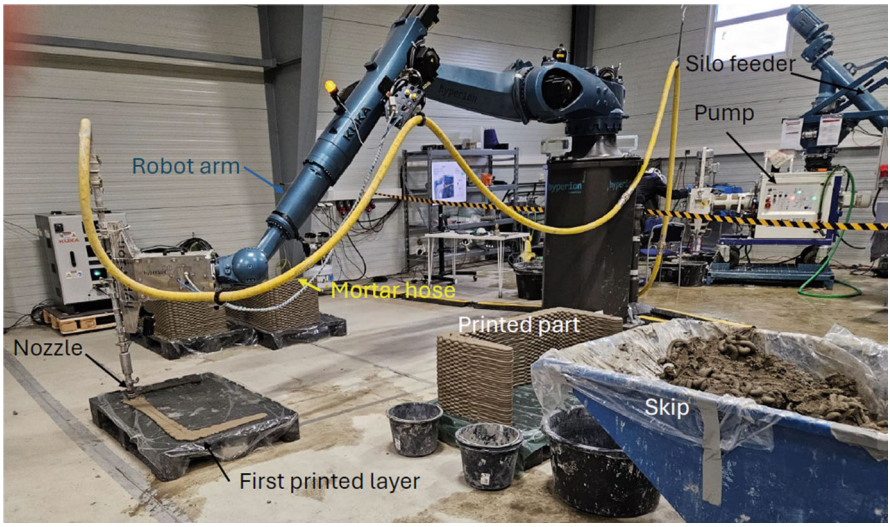

Fig. 1 A view of the 3D printing process

process is shown in Fig. 1. This type of concrete 3D printer uses dry mortar mixes with a maximum particle size of 2 mm. The dry mortar is fed into the pump where it is mixed with water and then pumped through the hose. At another side of the hose is the printing head with the printing nozzle. The robot arm controls the motion of the printing nozzle and creates 3D-printed parts layer by layer. The usual printing velocity is 245 mm/s, and nozzles of 18 mm and 20 mm are used.

Two commercially available dry 3D mortar mixes were tested in this chapter. The mixes are anonymized and denoted simply as mix A and mix B in order not to accidentally disclose any proprietary information or benchmark the mixes against each other. At the time of the demonstrations, the silo was filled with dry mix B, whereas mix A was tested only in the laboratory.

2.2 *Testing Equipment and Procedure*

The consistency of the mortar needs to be firm enough to support its own weight yet wet enough to flow well, have sufficient bonding between layers and prevent the formation of extrusion cracks. The "right" consistency is determined subjectively by the operator through visual observation of the flow. We supplement the subjective test of the consistency with the quantifiable drop flow table measurements performed in accordance with BS EN 1015-3:1999 [6], as illustrated in Fig. 2. One fills a conical form with mortar, measures the initial diameter of the cone when the form is removed, then performs 15 drops of the flow table and measures the increased cone diameter. The laboratory flow table was transported to the 3D printing site for field measurements i.e. the same flow table was used in the field and in the laboratory.

The exact dry mix design is proprietary information, and the printing operator specifies the amount of water added in the form of litres per hour, which means that the *w*/*b* of the printed mortar is not directly specified. The water-to-binder ratio (*w*/*b*)

Fig. 2 Subjective vs. objective control of 3D printing mortar consistency

surpassed the more traditional water-to-cement ratio (*w/c*) as other binders such as silica fume, fly ash, metallurgical slag and natural pozzolans become commonly added to cement. *w/b* is calculated as

$$w/b = \frac{w}{c + \sum(k_i \cdot p)} \approx \frac{w}{c + \sum p} \tag{1}$$

where w is the amount of water, c is the amount of cement and $k{\cdot}p$ is the amount of each additional binder multiplied by a corresponding coefficient [7].

The particle matrix model of concrete [8] interprets all particles smaller than 0.125 mm in diameter as part of the concrete matrix. The mass of the particles included in the concrete matrix can be calculated as

$$m_{0.125} = c + \sum p + m_{\text{filler}} \leq c + \sum p \tag{2}$$

where m_{filler} is the mass of particles <0.125 mm coming for the aggregates. Assuming m_{filler} to be small allows us to replace *w/b* with an approximate water-to-fine particles ratio (*w/f*)

$$w/f = \frac{w}{m_{0.125}} = \frac{\%\text{wt}_{\text{water}}}{\%\text{wt}_{0.125}} \tag{3}$$

w/f describes the amount of water in the concrete matrix in the same manner as *w/c* describes the amount of water in the cement paste. For a mix that contains no other binders or fine particles than cement, the matrix would consist of pure cement paste, making $w/f = w/b = w/c$. The advantage of using *w/f* instead of *w/b* is that to calculate w/f, one only requires to know the weight percentage $\%\text{wt}_{0.125}$ of fine particles (<0.125 mm). For any dry mix, this parameter can be determined by simple sieving analyses performed using a set of sieves with cell diameters of 4.0 mm, 2.0 mm, 1.0 mm, 0.500 mm, 0.250 mm, 0.125 mm and 0.063 mm. Before sieving, the mix was dried in an oven at a temperature of 110 °C for 24 h.

The strength of the hardened mortar was tested in accordance with the mortar strength testing standard [9]. Prismatic samples with dimensions of 40 mm × 40 mm × 160 mm were cast using steel forms, removed from the forms the next day and stored under water at room temperature up until testing at the ages of 1 day, 7 days and 28 days. Figure 3 illustrates the bending and compression testing of the prisms. A total of 6 prisms were tested at each age for each *w/f*; thus, a minimum of 18 prisms were cast for each *w/f* tested in the laboratory. For the field tests at the 3D printing site, a total of 24 40 mm × 40 mm × 160 mm prisms [9] and 6100 mm × 100 mm × 100 mm cubes [10] were cast. The cubes were stored under water and tested at the age of 7 days.

To summarize, the following experimental procedure was followed:

- Sieve analyses were performed to determine the content of fine particles (<0.125 mm) in each mix.

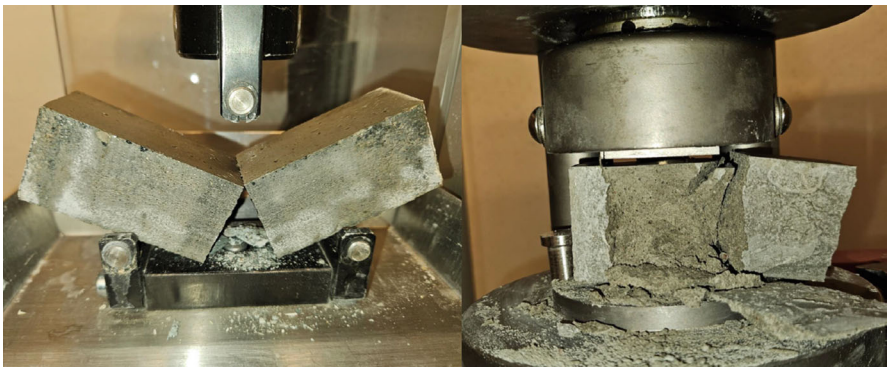

Fig. 3 Bending and compression testing of 40 mm × 40 mm × 160 mm prisms

- Field measurements of consistency combined with casting of samples were performed to determine the consistency and strength of the printed mortar. Note that *w/f* of the printed mortar is not known beforehand.
- Laboratory measurements of consistency and strength were performed for mixes with a known *w/f*.
- Field measurements and measurements of laboratory mixes were compared.

3 Results

The sieving analysis showed that dry mix A contained about 40.0% weight of particles <0.125 mm and dry mix B contained approximately 43.8% weight of particles <0.125 mm; both numbers provided are an average of more than three measurements. These high % weight of binders are typical for 3D printing mortar mixes, as shown in Zhang et al. [2].

Once the weight percentage of the fine particles was determined, we mixed and tested the four different w/f values in the laboratory for each mix, as shown in Table 1. In Table 1, "b" stands for "bending" and denotes the average flexural strength, whereas "c" stands for "compression" and denotes the average compression strength; the reported flow included in Table 1 is dynamic flow i.e. the diameter of the cone after 15 jolts of the flow table.

In addition to the laboratory mixes, two field measurements were performed to test the consistency and strength of the 3D-printed material. The quality of the first field casts performed on 25th September was deemed insufficient and was not tested at full strength; instead, the strength at the age of 3 days was tested (not included in Table 1). Another test not included in Table 1 is the test of 100 mm × 100 mm × 100 mm cubes at the age of 7 days for the second field cast. Those cubes displayed the strength of 47.7 MPa with the standard deviation of 3.2 MPa as opposed to the

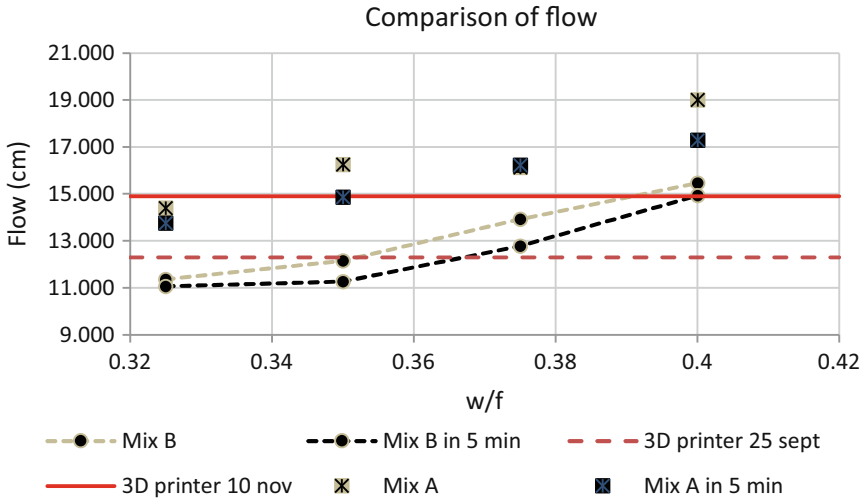

Fig. 4 Comparison of the mortar flow measurements in the laboratory and at the 3D printing site

compressive strength of 49.3 MPa (the value is underscored in Table 1) with the standard deviation of 2.8 MPa displayed by the prisms tested at the same age.

Figure 4 illustrates a comparison of the table flow measurements of the 3D-printed mortar at the site and in the laboratory; only dynamic flow i.e. values after the 15 table jolts are plotted. We can see that the printable consistency window

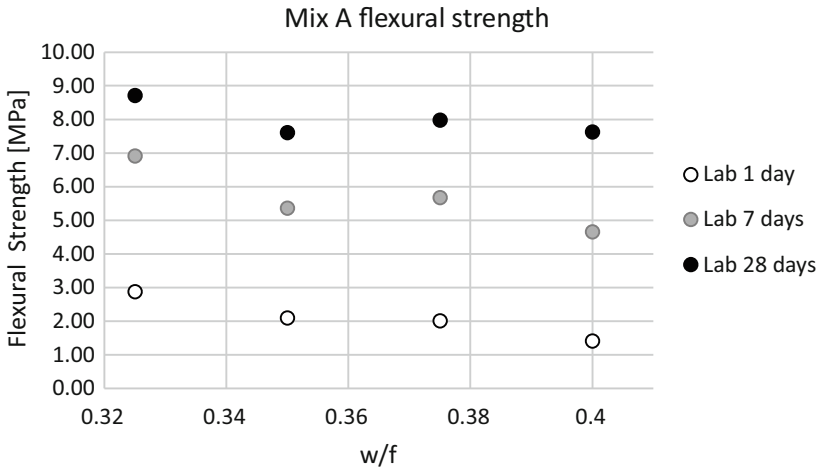

Fig. 5 Flexural strength of the prismatic samples for mix A

for dry mix B is approximately between a *w/f* of 0.35 and 0.40. Mortar made from dry mix A is more flowable at the same *w/f* in comparison with dry mix B, and its printable consistency window is likely to be at lower *w/f* values i.e. around 0.3 *w/f*. The conclusion that mix A's printable consistency lays around a *w/f* of 0.3 could be drawn from the flow measurements in Fig. 4 alone, but it was later confirmed by acquiring a technical data sheet from the producer in which the recommended water content is specified to be 12–13% of the dry mortar mass, which corresponds to $w/f = 12\%/40\% = 0.3$.

Figures 5 and 6 illustrate the evolution of the flexural strength and compressive strength of the mortar prepared from mix A, respectively, whereas Figs. 7 and 8 provide the same illustration for the dry mix B. The values of strength for the 3D-printed mix are from the second field measurements i.e. from 10 November 2023. Expectedly, one can see a decrease in the material strength with an increase of *w/f*. An interesting observation in Figs. 7 and 8 is that the 1-day strength of the printed mortar is lower than the strength of all mortar mixes tested in the laboratory, whereas for 28 days, the strength of the field samples falls between the strength of the laboratory samples of 0.35 and 0.375 *w/f*. A likely explanation is that the initial hardening of the mortar mixed in the laboratory (at ambient temperature of about 20 °C) is faster than the hardening of the mortar mixed in the printer (the ambient temperature in the hall was around 10 °C on the day of the test).

Figure 4 indicates that the *w/f* of the mortar printed on 10th November should be around 0.4 based on the flow measurements, whereas comparisons of the strength with the laboratory-mixed sample measurements in Figs. 7 and 8 indicate a *w/f* of 0.35 and 0.375, respectively. For the strength measurements for the field test of 25th September, the situation is the opposite; the levels of strength in Table 1 are slightly

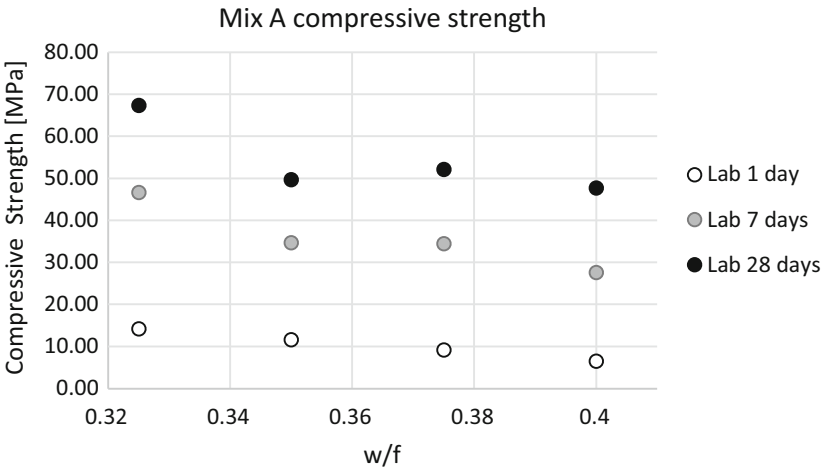

Fig. 6 Compressive strength of the prismatic samples for mix A

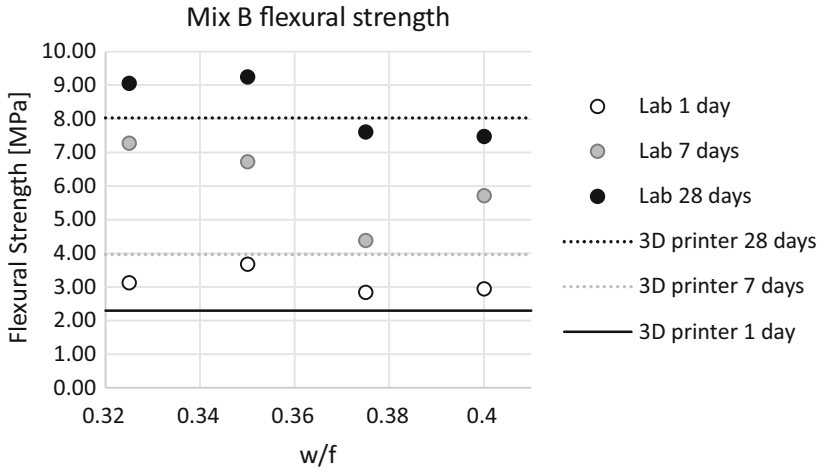

Fig. 7 Flexural strength of the prismatic samples for mix B

lower than one would suggest based on the *w/f* determined by comparing the flow values measured in the laboratory and at the 3D printing site. Thus, the flow measurement comparison serves as a viable but relatively crude estimate of *w/f* with an error of about ±0.05 *w/f*.

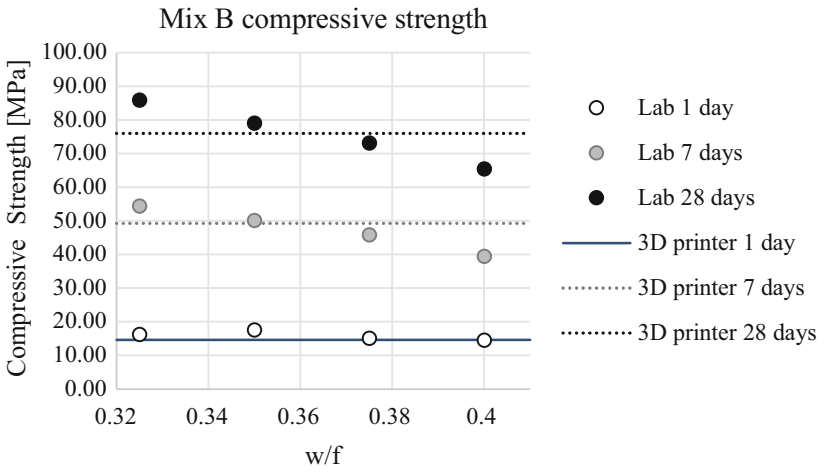

Fig. 8 Compressive strength of the prismatic samples for mix B

4 Conclusions

The aim of this study was to quantify the amount of strength variation one might expect from 3D-printed mortar of unspecified composition due to routine adjustment of the water content by the printer operator. The following conclusions were drawn:

- Replacing *w/b* with *w/f* is a viable way to handle mortar mixes of unspecified composition.
- A comparison of the flow measurements of the laboratory mixes of a known *w/f* and field mix provides an approximate crude estimate of the field mix *w/f*. A comparison with the strength measurements indicates an error of about ±0.05 *w/f*.
- The printable consistency window for mix B was approximately between 0.35 and 0.4 *w/f*, which corresponds to 79.1 MPa and 65.5 MPa of the mean compressive strength. Thus, about 20% of strength variation could be expected within the printable window of consistency.
- The difference in the mean strength between the two field measurements was about 15%, thus reinforcing the previous conclusion.
- The difference between the 7-day mean compressive strength tested on prismatic samples after the mortar standard [6] and the compressive strength of cubes tested after the concrete standard [10] was less than one standard deviation. Thus, use of prismatic samples provides a reliable strength estimate.
- The laboratory cast mixes noticeably overestimate the 1-day flexural strength of the mix compared to the field casts.

5 Discussion and Further Work

The strength measurements in this study were limited to mould cast mortar, whereas for a 3D-printed concrete structure, the bonding strength between the layers also plays an important role. The compressive strength of 3D-printed concrete would be lower than that of the corresponding cast mix due to the influence of the bonding strength between the layers [2, 11, 12]. The results found in the literature show examples of a 12–22% reduction of compressive strength [5] of printed mortar in comparison with the cast mix. Our study has shown about 20% of strength variation in cast mix due to routine adjustment of water content during printing. Combining these factors would suggest that, in the worst case scenario, the strength of a 3D-printed structure might be as low as 60–70% of that of a cast mix used for printing. However, the lowest interlayer bond strength is unlikely to be combined with the highest water content, making the overall reduction of strength less severe. A systematic study of the influence of water content variation in 3D-printed mortar on both the bond strength and mould cast strength is planned as further research work in order to produce more detailed recommendations on the appropriate safety factors on the strength and connection between the strength of mould cast mortar and that of a 3D-printed structure.

1 Introduction

Innovative materials and technologies in construction have spurred interest in fly ash-based geopolymer materials for three-dimensional (3D) printing. This study aims to design a 3D printer tailored for efficiently constructing multi-layered geopolymer walls. The geopolymer mixture, including fly ash, sand, sodium silicate, sodium hydroxide, and water, undergoes rapid curing via ohmic heating induced by alternating current (AC) voltage. After analyzing existing 3D printer designs, a

bespoke printer was developed with a rotating auger assembly for controlled extrusion and parallel copper electrodes for AC heating during printing. The resulting printer successfully demonstrates the feasibility of electrically heated geopolymer wall construction. This research investigates ohmic heating's role in expediting the curing process of Class F fly ash-based geopolymer cementitious (GPC) materials and outlines the prototype development of the 3D printer. This advancement presents eco-friendly alternatives in construction, potentially replacing traditional methods of using cement concrete.

Coal-fired power plants are vital for global electricity production, contributing about 20% in the United States and over 36% worldwide [1]. However, coal combustion produces hazardous by-products like fly ash, with the United States alone generating 40.8 million tons and global production of 500 million tons annually [2, 3]. While fly ash is useful in various industries, its main application is in Portland cement concrete, enhancing properties such as hydration and workability. Unfortunately, more than half of the produced fly ash ends up in landfills, posing environmental risks due to potential contamination of soil and groundwater by heavy metals and toxins [4]. There are two main types of fly ash, Class C and Class F, each with distinct properties. While both classes of fly ash are useful for concrete production, the higher calcium content in class C fly ash allows it to be used in higher concentrations than class F fly ash [5]. Geopolymer, a relatively recent development, shows promise as an alternative to traditional concrete, especially in smaller-scale projects. However, further research is needed to make it a viable alternative to conventional cement concrete.

Several studies have been conducted to evaluate the mechanical properties and feasibility of rapid-curing geopolymer concrete (RCGPC) compared to traditional OPC and oven-cured geopolymer concrete (OCGPC) [6, 7]. Additionally, the application of electrically conductive concrete (ECON) in heated-pavement systems (HPS) [8] shows promise in melting ice and snow, although widespread implementation remains a challenge. Ionic conductive mortar presents another innovative application for indoor heating systems, demonstrating stable electrical conductivity and resistance to repetitive heating cycles. Ionic conductive mortar has potential applications in indoor radiant heating floor tiles and partition walls [9]. Experimental findings indicate that the resistivity of this mortar increases with time but stabilizes after 28 days. When subjected to electric voltage, the mortar exhibits temperature increases, with significant drops in resistivity observed under both AC and DC voltages. Repetitive electric-heating cycles do not affect the mortar's hydration products or internal structures, maintaining stable electrical conductivity over time [10]. An increase in reactive recyclable material content beyond 20% led to decreased strength and workability of the material. Longer curing times, between 7 and 28 days, improved compressive strength but reduced flexural strength. Test samples showed varying strengths between layers, indicating a compromise between strength values and recyclable material content in geopolymer development [11].

The development of 3D printing technologies offers new avenues for both geopolymer and conventional concrete applications. Geopolymer's rapid curing property and high compressive strength make it particularly suitable for structural

3D printing applications. This technology allows for the creation of structural members or unique geometries on construction sites without the need for special ordering of materials or longer curing times associated with Ordinary Portland Cement (OPC) construction.

The primary focus of this study is to analyze the printing parameter prerequisites for sustainable 3D printable geopolymer materials. This involves developing a prototype through the creation of engineering drawings, fabrication, and procurement of lab-scale components for the printer, followed by their assembly. Eventually, the study aims to utilize fly ash to produce rapid-curing geopolymer, offering a low-carbon alternative to ordinary Portland cement. Unlike traditional concrete, geopolymers can be rapidly cured with added heat, setting within minutes instead of hours or days. A properly formulated geopolymer mix achieves full strength within 24 hours, making fly ash a potential replacement for concrete rather than just an additive.

2 Design Consideration for a 3D Printer for Geopolymer Specifications

In the realm of 3D printing, meticulous attention to detail in both material selection and system design is paramount to the functionality and longevity of the printing apparatus. This section delves into the critical considerations surrounding the materials chosen for the printer's components, the microcontroller and control system governing its operations, the motion control methodology employed, and the current implementation of axes in the printer's design.

Materials Selection Components of the 3D printer that come into direct contact with geopolymers must exhibit high chemical resistance and inertness to withstand exposure to concentrated base solutions. This requirement ensures that the printer components remain unaffected by the corrosive nature of the geopolymer material over time, thus maintaining the printer's structural integrity and longevity.

Microcontroller and Control System The Prototype 3D Printer utilizes a programmable microcontroller to govern its operations. Specifically, an off-the-shelf Arduino Mega serves as the central processing unit, complemented by a CNC shield. This setup enables precise control over stepper motors, essential for guiding the printer's movements during the printing process. The system also runs the Marlin Firmware, facilitating user interaction through an LCD screen, and providing real-time monitoring and control capabilities.

Motion Control via G-Code Movement along the X and Z axes of the 3D printer is programmed using G-code instructions. Generated as an output of slicer software, such as Cura, G-code allows for seamless integration with a wide range of Computer-Aided Design (CAD) software and slicer applications. This compatibility

ensures flexibility in choosing design software and simplifies the workflow for users, enhancing accessibility and usability.

Dual-Axis Implementation The current design of the 3D printer incorporates motion control along only two axes, namely the X and Z directions. While this configuration simplifies the system's complexity and reduces manufacturing costs, it limits the printer's capabilities to printing objects with predominantly planar geometries. However, future iterations of the printer may explore the incorporation of additional axes to enable more complex 3D printing capabilities, further expanding its application potential.

3 Present Design Constraints

Achieving high-quality printed samples in geopolymer materials 3D printing demands meticulous adherence to layer precisely. This section examines essential considerations such as temperature limits, shaft alignment, layer dimensions, and printer frame specifications, all crucial for achieving optimal printing outcomes.

Temperature Limitation It's crucial to ensure that the temperature of printed geopolymer samples does not exceed 80 °C. This limitation is based on current research findings, which have provided performance data up to this temperature threshold. Exceeding this temperature limit could lead to undesirable consequences such as material degradation, warping, or loss of structural integrity. Therefore, maintaining strict temperature control during the printing process is essential to ensure the quality and functionality of the printed samples.

Shaft Alignment The X-gantry shafts, which play a critical role in guiding the movement of the printer's print head along the X-axis, must not exceed 2° of misalignment or deflection. Misalignment beyond this threshold can result in inaccuracies in the printed objects, leading to dimensional errors or inconsistencies. Precise alignment of the gantry shafts is essential for achieving precise and reliable printing results, particularly when printing intricate or detailed designs.

Layer Dimensions Each layer of printed geopolymer must adhere to specific dimensional requirements, with dimensions of 12 inches in length, 1 inch in width, and ½ inch in thickness. Consistency in layer dimensions is essential for ensuring uniformity and structural integrity in the printed objects. Deviations from these prescribed dimensions could compromise the overall quality and functionality of the printed samples, making adherence to these specifications critical for successful printing outcomes.

Printer Frame Specifications The 3D printer frame must be designed to accommodate a build area of 1 meter by 1 meter with a height of 1 meter. A spacious build area provides ample room for printing larger-scale objects and enables versatility in printing various-sized samples. Additionally, a sturdy frame construction is

necessary to support the weight of the printing components and maintain stability during the printing process. The specified frame dimensions ensure compatibility with the desired printing requirements and facilitate the production of larger and more complex printed objects.

Overall, precise adherence to these specified requirements is essential for achieving optimal printing outcomes and ensuring the quality, accuracy, and functionality of the printed geopolymer samples. Each requirement addresses specific aspects of the printing process, ranging from temperature control and mechanical precision to dimensional accuracy and structural support, all of which are crucial for successful 3D printing with geopolymer materials.

4 Design Steps and Final Design

A total of four prototypes were developed during this investigative study. The main components in the prototype 3D printer (Fig. 1) include—Base plate, X and Z direction frame, Steppers motors, ACME lead screw, Belt Drive, Hopper to store and feed geopolymer, Extruder, Nozzle, and Electrical curing system. It was found that the viscosity of the geopolymer mix played a significant role, requiring the redesign of the auger inside the hopper. The principal component that required continuous improvement was the auger and based on different redesigned models of augers (see Fig. 2), four different versions of the prototype printer (MK1, MK2, MK3, and MK4) were made.

The first auger design, MK1, produced too much friction between the extruder body and auger blades, preventing the consistent flow of geopolymer out of the nozzle. The MK2 design attempted to reduce the amount of friction by reducing the number of helical revolutions of the auger blades. This increased space allowed

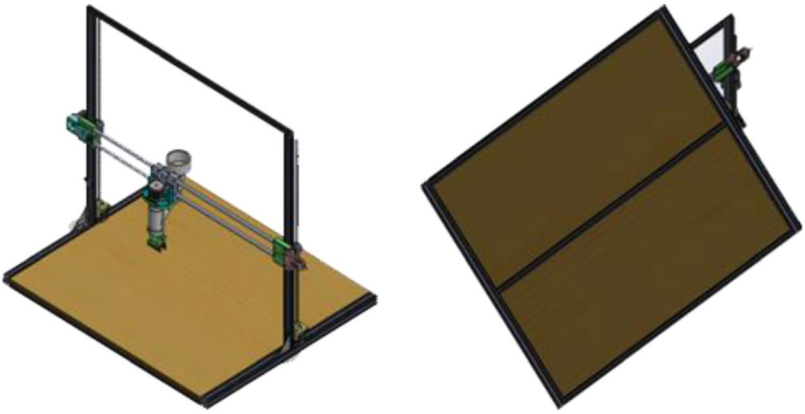

Fig. 1 CAD rendering of prototype form isometric view (left) and bottom view (right)

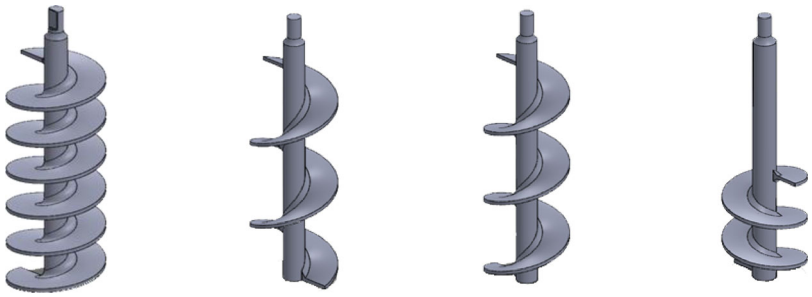

Fig. 2 Auger designs—from left to right—MK1, MK2, MK3, and MK4

Table 1 Different design parameters for Augers

Design	Shaft diameter (in.) mm	Helix length (in.) mm	Helix RPM	Diametral clearance (in.) mm
MK 1	(3/8) 9.53	(6) 152.4	6.0	(0.01) 0.254
MK 2	(3/8) 9.53	(6) 152.4	2.5	(0.01) 0.254
MK 3	(3/8) 9.53	(6) 152.4	3.0	(0.01) 0.254
MK 4	(7/16)11.11	(3) 76.2	2.5	(0.05) 1.27

the geopolymer to leak out of the nozzle. The MK3 design aimed to improve MK2 by increasing the number of revolutions from 2.5 to 3. This helped reduce the leaking but did not eliminate the issue, and ultimately, the amount of geopolymer leaving the nozzle was uncontrollable. Finally, the MK4 design addressed the issues the three previous designs faced, reducing the helical blade length from 6″ to 3″, while using only 2.5 helical revolutions of the blade. In this design, the diametral clearance was also increased from 0.01″ to 0.05″. These changes reduced friction while restricting the flow of geopolymer, allowing for controlled extrusion. The MK4 design was implemented in the final version of the 3D printer. Table 1 shows the dimensions of four different augers tried during the development of this prototype.

The final design of the 3D printer represents an improvement over previous iterations in several key areas. Firstly, the design has been streamlined by simplifying both the auger mechanism within the hopper and the nozzle, enhancing ease of assembly and operation. Additionally, ¼″ ACME lead screws have been replaced with M10 metric lead screws, contributing to smoother and more precise movement during printing. To bolster structural integrity, off-the-shelf corner brackets have been incorporated for the Z-rail brace, ensuring robust support. Furthermore, the addition of three 20 × 20mm extruded aluminum rails at the base of the printer enhances stability and rigidity. Finally, two sheets of 10 mm plywood have been introduced to serve as the build surface, providing a reliable foundation for printing operations. These refinements collectively enhance the functionality and performance of the 3D printer, paving the way for more efficient and reliable printing outcomes. Figures 3, 4, and 5 show some SolidWorks renderings of the final design.

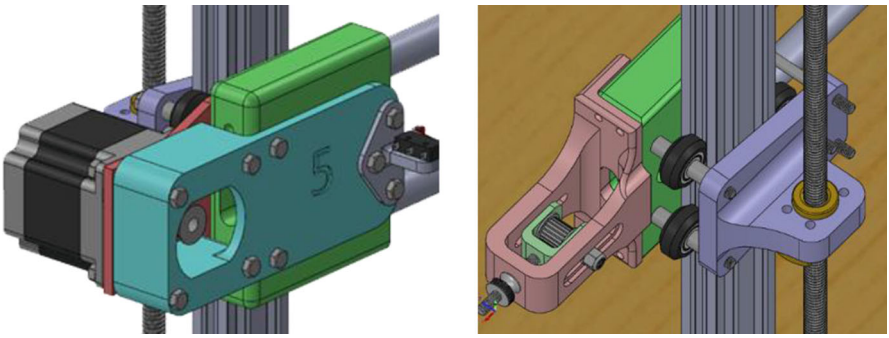

Fig. 3 X-axis motor mount (left) and isometric view of the x-axis belt tensioner

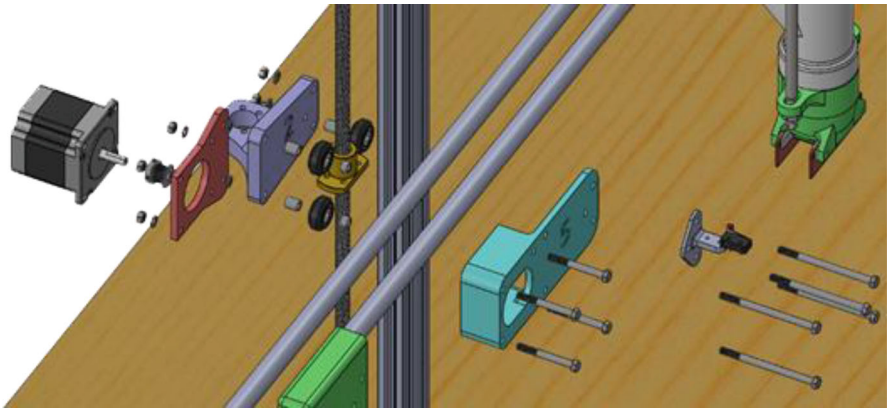

Fig. 4 X-axis motor mount exploded view

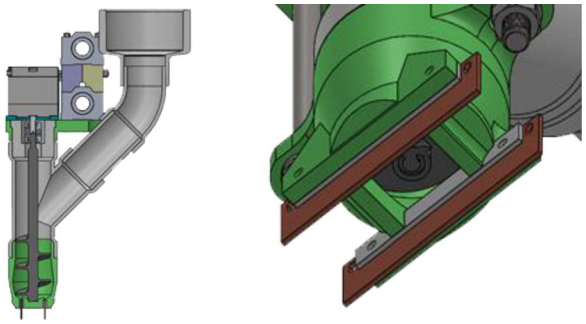

Fig. 5 Extruder section view (left) and designed nozzle outlet (right)

The 3D printer developed for this work deviates significantly from conventional 3D printers, primarily due to the utilization of geopolymer as a printing material. However, inspiration was drawn from established fused deposition modeling (FDM) printers to leverage existing technology and avoid unnecessary duplication of effort.

Unlike commercial 3D printers that employ a hot end to extrude melted thermoplastics through a nozzle, the printer constructed for this project employs a stepper motor-driven auger to propel uncured geopolymer through the nozzle. Upon extrusion, the geopolymer encounters a pair of current-conducting electrodes, triggering rapid setting and curing. Given the unique nature of this extrusion and curing process, each design incorporates a similar extruder setup. Moreover, all considered designs incorporate a hopper, serving as a reservoir to channel geopolymer into the extruder body, where the auger facilitates extrusion through the nozzle. For the construction of a proof-of-concept prototype, off-the-shelf PVC piping and connectors are utilized to fabricate the hopper and extruder body. PVC was selected for its chemical resistance to the sodium hydroxide present in the geopolymer, ensuring the durability and longevity of the components.

5 Results

The comprehensive evaluation of the final design encompassed scrutinizing its motion control capabilities, extrusion and curing functionalities, and print accuracy, all pivotal aspects for successful geopolymer printing. Ensuring the accuracy and reliability of the motion control system is paramount for proper geopolymer printing and the motion control system exhibited reliability and simplicity in calibration, with motors delivering more than sufficient power for the task at hand. The decision to implement metric M10 lead screws was validated by both the printer's performance and subsequent engineering analysis, owing to their low raising torque and minimal rotational backlash, ensuring precise motion and minimizing overworking of the stepper motors. Engineering analysis confirmed the adequacy of the two 16 mm linear motion shafts in preventing deflections exceeding 2°, with no detectable deflection observed upon assembly. Prior to print testing, a thorough analysis of the system's motion in the X and Z directions revealed no issues. Figure 6 below shows the fully assembled extruder and a printed first layer. However, despite these successes, challenges persisted in the extrusion and curing capabilities. Extensive testing of samples informed by static curing analysis revealed optimal feed rates for print moves, with favorable results observed in the printing of initial wall layers. Yet, consistent challenges such as nozzle clogging (Figs. 7 and 8) and runaway heating during subsequent layers were encountered, resulting in print discontinuations. Notably, defects such as wave-like patterns in double-layered prints were observed (see Fig. 9), indicating the need for further improvements to ensure consistent print quality and reliability in future iterations.

6 Discussion

The exploration of the rapid curing process in geopolymer reveals its vast potential for diverse applications, particularly as a 3D-printed cementitious material. However, achieving high-quality 3D-printed geopolymer presents several challenges that demand attention. Variations in the prime mover's operation often led to inconsistent extrusion, resulting in either under or over extrusion of the geopolymer. Under extrusion causes premature stutter moves, hindering proper curing, while over extrusion leads to the excessive deposition of geopolymer, surpassing the boundaries of the nozzle and impeding effective curing. Moreover, nozzle clogging occurs due to heat generated by the copper plates, leading to premature curing within the nozzle.

Fig. 8 Failed prints due to clogged nozzle

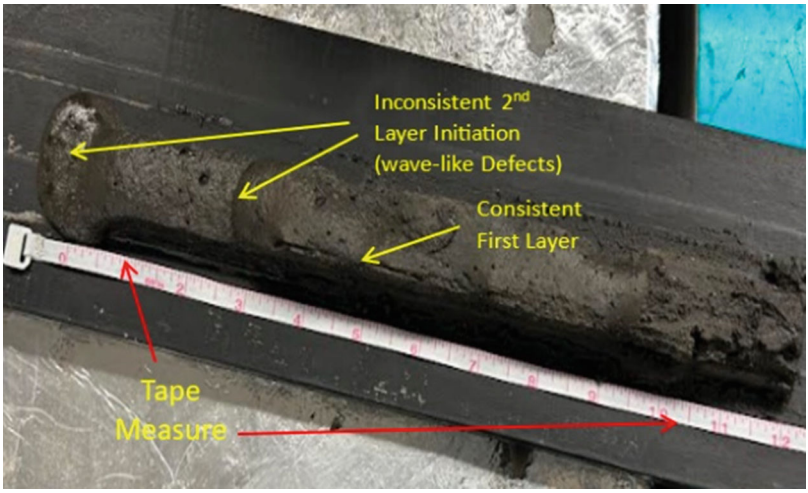

Fig. 9 Example of a two-layer wall with defects

Furthermore, the viscosity of geopolymer exhibits dynamic changes over time, initially presenting a high viscosity akin to the dough, which gradually decreases with continuous mixing, allowing for easier flow. However, prolonged mixing causes an increase in viscosity, posing challenges during 3D printing. These fluidic properties render geopolymer challenging to handle as a 3D printing material. Consequently, substantial research into material properties is warranted. Enhanced mixing procedures aimed at achieving consistency, coupled with further advancements in auger and nozzle designs, hold promise for enabling this machine to produce high-quality 3D-printed geopolymer in the future.

7 Conclusion

The exploration of the rapid curing process of geopolymer unveils its multifaceted potential applications, including its promising role as a 3D printing material, as evidenced by the outcomes of this project. A significant stride in this endeavor was the implementation of static rapid curing tests, which not only enhanced the research team's understanding of the geopolymer mixing and curing processes but also paved the way for practical implementation. The invaluable data gleaned from these tests not only informed the preparation for full-scale printing experiments but also served as a cornerstone for refining and optimizing the printer's performance. The robustness of the printer's frame and components was underscored by their resilience during numerous repeated tests. Engineering analysis conducted on critical components such as lead screws and linear motion shafts yielded a robust motion system, ensuring precise and reliable operation. Leveraging open-source Marlin firmware and widely accessible microcontrollers like the Arduino Mega and RAMPS 1.4 CNC board streamlined the electronic control aspects of the project, offering flexibility for future adaptations and enhancements. As the project neared its conclusion, forward-thinking considerations were made regarding the next steps for 3D-printed geopolymers. Notably, attention was drawn to the sensitivity of the mix design to water content, which directly influenced the viscosity of the mixture. This observation underscores the importance of fine-tuning mix compositions to optimize print quality and performance, laying a solid foundation for future advancements in 3D-printed geopolymer technology.

1 Introduction

Life cycle assessment (LCA) is an objective procedure for assessing the energy and environmental loads related to a process or activity, carried out through the identification of energy and materials used and waste released into the environment. The assessment shall cover the entire life cycle of the process or activity, including

extraction and processing of raw materials, manufacture, transport, distribution, use, reuse, recycling, and final disposal [1].

In its Communication on Integrated Product Policy [2], the European Commission concluded that LCA provides the best framework for assessing the potential environmental impacts in the construction industry. Following the Level (s) guidelines [3] and the European Green Deal [4], all EU countries started embracing the adoption of LCA methods. In Denmark, for instance, LCA is mandatory since 2023 for all new constructions over 1000 m^2 [5]. To support designers, engineers, and policy-makers, LCA protocols and case studies were developed to outline how to perform environmental assessments on buildings and industrial products. Nevertheless, a relatively limited number of studies have investigated the application of LCA to novel technologies and materials that could represent a suitable ecological alternative to current practices in the construction industry. In these cases, LCA could be pivotal to target research and communicate results [6]. Data scarcity, lack of previous research and precedents, and difficulties in applying standard protocols and software are recognized as the main barriers in the application of LCA to digital fabrication (DF) processes and bio-based materials [7, 8]. A methodological development of LCA is necessary in order to use this instrument to evaluate and steer research and innovation projects.

This study aims to design and verify a LCA-oriented methodology for the environmental assessment of DF with bio-based materials, highlighting opportunities and limits. The methodology is framed on the ISO 14040-44 standard [9, 10] and is tested on two case studies within the ERC funded Eco-Metabolistic Architecture project, carried out at the Center for Information Technology in Architecture (CITA) at the Royal Danish Academy: Radicant and Rawlam [11–13] (Fig. 1).

The study investigates how LCA can have a significant impact on the decision-making processes within a research laboratory and why it should be integrated as an early-stage design step. Considering the growing popularity of DF with bio-based materials, the implementation of the here illustrated methodology could be used for

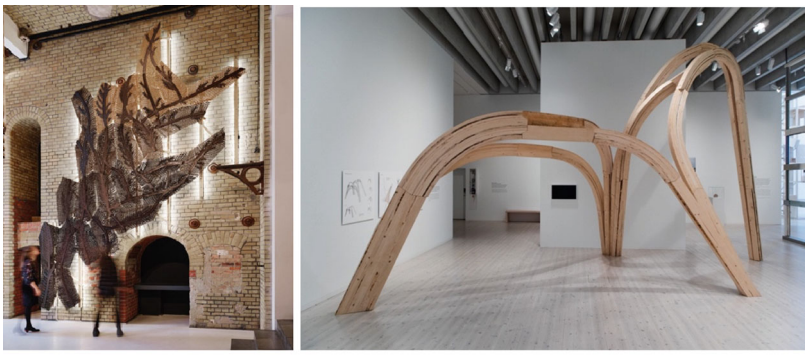

Fig. 1 (**a**) The Radicant project by CITA, Aedes Gallery, Berlin, 2022. (**b**) The Rawlam prototype by CITA, Bildmuseet, Umeå, 2021 [11–13]. (Courtesy of CITA)

the realization of environmental guidelines [18, 19] and the creation of digital databases, i.e. a "material library," with dedicated software applications, e.g., a digital platform [20] and plug-in for computational design tools [21].

2 Background

To analyze the current trends in literature (up to 2024) about LCA application to DF with bio-based materials, a scoping review is performed via Scopus web database. The query is prompted by the following combination of keywords, joined by the Boolean operators "AND" and "OR": "life cycle assessment" OR "LCA" OR "life-cycle assessment" AND "bio-based materials" OR "biomaterials" OR "bio-materials" AND "digital fabrication" OR "digital manufacturing" OR "advanced manufacturing" OR "additive manufacturing" OR "robotic fabrication" OR "robotic manufacturing". The query is limited to the fields of title, abstract and keywords.

The results show how this topic is still under-investigated, as "Product Sustainability Assessment" [22] is the only paper available. In this work, authors present an overview of the 3D printing technique and the materials used for the production, discussing how LCA application at every step of the production can help in achieving sustainable development along with the additive manufacturing techniques.

This lack of literature is examined by Kohtala and Hyysal [23], who state how reports on the sustainability of personal fabrication are emerging as the phenomenon spreads, often appearing as grey literature [24]. The few empirical studies that exist mainly focus on additive manufacturing, relevant to some digital fabrication equipment used in our research, such as studies on energy consumption and life cycle analyses [25, 26]. When compared to mass production processes, digital manufacturing has the potential to reduce material, waste, and energy, at least for small batches [27], and may mitigate negative impacts connected to supply chains [28]. However, toxicity of especially additive manufacturing materials remains a concern [29, 30], as well as the high energy consumption of digital fabrication.

3 Materials and Methods

3.1 Research Methodology and Assessment Method

The LCA methodology is organized into 4 steps, namely, flows, data, knowledge, and uncertainty.

In the "Flows" step, goal and scope of the assessment are defined and the life-cycle inventory (LCI) is performed. In this phase, the objective of the whole analysis is identified, the system boundaries are taken into account, and the functional unit of reference is expressed. In the LCI, all materials included in the analysis are listed and

tracked down to assess impacts, e.g. CO_2 emissions and energy consumption (modules A1–A3). For each material and each process unit, all the inputs (energy, water, and resources) and outputs (waste, pollution, and by-products) are examined and diagramed.

In the "Data" step, information about the materials and the processes is collected and calculated. Data are collected from different sources:

- The ÖKOBAUDAT generic database, a German-based platform included into the official LCA Danish software LCAbyg [14, 31].
- EPD Denmark [15].
- Other EPDs or studies in literature reporting LCA according to their technological or time representativeness, since they might be referred to different geographical contexts.

The calculations performed in this study are guided by specific impacts-related questions and are performed through a spreadsheet by converting the gathered data into the functional unit and adding impacts from transportation (depending on the different vehicle data from ÖKOBAUDAT) and energy use for manufacturing and construction (referring to the energy mix 2018). Modules A1–A3 (production stage) and A4–A5 (construction process stage) are considered. For transportation, the extraction and processing of the fuel are included. The production of the vehicle is not included in the balancing.

The "Knowledge" step corresponds to the life-cycle impact assessment—LCIA phase, in which the results are graphically explicated.

In the "uncertainty" step, a sensitivity analysis is performed to deal with possible inaccuracy of calculations, e.g. testing different materials or products [16, 17].

3.2 Limitations of the Study

To address the goal of the study, several limits in the application of standard LCA in our research have been identified, and workarounds—mainly based on assumptions—were established.

Only a few data are available about bio-based materials and biopolymers in terms of LCA, e.g. ingredients and machineries. Indeed, DF processes are not standard, as manufacturing technologies are often customized depending on use, materials, scale, etc. This means that data must always be adapted to the specific application. Most LCA software does not allow for custom-made database integration, or this operation is extremely labor intensive. Nonetheless, the use of spreadsheets more easily leads to miscalculations and errors.

3.3 *Radicant (Single-Product Assessment)*

Radicant is made of 24 custom 3D-printed panels based on a bone glue, water, glycerol recipe, with added fiber fillers (wood flour, wood bark, seagrass, and cotton bark). All panels have different amount of base mixture and fibers. Every panel consists of 2 layers: the "base" layer uses seagrass or wood flour as filler, in percentage around 15% per liter; the "leaf" layer uses cotton bark and wood bark as filler, in percentage around 9% per liter. The production process is divided into three phases:

1. 24 h cooking of a mix of bone glue, glycerol, and water
2. Base mixture mixing with filler fibers (20 min for 1 liter)
3. 3D printing with a custom-fixed extruder mounted on a universal cobot (Fig. 2)

Optional phases might involve the use of refrigerator to store the mixture and the bain-marie to keep parts at temperature before the mixing process.

The LCA focuses on the panels production, transportation to the site, and the whole assembly of the installation (A1–A5).

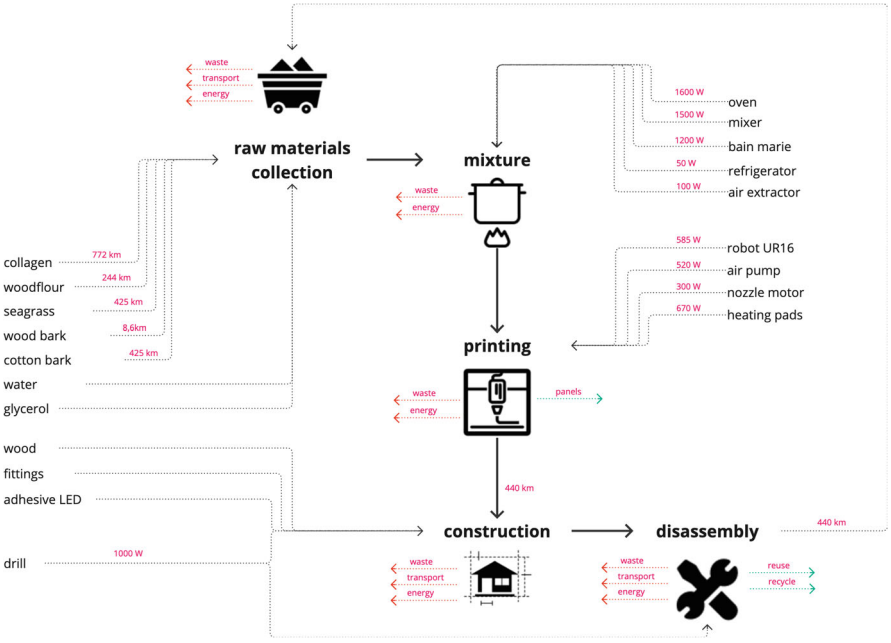

Fig. 2 Radicant material input and output flows map

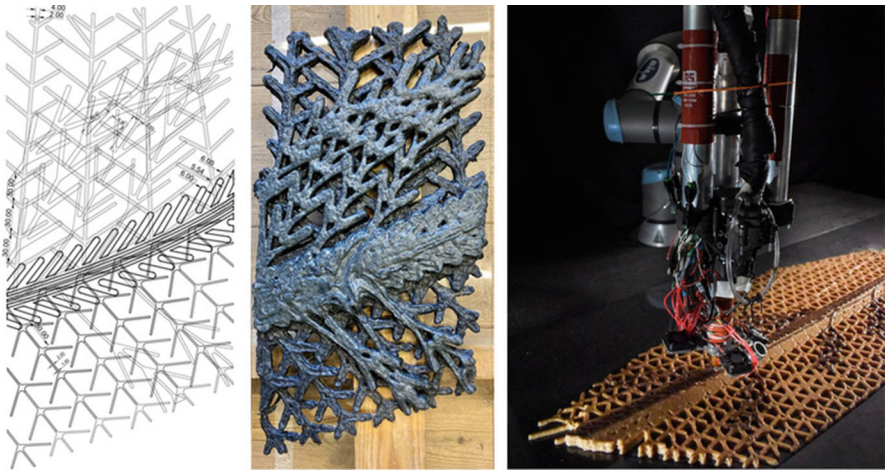

Fig. 3 Radicant panel digital fabrication process. Courtesy of CITA

Table 1 Ingredients and materials data related to their manufacturing phase (module A1)

Ingredient	Original functional unit	Source	Geographical context
Bone glue	1 kg	[20]	N/A
Wood bark	1 m^3	[32]	Serbia
Wood flour	1 lt	[33]	USA
Seagrass	1 kg	[15]	Denmark
Cotton bark	1 m^2	[15]	Denmark
Glycerol	1 kg	[34]	USA
Wood sticks	1 kg	[14]	Germany
Metal screws	1 kg	[14]	Germany
Adhesive LED stripes	20 million lumen h	[35]	USA

The LCIA is guided by specific impact-related questions, namely:

- Which of the materials from the recipe has the worst environmental score in terms of global warming potential (GWP)
- Which of the 24 panels of the Radicant exhibit has the worst environmental score in terms of GWP
- Which process phase has the worst environmental impact in terms of total use of non-renewable energy as primary resource (PENRT) (Fig. 3)

In A1–A3 LCA modules, all ingredients are mapped and restructured into their production phases (A1). Impacts are collected differently according to the data available for every ingredient. Water and construction materials data (timber sticks, metal fittings, and adhesive led stripes) are taken from the ÖKOBAUDAT database (Table 1). All values are converted to the functional unit of 1 kg. In A3, the manufacturing process is analyzed for each panel, specifically for every "base" and "leaf" layers.

3.4 Rawlam (Comparative Assessment)

The methodology is tested for the comparative analysis between Glulam data from the ÖKOBAUDAT database and the Rawlam prototype.

The Rawlam manufacturing process is divided into four phases:

1. CT scanning of spruce logs to detect wood knots, failures, etc.
2. Logs cutting into lamellas, plaining and thicknessing
3. Glulam pressing and replaining
4. Boards assembly

The LCA focuses on the timber beams manufacturing, transportation to the site, and the whole assembly of the installation (A1–A5). Since the aim of Rawlam is to optimize timber use in structural components manufacturing processes, LCIA was guided by specific impact-related questions, namely, the total amount of nonhazardous waste disposed (HWD), components for reuse (CRU), and materials for recycling (MFR) among phases A2–A3; the total amount of CRU in kg in phase A3 between Glulam and Rawlam; and the total amount of MFR in kg in phase A3 between Glulam and Rawlam.

The functional unit for the comparison is 1 kg. According to the assessment's purposes, A1 phase is considered not relevant for the analysis, as wood source for Glulam and Rawlam might be the same.

4 Results and Discussion

4.1 Radicant

The analysis of materials impact in Radicant helps to spot possible points to improve for environmental impacts reduction. In terms of GWP, animal glue and cotton stand as potential targets for enhancing the sustainability of the recipe.

The comparison between panels in terms of GWP highlights no significant differences in recipes impacts. Nonetheless, panels with wood fibers in both "base" and "leaf" layer as filler fibers demonstrate to have a better environmental score. A1 phase is the most impacting in terms of PENRT. Both transportation phases A2 and A4 have no significant weight on the overall evaluation. Most of energy consumption is thus embodied in material manufacturing, while the exhibition itself has low impact scores (Fig. 4).

To possible guide future printing projects, GWP data for 1 kg are converted to 1 meter of filament. Taking Panel 0 recipe as an example, the "base" layer (8 lt of materials) corresponds to 1.15E-02 kg CO_2 eq. per m. The "leaf" layer (3 lt of materials) corresponds to 2.54E-02 kg CO_2 eq. per m.

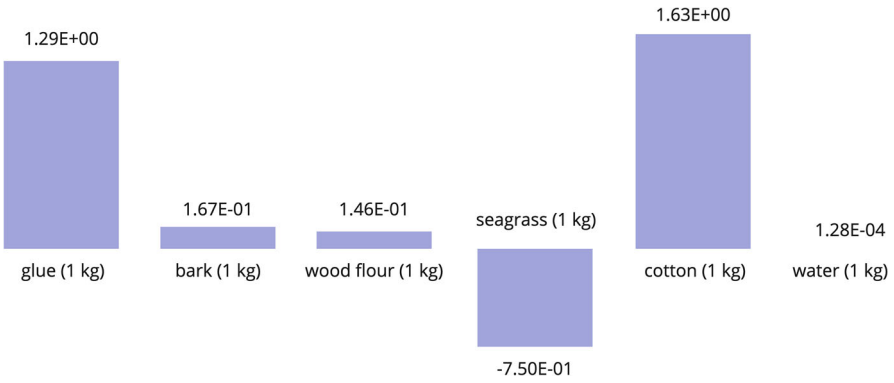

Fig. 4 GWP (Kg CO_2 eq.) analysis of Radicant panels ingredients considering A1–A3 LCA modules

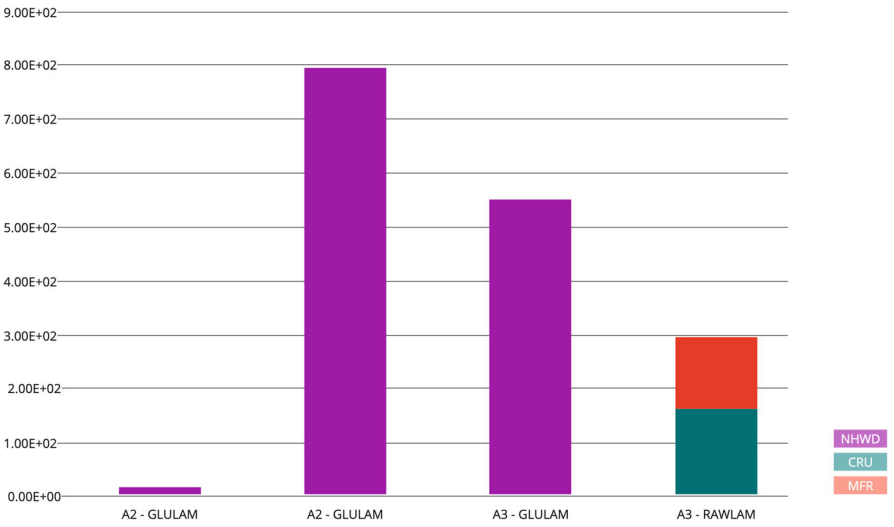

Fig. 5 Rawlam vs Glulam: LCA analysis for A2–A3 modules in terms of NHWD, CRU, and MFR (all expressed in kg)

4.2 Rawlam

Results from comparing A2–A3 phases between Glulam and Rawlam highlight significant differences in terms of NHWD from transportation in the latter, where logs are imported from Trieste (Italy). This suggests that is best to source wood locally when possible. In A3, Glulam produces more than 5.00E+02 kg of NHWD, while in Rawlam this is hugely reduced in favor of CRU and MFR. In particular, the Glulam EPD from ÖKOBAUDAT does not report any CRU or MFR amounts (Fig. 5).

4.3 Sensitivity Analysis

To deal with the data uncertainty and provide for reliable results, for both Radicant and Rawlam assessment, a sentitivity analysis is performed. This allows to understand the impact variation due to possible errors or ambiguity across individual components of the structures (i.e. panels for Radicant, boards for RawLam).

In the first case, the analysis focuses first on the GWP scores of the various panels, as shown in Fig. 6. While panels 1 and 16 display higher emissions due to their larger size (twice the dimensions of the other panels), panel 21 displays lower emissions due to the higher proportion of wood flour in the recipe (12.7%).

Other panels display similar GWP scores (2.56E+01 min, 2.77E+01 max., considering same-size panels). The 24 panels use 20 different recipes, and the study of their GWP scores therefore also provide data for a sensitivity analysis of the recipe's materials quantities. Figure 7 displays the highest and lowest percentages of material

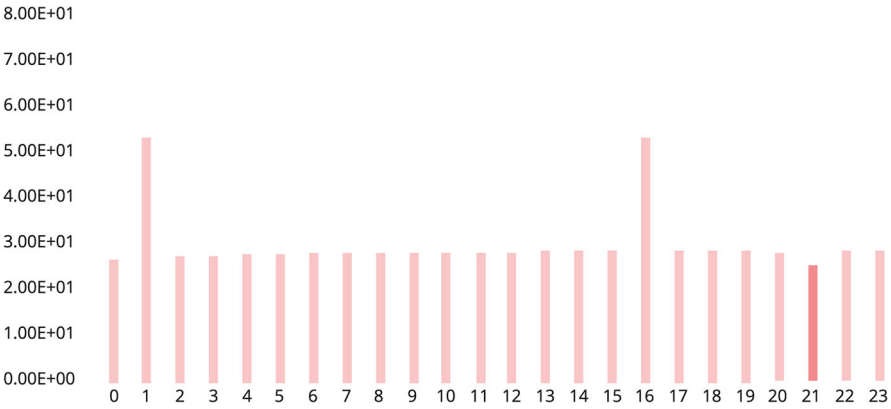

Fig. 6 GWP variation across panels

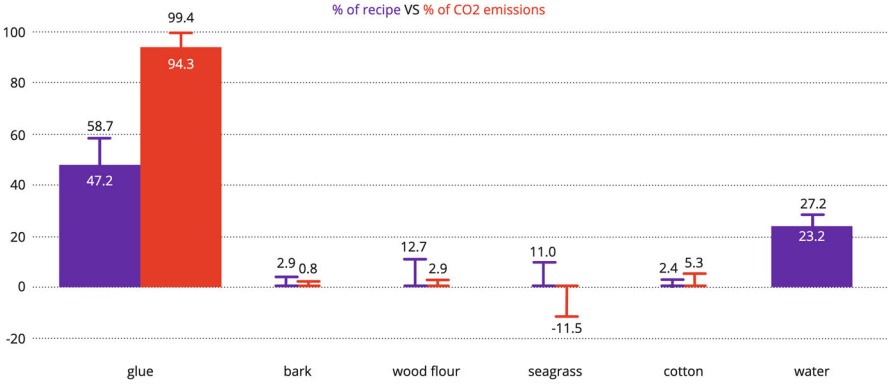

Fig. 7 Recipe variation sensitivity analysis. % of recipe (blue) vs % of CO_2 emissions (red)

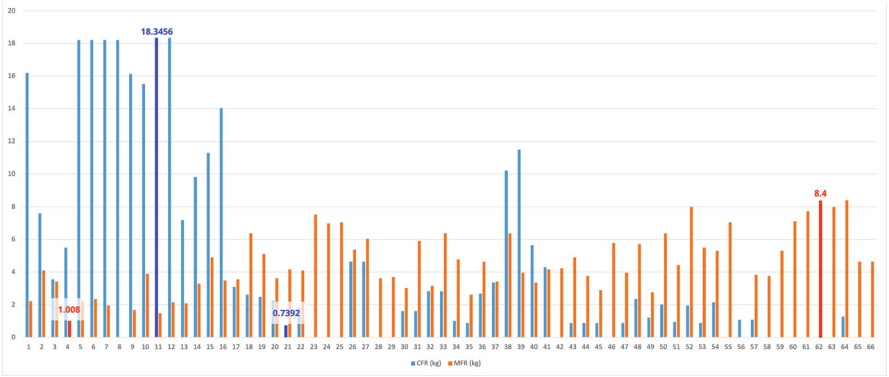

Fig. 8 Impact variation across Rawlam boards

quantities and of CO_2 emissions across all panels and recipes. It highlights which material has the largest influence over GWP variations when modifying the recipes. Bark and wood flour have the lowest impacts in comparison to material amounts, which informs further the low GWP score of panel 21. Cotton and glue display the highest impacts compared to material amount, and in particular the latter would be an ingredient to focus on in further material research.

In the second case, the sensitivity analysis focused on CRU and MFR scores of the different boards, as shown in Fig. 8. NHWD was not considered in the sensitivity analysis as the waste in this category originates in the fabrication process, not the boards themselves. This allows for a best- and worst-case scenario analysis, in which the amount of reusable/recyclable materials vary depending on the quality of the logs.

5 Conclusions

In this paper, the challenge of a LCA analysis of environmental sustainability of digital fabrication with bio-based materials in research stage is addressed by designing and testing a LCA-oriented methodology. This study is performed as an ex-post analysis on two different prototyped realized and exhibited by CITA, i.e. Radicant and Rawlam. In both cases, opportunities and limitations of the application of LCA to experimental practices for ecological alternatives in construction are exposed.

The limitations we encountered are mostly in terms of lack of data and uncertainty. To address these problems, we perform a sensitivity analysis, examining the range of errors and impact scenarios in both assessments, so to improve the reliability of results to inform a decision-making process.

Further developments of this study will focus on direct acquisition of data from manufactures. Also, a better connection between the spreadsheet and the design software (i.e. Rhinoceros/Grasshopper) might indeed help LCA to become a proper

decision support system. Eventually, a comparison between ex-post and during-development data might highlight significative changes in the results.

Finally, LCA allows for deeper reflections on sustainability of DF and questions the upscale and replication of experimental manufacturing research projects in different contexts. If applied at the very early stage of the process, LCA can serve as a design and research decision support system in the laboratory.

Acknowledgments The works described in this chapter are part of the Eco-metabolistic Architecture project that has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation program (grant agreement No 101019693). The collaboration between CITA and the Department of Architecture, Federico II was carried out since March 2023 within the ERASMUS PLUS KA1_"University for Innovation"—Project Ref. n. 2021-1-IT02-KA131-HED-000011202 mobility project promoted by the SEND Mobility Consortium, Italy. The activity was developed as part of the FoRWARD—Furniture Waste for circular design (MICS—NextGenEU, PE11, Spoke 4) research project, coordinated by Prof. Massimo Perriccioli and Prof. Marina Rigillo (Department of Architecture, University of Naples "Federico II"), and promoted by the Department of Architecture, the Department of Social Sciences and the Department of Law, University of Naples "Federico II" (IT), the Department of Engineering of the University of Palermo (IT) and the Department of Agricultural, Food, Environmental and Forestry Science and Technology of the University of Florence.

Authors Attributions All authors contributed to the study conception and design. Material preparation, data collection, and analysis are performed by Giuliano Galluccio. The first draft of the manuscript is written by Giuliano Galluccio, Martin Tamke, and Nadja Gaudillière-Jami, and all authors commented on previous versions of the manuscript. Sensitivity analysis is performed by Giuliano Galluccio, Nadja Gaudillière-Jami, and Paul Nicholas. All authors read and approved the final manuscript.

1 Introduction

Concrete is the most widely used construction material accounting for approximately half of all human production throughout history [1]. The production of one ton of cement emits around 600 kg of CO_2 [2]. With a global cement production estimate of 4.2 billion tons, this results in about 2.5 billion tons of CO_2 emissions [3]. This accounts for roughly 7.2% of the total global carbon emissions in 2021 [4]. Strategies to decrease carbon emissions in the cement and concrete industry include carbon capture and storage (CCS), reduced binders like ordinary Portland cement (OPC) clinker and optimizing material use through improved processes and structural design [5]. This also means changing architectural vision [6], avoiding concrete where its structural performance is not required and use alternative materials instead [7], and optimizing the communication among the entire production value chain [6, 8].

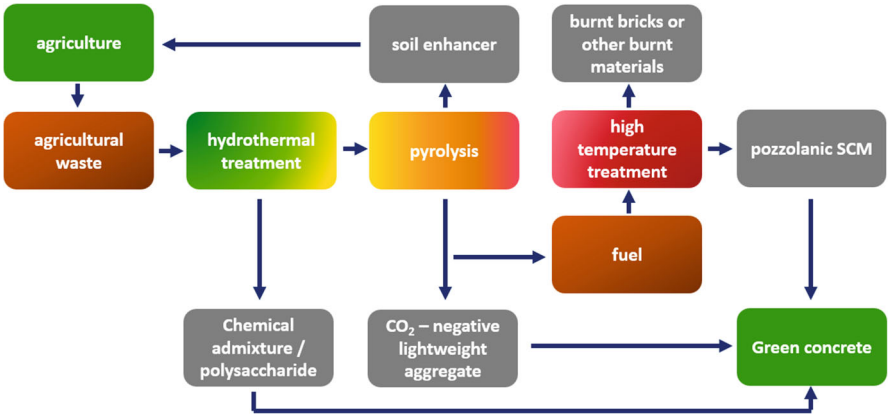

Fig. 1 Possibilities to convert agricultural waste to different materials useful to produce eco-friendly concrete. (Adopted from Schmidt et al. [16])

While CCS technologies are not yet market-ready [5, 6], policies for materials saving and circular technologies also require time to implement. The most promising technologies currently are carbon-reduced concrete types that incorporate supplementary cementitious materials (SCM) as clinker replacement. Since traditional SCMs like fly ash and ground granulated blast furnace slags become scarce and their sustainability questioned, new materials like limestone calcined clay compounds [9] and bio-based reactive SCMs [10–13] are being explored as alternatives. While the feasibility of bio-based cementitious materials depends on regional specifications, supply chains, and infrastructures, it seems to be more promising in the global South and particularly Africa and South America as they are also more suited to reducing the carbon footprint during concrete production rather than cement production [12, 14, 15]. By utilizing agricultural waste materials through processes like hydrothermal treatment, pyrolysis, and ash processing, low carbon or even carbon negative SCMs can be derived, while in parallel generating water reducing agents, energy, and chemical pre-cursors [11] (Fig. 1).

Biochar, which is the product of pyrolyzing process under limited oxygen supply, has shown promise in effectively capturing CO_2 from the atmosphere [17]. This, however, requires the use of bio-based waste materials and not fresh biomass. The carbon sequestration capability of biochar is particularly critical in the context of global efforts to combat climate change and reduce atmospheric CO_2 levels. Potential biomass for clean char production includes agricultural residues, wood waste, agri-food waste, manure, and municipal/industrial sludge. The generation of biomass waste, particularly from agriculture and forestry, is substantial, estimated at approximately 140 gigatonnes per year globally. This significant amount of biomass waste not only contributes to greenhouse gas emissions if left untreated but also represents a considerable environmental pollution challenge [18]. However, when converted into biochar, which is considered as relatively inert, this biomass waste can serve as a valuable resource for CO_2 sequestration.

Research has indicated that converting agricultural waste into biochar could have a notable impact on reducing CO_2 levels. The production of 373 million tons per year of biochar from agricultural waste could sequester around 500 million tons of CO_2 annually. This amount of sequestration equates to roughly 1.5% of the global annual CO_2 emissions, demonstrating the potential of biochar in contributing to global carbon mitigation efforts [19, 20]. The potential benefits of biochar extend beyond carbon sequestration. Utilizing different types of biomass waste for biochar production not only contributes to further reductions in carbon emissions but also supports the advancement of a circular economy. This is achieved through the development and application of biochar in new areas, such as the creation of innovative biochar-infused construction materials. These materials not only help in valorizing waste but also reduce the carbon footprint of the construction sector [21].

Additionally, integrating biochar into the construction industry could yield economic advantages, particularly through mechanisms like carbon trading, thereby encouraging the construction sector to lower its CO_2 emissions [22, 23]. According to the European Biochar Certificate, the conversion ratio of carbon to CO_2 (where 1 ton of biomass can capture up to 3.67 tons of CO_2) illustrates the potential effectiveness of biochar in carbon sequestration. During pyrolysis, the percentage of carbon retained in biochar can vary widely, from a few to approximately 80%, dependent on the biomass's chemical composition and the parameters of the pyrolysis process [24, 25]. This variability underlines the importance of optimizing pyrolysis conditions to maximize the carbon sequestration capability of biochar, further contributing to the broader efforts of decarbonization and environmental sustainability. This paper presents a comprehensive evaluation of the optimal method for incorporating significant amounts of biochar into concrete mixtures, and examines its impact on CO_2 sequestration, thereby contributing to the achievement of carbon neutrality in concrete production.

2 Ways of Incorporating Biochar into Concrete

2.1 Biochar as a Filler

Integrating biochar as a filler in cement (i.e., during cement manufacturing) can lead to the development of a composite cement variant that diminishes the dependency on traditional OPC. This approach will contribute to a reduction in carbon emissions associated with the production processes of cement. The rationale behind this is: biochar, a carbon-rich product derived from the thermal decomposition of organic materials in an oxygen-limited environment, necessitates significantly lower energy inputs for its production compared to the energy-intensive processes required for manufacturing conventional OPC. In this scenario, biochar would play a role as a filler like limestone. Yet, without real contribution to the mechanical properties, the presence of biochar due to the initially embodied carbon would benefit in overall improvement of concrete sustainability.

2.2 Biochar as Supplementary Cementitious Material (SCM)

The utilization of biochar as a SCM for cement in concrete represents a significant advancement in sustainable construction methods. Biochar, which is derived from the pyrolysis of biomass, not only offers an environmentally friendly alternative to traditional cement but also acts as an effective carbon sink. As scientists continue to refine the composition of biochar and its distribution within the concrete mixture, the engineering community is actively exploring the optimal balance between biochar and other components of concrete. Yet, depending on the biochar properties, the maximum cement replacement by biochar without compromising mechanical properties is 5–10 vol.%. Yet, in this scenario, biochar could not be recognized as SCM, since it does not positively contribute to hydration process.

2.3 Biochar as Concrete Aggregates

Incorporating biochar as a substitute for traditional aggregates like sand and stones in concrete mixes is a viable option. The porous structure of biochar aids in lowering the density of concrete, resulting in a lighter and potentially better insulating material. In the world of concrete, where aggregates (fine and coarse aggregates) make up most of the concrete (i.e., about 70–85% of the components), biochar's innovative integration as an aggregate substitute/replacement or lightweight aggregate is a game-changer for sustainable construction. Replacing a part of aggregates with biochar can result in lower density and improved thermal-insulating properties. The lower density and higher porosity are advantageous for lightweight concrete applications. By replacing all normal lightweight aggregates with biochar aggregates, a combination with high strength cement paste can create lightweight high-performance concretes.

It should be noted that the particle size of biochar can potentially impact the overall substitution potential of biochar in concrete. Since it affects surface area and porosity, changing workability and mechanical properties. Fine particles have a larger surface area and possibly can improve bonding with cement. However, they may increase water demand and be challenging to handle. Coarse particles can affect mix homogeneity and reduce certain properties. Optimizing biochar particle size is crucial for balancing carbon sequestration with structural performance and workability. The subsequent section demonstrates and discusses the impact of biochar particle size on CO_2 sequestration.

3 Biochar Particle Size and Its Effect on CO_2 Sequestration

Due to its porous and weak structure, biochar does not contribute to strength; however, it has been shown that small amounts of biochar can increase the strength properties slightly [26]. It was found that the presence of biochar can have a micro-filler effect [27]. Yet, the presence of biochar was observed to contribute to a refinement and better dispersion of the porous network of the cementitious matrix that leads to significantly reduced unwanted large diameter compaction pores [28–30].

A 15% substitution of cement with biochar can lead to a CO_2 reduction similar to Limestone Calcined Clay Cement [31]. However, achieving a true net-zero status requires incorporating larger amounts of biochar, which includes the replacement of portions of sand and aggregates. To improve biochar utilization without significantly affecting concrete performance, a detailed examination of the interactions among cement paste, liquid phase, and biochar particles is necessary. Recent research has highlighted a significant interaction between porous biochar particles and cement paste. The degree of biochar particle pore filling, whether partial or complete, is influenced by factors such as the presence of superplasticizers, age, and biochar type [26]. This interaction is crucial for understanding the impact on the structural behavior of concrete, as filled pore channels exhibit different properties compared to unfilled ones, with filling degree dependent on biochar particle size.

The filling of pore channels, coupled with potential changes in the interfacial transition zone (ITZ) and cement paste chemistry, has a notable impact on the structural behavior of concrete. Factors like pore diameter, influenced by biochar processing, and the rheology of the paste and aqueous phase determine whether biochar channels are filled with hydrates. The aqueous phase of cement paste, particularly in the presence of polymers, plays a key role in rheology [13, 26] and directly affects whether pores are filled with hydrates or left empty. Understanding these intricate relationships is essential for optimizing the incorporation of biochar into concrete systems.

Depending on the biochar particle size, it can be added to concrete as a cement replacement, as fine aggregate replacement and as a coarse aggregate replacement (Fig. 2). It is believed that depending on the size of the biochar particles, the pore filling effect varies. The cement paste can easily access small biochar particles due to their huge surface area. However, as the size of the biochar particles increases, the filling effect decreases. If biochar with particle sizes similar to coarse concrete aggregate is used, the biochar content in the cement-based material would significantly increase. In construction areas where high strength is not a requirement, biochar can compensate for reduced strength properties by providing additional values such as lightness, ion absorption, or enhanced physical properties.

To demonstrate the replacement effect according to the biochar particle size, the negative and positive climate effects of the mixture constituents are projected. The CO_2 impact is calculated according to embodied carbon (EC) criterions calculated in $kgCO_2/kg$ according to [32] (in Tables 1, 2, and 3). In an in-depth analysis

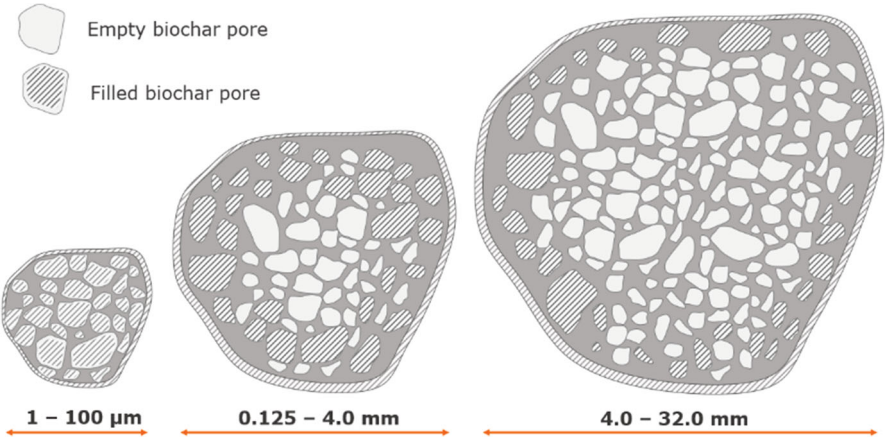

Fig. 2 Schematic representation of biochar particles of different sizes, and pore-filling effect depending on size; (**a**) biochar as cement replacement; (**b**) biochar as fine aggregate replacement; (**c**) biochar as coarse aggregate replacement

Table 1 Scenario A—embodied carbon of standard concrete mix design, no biochar is used

Component	GWP	Density	kg/m^3	l/m^3	kgCO_2/kg
Cement	0.83	3.1	350	113	290.5
Biochar	−2.5	1			0.0
Water	0.13	1	200	200	26.0
Aggregates	0.005	2.65	1821	687	9.1
				1000	325.6

Table 2 Scenario B—embodied carbon of standard concrete mix design with 10 vol.% replacement of cement by biochar with a specific gravity of 3.1 and 1.0, respectively

Component	GWP	Density	kg/m^3	l/m^3	kgCO_2/kg
Cement	0.83	3.1	315	102	261.5
Biochar	−2.5	1	11	11	−28.2
Water	0.13	1	200	200	26.0
Aggregates	0.005	2.65	1821	687	9.1
				1000	268.3

Table 3 Scenario C—embodied carbon of standard concrete mix design with 20 vol.% replacement of aggregates by biochar

Component	GWP	Density	kg/m^3	l/m^3	kgCO_2/kg
Cement	0.83	3.1	350	113	290.5
Biochar	−2.5	1	137	137	−343.5
Water	0.13	1	200	200	26.0
Aggregates	0.005	2.65	1457	550	7.3
				1000	−19.8

contrasting scenarios A and B, as delineated in Tables 1 and 2, an intriguing environmental benefit emerges when 10% of the cement volume is substituted with biochar. This substitution results in quantitatively 18% reduction in the carbon footprint, equating to 57.3 kg of CO_2 per kg of concrete. This finding underscores the potential for biochar as an eco-friendly alternative in concrete production, contributing to a substantial decrease in the concrete's overall carbon footprint. Despite the notable decrease in carbon emissions achieved through the initial substitution process, Scenario C, as detailed in Table 3 (i.e., substituting approx. 20% of the total aggregates with biochar), results in this scenario are particularly compelling, demonstrating that such a replacement strategy even make concrete not only carbon neutral but rather carbon negative. This denotes that the concrete's manufacturing process, from production to usage, has a net carbon emission of zero, effectively balancing the amount of carbon released with the amount offset or sequestered. Consequently, this advancement would be a significant step forward in the quest for sustainable building materials, offering a tangible solution to the construction industry's carbon emission challenges.

At a cement volume, replacement of approximately 60% real net-zero concrete is possible, but it comes at the price of reduced mechanical strength. Utilizing biochar as a replacement for aggregates rather than directly substituting cement could potentially allow for greater biochar content without significantly impacting concrete's binding properties. Nevertheless, an increased biochar amount necessitates a careful balance to maintain concrete's strength and durability. Optimal concrete performance hinges on a meticulous mix design, considering aggregate types and size distribution, water–cement ratio, and other additives. Compliance with industry standards and conducting proper testing are imperative to ensure the concrete fulfills the required structural and safety specifications. The selection of an appropriate method for incorporating biochar depends on the specifications of the specific application, desired properties, and the use of the final product.

4 Conclusions

In summary, biochar can be incorporated in concrete right at cement production (i.e., as additive) or to production of the concrete materials as replacement for binder or powder components, or aggregates. The comparative analysis of the scenarios offers insights into the role of biochar in reducing the carbon footprint of concrete. By systematically replacing a portion of the cement and aggregates with biochar, the research reveals a scalable approach to achieving more sustainable construction practices. The embodiment of higher amount of biochar in concrete allows to make cement-based materials carbon neutral. Utilizing biochar as a replacement for aggregates rather than directly substituting cement can make concrete not only carbon neutral but even carbon negative, depending upon the replacement rate. These findings highlight the potential for considerable environmental benefits and pave the way for future studies on the application of biochar in the construction

industry, emphasizing the need for innovative materials that contribute to the mitigation of global climate change.

1 Introduction

Ultra-high-performance concrete (UHPC) represents a groundbreaking advancement in modern construction materials, celebrated for its superior mechanical attributes, including exceptional compressive strength, durability, and resilience against environmental stressors. This innovative material has catalyzed a paradigm shift in construction practices, setting new standards for efficiency and performance. However, the quest for sustainable construction materials has illuminated the environmental footprint of UHPC, particularly its carbon emissions stemming from high Portland cement content—a critical issue given the construction industry's significant contribution to global carbon emissions. UHPC has gained significant attention in recent years as a promising alternative for conventional concrete to improve construction practices [1]. The push for sustainability within the construction sector

has led to significant interest in making UHPC more eco-friendly by optimizing its ingredient mix. Given the cement industry's substantial contribution to global carbon emissions—about 7%—there is a critical focus on reducing the carbon footprint of UHPC, traditionally high in Portland cement content (800–1000 kg/m^3) (Fig. 1). This high cement content, while contributing to UHPC's strength, also poses environmental and economic concerns due to the energy-intensive cement production and the resultant unhydrated cement in the low water-to-binder ratio mix [1–5]. These factors challenge the wider adoption of UHPC despite its superior performance. The solution lies in developing a new UHPC mix design with reduced environmental impact, starting with binder system optimization to lower cement use without sacrificing performance [6–9].

Portland limestone cement (PLC) has emerged as a viable, eco-friendlier alternative to ordinary Portland cement (OPC) for UHPC production, as it incorporates limestone during the clinker grinding process, aligning with ASTM C595 [10] and AASHTO M 240 [11] standards for up to 15% limestone content. This substitution not only significantly reduces CO_2 emissions but also maintains or enhances the concrete's performance. Additionally, the use of supplementary cementitious materials (SCMs) like silica fume and glass powder—industrial byproducts with pozzolanic properties—can further decrease cement use in UHPC by reacting with calcium hydroxide to form additional cementitious compounds, thereby improving strength, durability, and reducing permeability. In response to the high costs and environmental impact of proprietary UHPC mixes, this research proposes a nonproprietary mix utilizing PLC to cut CO_2 emissions and glass powder as a pozzolanic replacement for silica fume, aiming to develop an accessible, cost-effective, and environmentally sustainable UHPC mix.

2 Experimental Program

2.1 Materials

The materials used for UHPC binder system consist of OPC Type II, PLC, silica fume, fine aggregate, glass powder, high range water reducer, and water. Two types

of cement were used in this research: OPC meets the requirement for ASTM C150-18 [12], and PLC meets ASTM C595 [10] requirements as a Type IL cement. The main physical properties of OPC and PLC are presented in Table 1.

In this study, a dry densified silica fume possessing a purity of over 95% SiO_2 was utilized. This material, which complies with ASTM C 1240 and features a specific gravity of 2.2, was supplied by Master Builders Solutions. In addition, the research also made use of a glass powder derived from waste fiberglass, which has a median particle size of 6 μm and a specific gravity of 2.6.

Fine sand which was a combination of natural sand and crushed sand with specific gravity of 2.68 and maximum size of 2.38 mm was employed.

2.2 Mixture Proportion

After a series of experimental trials, the ratio of sand to binder materials—comprising cement and either silica fume or glass powder—was adjusted. This adjustment was crucial due to its significant impact on the strength development of UHP binders. A comparison between selected materials used in the sustainable and conventional mixtures is presented in Table 2. For all mixtures, the water-to-cement (w/c) ratio was consistently maintained at 0.22, and a high-range water-reducing agent (HRWRA) was incrementally added to achieve the desired fluidity, measured as a flow range from 200 mm to 250 mm.

2.3 Test Plan

Flowability

The flowability tests for the UHPC mortars were carried out in accordance with the ASTM C1437 standard [13], adhering to the criteria outlined in ASTM C1856

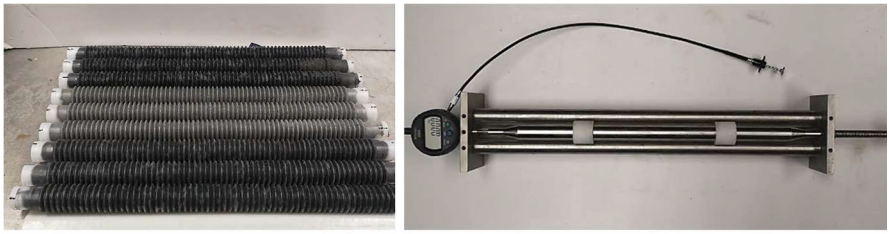
Table 1 Physical data for OPC and PLC

	Blaine fineness [cm^2/g]	Specific gravity	Initial setting time [min]	Final setting time [min]
OPC	4030	3.15	86	187
PLC	4426	3.08	95	155

Table 2 Selected materials in ordinary vs. sustainable UHPC mixtures

NP-UHPC with ordinary materials	NP-UHPC with sustainable materials
Ordinary Portland cement (OPC)	Portland limestone cement (PLC)
Silica fume	Waste glass powder
Natural sand (MSA: 2.36 mm)	Natural sand (MSA: 2.36 mm)
HRWR	HRWR
Water	Water

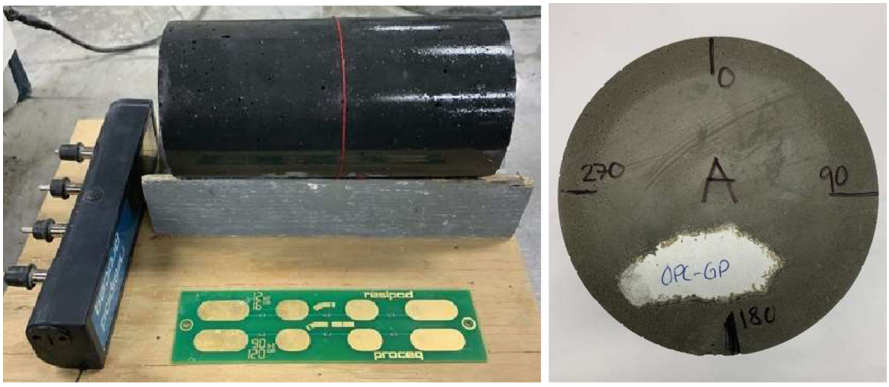
Fig. 2 (**a**) Slump flow cone with UHPC mixture and (**b**) average flow measurements



[14]. The cone container, which is shown in Fig. 2a, was filled once with the mortar mixture without tapping. After lifting the cone, the spread of the UHPC mortar was measured at two perpendicular points, D_1 and D_2, after a 2-minute interval, as illustrated in Fig. 2b. The average of these measurements determined the flow, which per standards should range between 200 and 250 mm for optimal flowability performance.

Compressive Strength

Compressive strength is a fundamental parameter in the mix design of UHPC, highlighting the material's ability to withstand loads without failure and indicating its load-bearing capabilities. This research adheres to ASTM C109 [15] standards for assessing the compressive strength of UHPC mortar specimens, utilizing $50 \times 50 \times 50$ mm^3 cubes and subjecting them to a loading rate of 300 lbs./s (1334 N/s). For fiber-reinforced samples, ASTM C1856 standards prevail, requiring cylindrical specimens of 3 by 6 inches (75 mm by 150 mm). Each mixture is represented by three samples to determine its average compressive strength, with tests conducted at four critical ages: 3, 7, 28, 90 days.



Shrinkage

Autogenous shrinkage in concrete, particularly evident in mixes with low water-to-cement ratios, is attributed to volume reduction during the hydration of cementitious materials. This process involves the formation of hydrates as water reacts with cement, leading to a demand for water and its consumption, which in turn causes shrinkage. To accurately measure autogenous shrinkage without the interference of water evaporation, the bulk strain of a sealed mortar specimen is assessed, ensuring that any water movement is solely due to hydration. This method, conducted in accordance with ASTM C1698 [16], utilizes molds made from corrugated plastic tubes, which are filled with mortar. These tubes, detailed in Fig. 3a, measure 420 ± 5 mm in length and have an outer diameter of 29 ± 0.5 mm. A dilatometer

(a) (b)

Fig. 3 (**a**) Corrugated molds filled with UHPC mixture and (**b**) test set-up for autogenous shrinkage

(a) (b)

Fig. 4 (**a**) Test setup for surface resistivity and (**b**) sample marking

is employed to measure the shrinkage, comparing the length of the mortar-filled tubes to a reference bar as shown in Fig. 3b. These measurements are taken daily over a period of at least 28 days to monitor the progression of autogenous shrinkage.

Surface Resistivity

In this study, electrical surface resistivity (measured in kΩ-cm) serves as a critical metric for assessing the durability, permeability, and potential for chloride penetration, directly influencing the corrosion risk of embedded reinforcement. Utilizing a 4-point Wenner probe, as depicted in Fig. 4a, the electrical resistivity of UHPC mixtures was evaluated. This procedure aligns with AASHTO T 358 [17] standards and involves testing three cylindrical specimens, each 100 mm in diameter and 200 mm in height, after a curing period of 28 days. For minimizing inaccuracies arising from electrical field disruptions caused by steel fiber integration, only the binder samples was utilized for this test. To ensure consistency, the surface of all specimens was moistened before measurements were taken. Each specimen underwent two resistivity measurements at four different angles—0°, 90°, 180°, and 270°—as shown in Fig. 4b. The average resistivity for each specimen was calculated, followed by an overall set average derived from the three samples,

providing a comprehensive assessment of the UHPC mixtures' electrical resistivity properties.

3 Results and Discussions

3.1 Flowability

The data presented in Table 3 demonstrate that all examined UHPC mixtures achieved a flow exceeding 200 mm, meeting the ASTM C1856 requirements. A consistent flow range from 230 mm to 250 mm was observed across all mixtures, indicating their self-consolidating properties. These results highlight the capability of the UHPC mixtures to be efficiently cast without the need for mechanical vibration. Further examination of Table 3 indicates that UHPC mixtures containing Type IL and a higher proportion of glass powder demonstrated superior flowability while requiring a reduced quantity of high-range water-reducing agent (HRWRA) compared to mixtures incorporating OPC and silica fume at same water-to-binder ratio. This suggests that the synergy between glass powder and Type IL PLC can significantly enhance the workability of UHPC formulations. Such an improvement points toward a potentially cost-effective strategy for optimizing UHPC mix designs.

3.2 Shrinkage

Table 4 details the autogenous shrinkage-induced deformation in different mixtures after a 28-day period, highlighting the variance in deformation across the mixtures. The OPC mixed with Silica Fume (SF) reported the highest deformation, underscoring significant autogenous shrinkage in mixtures containing silica fume. This is attributed to silica fume's high surface area and its substantial water demand during the hydration process compared to glass powder. Conversely, mixtures incorporating glass powder showcased markedly less deformation than those with silica fume alone, indicating the beneficial impact of glass powder in reducing shrinkage. When comparing OPC- and PLC-based mixtures, OPC mixtures were found to exhibit greater deformation, suggesting a higher susceptibility to long-term

Table 3 Results of flow table test

Mix ID	Flow (mm)	HRWR (%)
OPC-SF	231	4.0
OPC-SF-GP	238	3.9
OPC-GP	245	3.6
PLC-SF	241	3.5
PLC-SF-GP	248	3.3
PLC-GP	250	3.2

Table 4 Autogenous shrinkage results

Mix ID	Length deformation (10^{-6} m/m)
OPC-SF	−311.90
OPC-SF-GP	−271.44
OPC-GP	−223.59
PLC-SF	−213.18
PLC-SF-GP	−167.52
PLC-GP	−126.10

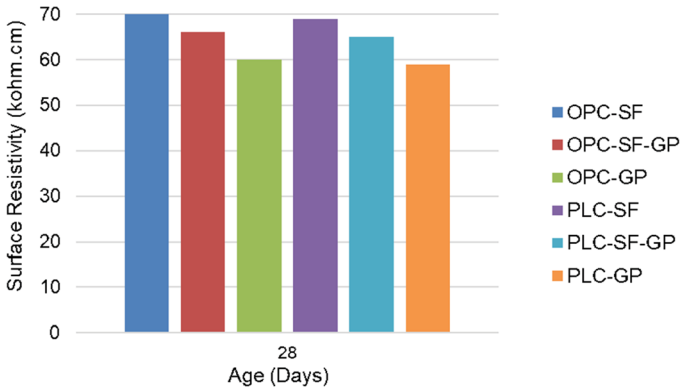


Fig. 5 Electrical resistivity results for tested UHPC binders

autogenous shrinkage. This could be due to OPC's higher clinker content, which increases water consumption for hydration. The inclusion of limestone in PLC mixtures appears to mitigate autogenous shrinkage, possibly by enhancing the pore structure within the concrete.

3.3 Surface Resistivity

The analysis of surface resistivity across all UHPC specimens revealed high electrical resistivity, attributable to the use of pozzolanic materials, a low water-to-cement ratio, and the minimization of voids through fine and well-graded material distribution within the matrix. Specifically, glass powder exhibited excellent performance in enhancing electrical resistivity, signaling its potential to significantly improve UHPC durability. Furthermore, the introduction of silica fume across all cement bases markedly improved resistivity (Fig. 5). This improvement is largely due to silica fume's reaction with calcium hydroxide, leading to the formation of additional calcium silicate hydrate, which effectively densifies the microstructure and impedes ion flow. Silica fume's ultrafine particles also play a critical role in disrupting the connectivity within the concrete's pore network, further enhancing resistivity. Overall, the results suggest that replacing OPC and silica fume with PLC and glass

powder does not compromise the concrete's electrical resistivity, thereby maintaining or potentially enhancing its durability.

4 Conclusions

The use of PLC and waste glass not only enhanced the workability of concrete but also reduced the reliance on superplasticizers. This adjustment in the concrete mix design led to optimized material utilization and environmental benefits by minimizing chemical additive usage. PLC-based concrete exhibited lower shrinkage rates, a desirable property for structural durability. Conversely, the addition of silica fume to both OPC and PLC mixes increased shrinkage, attributed to its greater water demand and expansive surface area. In terms of surface resistivity and durability, incorporating silica fume into concrete significantly enhanced surface resistivity in both OPC and PLC mixes after 28 days, signaling improved durability. Notably, all binder combinations surpass the acceptable range for surface resistivity, affirming no concerns regarding durability with the chosen materials. By adopting PLC and waste glass in UHPC formulations, material costs can be significantly reduced, potentially halving expenses while still achieving properties sufficient for a variety of structural applications. This approach not only economizes construction but also advances sustainability in the building and bridge industry.

1 Introduction

Ultra-high-performance concrete (UHPC) might be a competitive alternative to conventional concrete for some purposes. One important argument might be the potential for reducing the CO_2 footprint through a reduction in material consumption. This has been shown in previous life cycle assessments (LCA), e.g., [1–3]. A substantial reduction is possible for some structural elements, as the superior strength opens for reducing the material consumption. Durability also favors UHPC.

However, the CO_2 footprint is far higher for UHPC, compared to equal volumes of conventional concrete [4]. The main reason is the high amount of cement and high-strength steel fibers [4, 5]. Reducing the content of Portland clinker, which is the main binder in most modern cement types for structural use, will contribute to reducing the CO_2 footprint of UHPC. Many studies focus on experimental research on partial cement substitution with various by-products, waste, or natural ores that are locally available. This includes materials such as glass powder [6], quarry-stone

powders [7], red mud [8], and lead-zinc tailings [9]. There are two restrictions to the industrial relevance of these approaches, at least within a modest time frame. One is lacking compliance with existing standards for most of these materials. The time frame needed for revising standards based on limited research projects is vast. The second limitation is that industrial application normally requires a stable and rich supply of materials. This is often a problem when utilizing locally available by-products from other production. Despite the superb quality and the high relevance of this research, in the long run, industrial utilization of the topics that are researched is often distant. Other researchers have focused on substituting cement with more conventional replacement materials like limestone powder [10], fly ash, and GGBS [11–13]. This is closely related to our topic, as these materials are the dominant cement-substituting materials that are utilized in the pre-accepted blended cement. Only a few researchers have investigated the effect of using pre-accepted blended cement types [14, 15].

In the study presented in this paper, the potential for producing UHPC with alternative pre-accepted cement types is investigated. The contribution of this work is to strengthen the documentation on the use of pre-accepted cement types and to investigate how the use of these binders in UHPC is influenced by using locally available materials in Norway. This includes cement types CEM II and CEM III with 30 and 70% GGBS, respectively, while using the pure ordinary Portland cement (OPC) cement class CEM I as a reference. All classes are stated according to the CEN standard *EN 197-1*. A laboratory investigation was executed, measuring the strength performance of these alternatives. In addition, a measurement of fresh state consistency and a comparison of CO_2 footprint was conducted.

2 Materials and Methods

2.1 Material and Mix-Proportions

Three types of pre-accepted cement were applied: CEM I, CEM II, and CEM III in accordance with the European cement standard *EN 197-1*. The CEM I applied was an ordinary cement with 95% Portland cement clinker. The CEM II was a Portland-composite cement with 30% ground-granulated blast-furnace slag (GGBS), while the CEM III was a Blast furnace slag cement with 70% GGBS. The different types of cement were applied in the same UHPC mix, based on locally available constituents in Norway. Table 1 shows the different materials with specifications according to technical data sheets.

Table 2 shows the compressive strength properties and CO_2-eq of the different cement types. The data is found in the technical data sheets and Environmental Product Declaration (EPD) by the producer.

The UHPC mixes are shown in Table 3. The w/b-ratio and steel fiber content was kept constant for all mixes, 0.23 and 2 vol.%, respectively. The small differences in recipes are due to differences in density between the cement types.

Table 1 Materials

Materials	Specifications
Cement	CEM I 52.5 R *EN 197-1*. Density 3.15 g/cm^3
	CEM II/B-S 52.5 *EN 197-1*. Density 3.05 g/cm^3
	CEM III / B 42.5 L-LH/SR *EN 197-1*, density 2.94 g/cm^3
Microsilica	Undensified microsilica, SiO2 > 90%, bulk density of 200–350 kg/m^3
Filler	Limestone filler for concrete production, density: 2720 kg/m^3
Sand	Sand from local producer, size 0–6 mm, density: 2660 kg/m^3.
Superplasticizer	Specially composed for UHPC production, 40% active content, density: 1080 kg/m^3
Steel fibers	Cord steel wire, brass colored, length (l_f): 12.5 mm, diameter (d_f): 0.175 mm, tensile strength: min. 2800 N/mm^2

Table 2 Properties of cement according to data sheets

Superplasticizer	13	13	13
Steel fibers	157	157	157

2.2 Mixing and Casting

The UHPC mixes were produced in a small planetary mixer for mortars at standard laboratory conditions (*ASTM C305*). Three liters were mixed for each mix. The procedure of mixing was applied according to previous experience [16]:

1. Mixing the dry materials for 30 seconds at low speed (107 rpm)
2. Adding water and superplasticizer
3. Mixing for 30 seconds at low speed (107 rpm)
4. Pausing the mixer for 90 seconds

5. Mixing at medium speed (198 rpm) for 120 seconds
6. Mixing at high speed (361 rpm) for 15–30 seconds

After mixing, the consistency of the fresh mortar was measured by a flow table for cement mortar in accordance with *NS-EN 413-2*, without jolting. For each mix, six test prisms of 40 mm × 40 mm × 160 mm were cast and compacted using a jolting apparatus, according to *NS-EN 196-1*. The test specimens were covered with a plastic film to avoid drying and de-molded after approximately 24 hours.

2.3 Test Program

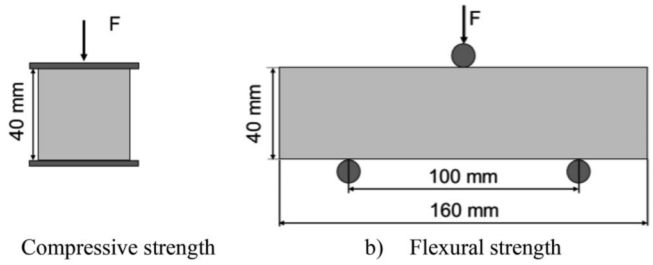
The prisms were tested according to the European standard *NS-EN 196-1* (Fig. 1). Both compressive strength and flexural strength were tested after 28 days of curing. First, the prisms were tested in bending and then both halves of each prism were tested in compression. The bending test only includes testing until cracking, not the post-cracking behavior. The effect of two different curing regimes was investigated:

- Heat curing: curing at elevated temperature for 72 hours (including gradual increase and decrease in temperature). The specimens were submerged in water in a heat chamber at 90 °C. After the heat curing, the specimens were stored in water tanks at 20 °C until testing.
- Normal curing: The specimens were cured submerged in water at 20 °C until testing.

Table 4 shows an overview of the conducted tests and curing regimes.

3 Results and Discussions

The influence of using cement with a lower content of Portland clinker was studied on the strength of test specimens. In addition, a comparison of CO_2 footprint was conducted. The results are shown in the following.



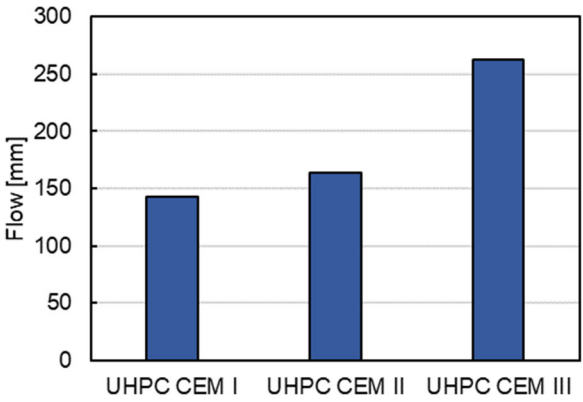


Fig. 1 Test setup of strength properties. (**a**) Compressive strength. (**b**) Flexural strength

Table 4 Test program

Mix	Test	Specimens tested	Curing	Test age
UHPC CEM I	Compressive strength	6	90 °C 72 h, 20 °C	28
	Flexural strength	3	90 °C 72 h, 20 °C	28
UHPC CEM II	Compressive strength	6	90 °C 72 h, 20 °C	28
	Flexural strength	3	90 °C 72 h, 20 °C	28
UHPC CEM III	Compressive strength	6	90 °C 72 h, 20 °C	28
	Flexural strength	3	90 °C 72 h, 20 °C	28

Fig. 2 Flow in mm

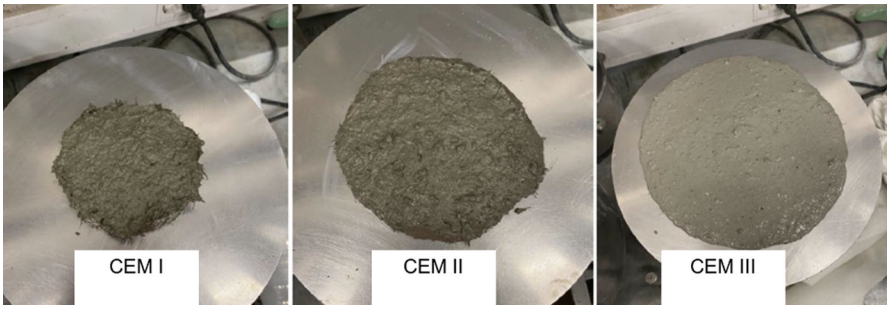

Fig. 3 Flow measurement of the three different UHPC mixes

3.1 Workability

The workability of the mix was measured through flow. The results are presented in Figs. 2 and 3. As can be seen, the water demand decreases with the addition of GGBS, giving higher flow values. Shi et al. (2019) [17] and Wu et al. (2017) [13] also experienced an increase in flow with an increase in GGBS content. This might allow for further reduction in w/b-ratio, which might reveal a potential for further improving the strength properties of UHPC with a high content of GGBS.

3.2 Strength Properties

Figure 4 shows the average 28-day compressive strength for the different mixes, using normal curing and heat curing. Error bars showing the standard deviation are included for all series, to visualize the span in results.

After curing at 20 °C for 28 days, the mixes with CEM I and CEM II obtained compressive strength higher than for the mix with CEM III. There is a slight difference between the two, with the CEM II mix showing the highest compressive strength. However, considering the variation in results for these series, demonstrated with error bars for standard deviation overlapping, it is not claimed that the difference in average values is significant. The compressive strength obtained for the mix with CEM III, which is 10% lower and outside the standard deviation of each, might be significant. The lower level of compressive strength achieved by the CEM III mix after 28 days of curing at 20 °C might be a delay caused by the hardening mechanisms of the GGBS binder being slower than that of the Portland cement clinkers.

Considering that the CEM III is classified 42.5 MPa according to *NS-EN 197* standard while both the CEM I and CEM II are classified 52.5 MPa, this might be a possible explanation for the difference in average compressive strength at 20 °C. However, considering the results after curing a period at elevated temperature seems to overrule this as an explanation for heat curing.

After curing at 90 °C for 72 hours before submerging in water at 20 °C for the remaining time up to 28 days, similar results are obtained for all three cement types. It has been claimed in earlier research that curing cement materials with a high content of pozzolanic binders at elevated temperatures has the potential to create high-capacity C-S-H components that would not be created at lower temperatures, independent of curing duration. Whether this is also relevant for latent hydraulic binders like GGBS, is not known to the authors. Regardless of this, the result of this experiment, is that when curing at 90 °C for 72 hours as the first part of the curing regime, any of the binders CEM I, CEM II, and CEM III applied yield corresponding

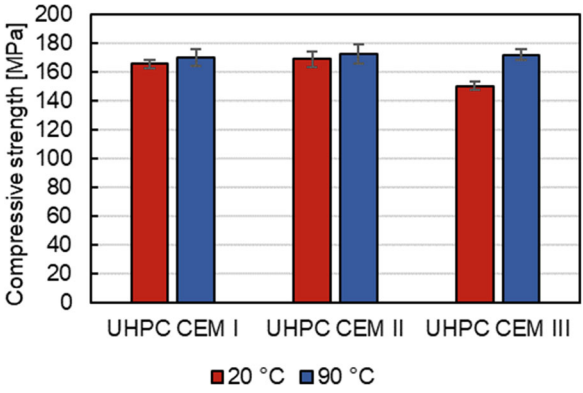

Fig. 4 Compressive strength after 28 days, with error bars showing the standard deviation

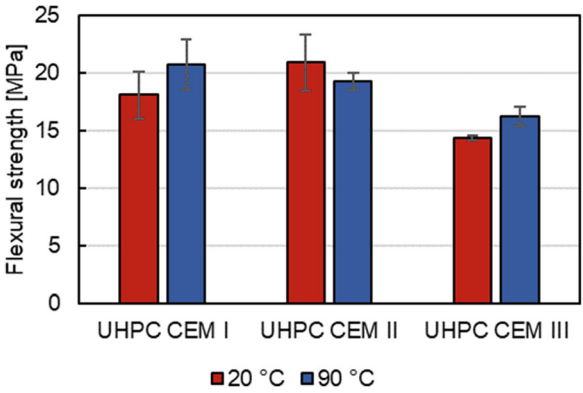

Fig. 5 Flexural strength after 28 days. Error bars show the standard deviation

compressive strength of the UHPC mixes as achieved when applying CEM I or CEM II and curing for 28 days given standard curing at 20 °C.

Figure 5 shows the 28-day flexural strength for the different mixes after normal curing and heat curing.

As for the compressive strength, the results for the mixes containing CEM I and CEM II are corresponding. The difference between these two seems to be substantial. However, noting that also the variability for these is higher than for the compressive strength and that the error bars are strongly overlapping, this difference might turn out not to be significant. Calculating significance based on only three results seems not to be meaningful and is consequently not executed. It is well known that the variability of tensile-related strength properties in fiber-reinforced concrete is high. Thus, these results are considered to be "normal."

Despite the variability, the results of the CEM III containing mix might seem to be lower than the CEM I and CEM II mixes. As shown in Fig. 2, the consistency of the mixes is strongly varying, with flow increasing correspondingly to the content of GGBS in the binder. The flow of the CEM III mix is so high that it was suspected that the fibers might have sunk to the bottom as a result of gravity during the jolting treatment, which was part of the casting procedure of all prisms. To reveal whether this had happened, the CEM III prisms where cut into halves, and the cross sections examined. It was confirmed that agglomerations of fibers appeared at the bottom of these prisms during casting. The corresponding was not observed for the prisms made from the CEM I and CEM II mixes, when exposed to the same examination.

To secure the plane and parallel surfaces in the testing machine during bending, all prisms were rotated 90 degrees compared to the casting orientation. Thus, an unproportional part of the fibers was situated at one-half the CEM III mix prisms during testing. This is anticipated as at least a part of the reason for the lower flexural strength of the prisms made from the CEM III mix. Whether this is the explanation for all of the differences, cannot be evaluated.

The presented results are only covering strength-based properties. However, durability properties are crucial for practical application. It is expected that the durability properties of UHPC made with CEM II and CEM III classes of cement

will be satisfactory, due to the pre-acceptance and experiences with CEM III in conventional concrete. However, for practical applications, this assumption needs to be confirmed as even the use of well-known cement types in "novel" materials such as UHPC while also utilizing local aggregates, might have some unexpected consequences. The durability properties will constitute the next step in our research following what is presented in this paper.

3.3 *Comparison of CO_2 Footprint*

A comparison of the CO_2 footprint is executed by using values from the EPDs supplied by the producers (Table 2). The calculations include life phases A1 to A4, meaning the production process (A1-A3), in addition to the transportation of these materials to market (A4).

Figure 6 shows the emission of CO_2-eq/m^3 for each of the three UHPC mixes when only evaluating the emissions stemming from the cement of the UHPC mixes. This simplification is reasonable. The majority (>95%) of the CO_2-eq. emissions from UHPC materials stem from the consumption of cement and micro-steel fibers [4, 18].

Comparing emissions from UHPC mixes with fibers excluded as shown in Fig. 6 is relevant even if the use of UHPC materials without fibers is rare due to brittleness. This is because the actual level of fiber content is adjusted to accommodate the purpose of each single use. A reduction of 67% kg CO_2-eq. was obtained, when substituting CEM I with CEM III.

Figure 7 shows the results of emissions from the UHPC mixes when a volume of 2% micro-steel fibers is included. The emissions from the steel fibers are 2.67 kg CO_2-eq/kg [5], which reduces the effect of substituting one binder with another in the UHPC mix. Still, a potential of 40% reduction in kg CO_2-eq is demonstrated when using CEM III as a binder, compared to using CEM I.

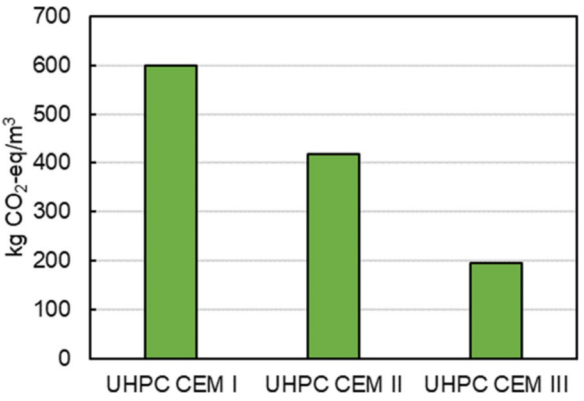

Fig. 6 kg CO_2-eq/m^3 of UHPC only including emissions from cement

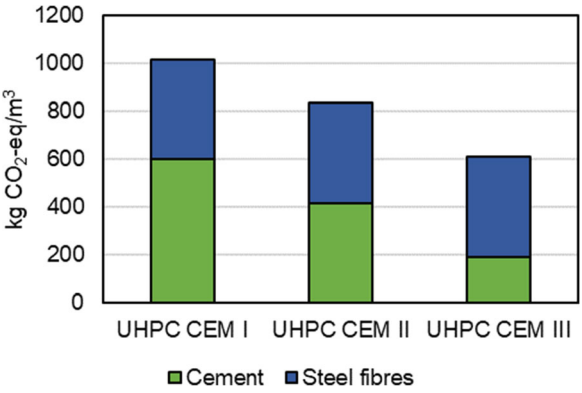

Fig. 7 kg CO_2-eq/m^3 of UHPC including emissions from cement and micro steel fibers

4 Conclusions

In this study, the impact of producing UHPC with alternative pre-accepted cement types was investigated through laboratory experiments. The intention was to investigate the potential for reducing the CO_2 footprint related to production of UHPC, based on materials that are accepted for industrial use through the existing standard (at least in Europe):

- After curing at 20 °C, the 28-day compressive strength was similar for the CEM I (OPC cement) and CEM II (30% GGBS) UHPC mixes, and lower for the CEM III (70% GGBS) mix. With curing at elevated temperature (90 °C the first 72 hours), the difference was eliminated.
- The flexural strength was similar for the UHPC mixes made with CEM I and CEM II, but lower for CEM III. However, it was revealed that in the prisms made from the CEM III mix, there was an uneven distribution of fibers, resulting in less amount of fibers to contribute to flexural strength. The prisms made from the mixes containing CEM I and CEM II did not have the same uneven fiber distribution.
- The consistency of the three mixes was varying, with flow increasing correspondingly with the content of GGBS in the binder. The high flow of the CEM III mix combined with the jolting procedure used for compaction during casting (and gravity), is anticipated to explain the uneven distribution of fibers.
- A simple comparison of emission of CO_2-eq/m^3 was performed to compare mixes made with CEM I, CEM II, and CEM III, respectively. A considerable reduction in emissions was demonstrated: up to 67% for the mortars excluding fibers, and 40% when including two volume percent of micro fibers made from high-strength steel.
- Considering the difference in flow when using the three different cement types, it seems more reasonable to aim at harmonizing the consistency rather than the w/b ratio. Two arguments for this procedure would be that:

1. This would probably remove the problem with uneven fiber distribution, as the act of gravity during jolting would not influence one UHPC mix more than the other.
2. Reduction of water would be the preferred way to reduce the flow of the mixes with higher GGBS content. In addition to changing the flow of fresh mortar, this would reduce the w/b ratio of the mixes with higher GGBS content. Thus, it would probably also relieve a potential for improving the strength properties that might be advantageous for these materials.

1 Introduction

In response to the urgent need for sustainable development, the construction industry is undergoing a paradigm shift toward more environment-friendly and resource-efficient practices. This transformation is primarily driven by the recognition of the construction sector's environmental impact, including its substantial energy consumption, high carbon dioxide (CO_2) emissions, and extensive resource depletion. Consequently, there is a growing emphasis on the adoption of innovative materials and technologies that can contribute to the realization of net-zero building solutions, aiming to minimize the environmental impact of construction activities while maximizing energy efficiency and occupant comfort.

A notable focus within the field of sustainable construction is the advancement and application of lightweight ultra-high-performance concrete (LUHPC). LUHPC stands as a pivotal development in concrete technology. In comparison to regular

concrete, this type of material has lower self-weight, reduced environmental impact, and more sustainable materials while providing exceptional mechanical properties and durability, similar to ultra-high-performance concrete (UHPC) [1–5]. The crucial features of LUHPC are its reduced density and relatively high volume of voids, which can improve thermal performance and energy conservation in buildings, hence reducing CO_2 emissions [6]. As a result, LUHPC is an attractive choice for a wide range of construction applications, including net-zero buildings and infrastructure projects.

The adoption of LUHPC in construction projects holds the potential to revolutionize traditional building practices by enabling the construction of lighter, stronger, and more sustainable structures [5, 6]. However, the effective implementation of LUHPC relies on its fresh properties, notably its workability and autogenous shrinkage. Adequate workability is essential for ensuring the quality and mechanical performance of the LUHPC, while autogenous shrinkage is a critical factor in mitigating cracking and other durability concerns [7, 8]. Moreover, conducting a thorough carbon footprint assessment of LUHPC is imperative for its integration into sustainable construction processes.

To address these challenges and capitalize on the potential of LUHPC for sustainable construction, a comprehensive understanding of its fresh properties and carbon footprint is essential. This necessitates an effective analysis employing a multidisciplinary approach that integrates existing literature with a meticulous analysis of experimental data. Through the utilization of the combined knowledge and skills of researchers, engineers, and industry experts, valuable insights can be obtained into the behavior of LUHPC, thereby identifying opportunities for optimization and enhancement.

In this context, the objective of this chapter is to examine the fresh properties and carbon footprint of LUHPC by evaluating the influence of various factors. Through a review of the existing literature and analysis of experimental data, this chapter will contribute to the body of knowledge on LUHPC technology and provide valuable guidance for researchers, practitioners, and policymakers interested in promoting sustainable construction practices. By highlighting the potential benefits associated with the utilization of LUHPC in net-zero solutions, this study aims to facilitate informed decision-making and innovation in the construction industry.

2 Materials

The production of LUHPC involves meticulous selection and processing of raw materials. The key ingredients of LUHPC typically consist of Portland cement, supplementary cementitious materials (SCMs), standard fine aggregates, lightweight aggregates (LWAs), water, and chemical admixtures. In numerous studies, Class I 52.5N Portland cement (CEM 1 52.5N) was used in LUHPC mixtures due to its higher compressive strength compared to other types of Portland cement. SCMs can be replaced with Portland cement to produce cementitious materials. Various SCMs,

such as silica fume, flash ash, and natural zeolites, are commonly employed to enhance particle packing density, hydration degree, internal curing, and reactivity [9–12]. In addition, superabsorbent polymers (SAPs) were reported to provide internal curing for high cementitious content mixtures [13].

LWAs are an essential component and a key factor in the manufacturing of LUHPC [14]. According to Eurocode 2 [15], LWAs are characterized by a particle density below 2000 kg/m^3. Previous studies have shown that the inclusion of LWAs can significantly contribute to producing a concrete mixture with a compressive strength exceeding 120 MPa at 28 days, while maintaining a density below 2100 kg/m^3, surpassing the 50 MPa.m^3/t 28-day specific strength threshold suggested by Meng et al. [16] for defining LUHPC characteristics [17]. The addition of large amounts of air voids, which can be supplied by stable foams or chemical gases (commonly known as air-entraining agents), is another effective method for LUHPC production [18]. Notably, specific chemical admixtures such as phase change materials (PCMs) have been utilized to produce LUHPC with promising results [19].

3 Results and Discussion

3.1 Workability

Workability, a fundamental characteristic of LUHPC, is essential for ensuring proper mixing, handling, and placing during construction. The slump flow test is commonly employed to measure the workability of LUHPC. Several factors influence the workability of LUHPC, including the incorporation of LWAs, chemical admixtures, and the water-to-binder (w/b) ratio.

The addition of LWAs significantly impacts the workability of LUHPC due to the physical properties of the aggregates. LWAs with quasi-spherical particle shapes have been reported to enhance workability by reducing water demand [16]. Additionally, LWAs with smooth and spherical shapes provide ball bearing and lubricant effects, further improving workability [20]. Conversely, LWAs with rough particle shapes, such as shale ceramsite, can reduce workability due to increased friction with the cement paste [21]. Importantly, LWAs possess lower density and higher porosity compared to normal-weight aggregates (NWAs), leading to reduced LUHPC density and increased cement paste lubrication and workability [14].

Studies have demonstrated that an increase in LWA content correlates with enhanced workability and higher slump flow [5, 14]. In this regard, Abadel et al. [14] reported that 30% LWA content increased the slump flow of LUHPC by 21%. However, an optimal LWA content exists for workability, as excessive LWA content can lead to a decrease in slump flow due to increased particle packing density and interparticle friction [5]. The water absorption characteristics of LWAs also influence LUHPC workability. Pre-saturation treatments have been shown to enhance workability by providing additional water to the mixture during mixing [7, 22–25].

Table 1 Summarized information on the workability of LUHPC

References	LWA content (by volume) (%)	HRWR range (binder mass %)	w/b ratio	Slump flow range (mm)
Abadel et al. [14]	0–30	2.68	0.210	189–230
Alanazi et al. [27]	0–10	2.67	0.200	184–210
Huang et al. [24]	0–50	0.42	0.200	270–290
Li et al. [28]	0–100	–	0.270	220–250
Liu et al. [29]	0–30	2.83	0.183	125–350
Lu et al. [6]	0–100	3.00	0.160	174–214
Meng et al. [7]	0–75	1.00	0.200	275–290
Meng et al. [16]	0–100	2.00	0.180	80–260
Meng et al. [26]	0–25	0.60–1.00	0.170–0.230	270–290
Shen et al. [25]	0–80	1.00	0.180–0.243	240–300
Teng et al. [23]	0–25	0.65–0.91	0.200	231–244
Valipour et al. [22]	0–60	1.05–2.02	0.200	260–280
Xie et al. [30]	0–100	1.25–2.26	0.200	180–200
Zhang et al. [21]	0–100	2.50	0.183	250–287

For instance, Huang et al. [24] observed a notable enhancement in slump flow by replacing 50% pre-saturated LWAs, resulting in an increase in the slump flow from 270 to 290 mm. Similarly, Shen et al. [25] reported that using 80% pre-saturated LWAs increased the slump flow of LUHPC by 25%.

Chemical admixtures, including air-entraining agents, can also affect LUHPC workability. The use of aerogel as an air-entraining agent has been shown to improve workability by facilitating particle movement [18]. The w/b ratio significantly affects LUHPC workability by determining the amount of water available for lubricating flow between particles [26]. In general, while a higher w/b ratio increases workability, achieving superior mechanical characteristics in LUHPC necessitates a w/b ratio in the range of approximately 0.18–0.23. Consequently, an appropriate dosage of superplasticizers, particularly high-range water reducers (HRWR), plays a critical role in achieving particle dispersion and facilitating the accurate casting of LUHPC [20].

Overall, optimizing LWA content, chemical admixtures, and the w/b ratio is essential for achieving maximum LUHPC workability without segregation. Table 1 provides a summary of the workability characteristics of LUHPC based on

the previous studies, including LWA content, HRWR range, w/b ratio, and corresponding slump flow range.

3.2 Autogenous Shrinkage

Autogenous shrinkage, a significant concern in ultra-high-performance concrete (UHPC), stems from self-desiccation during cement hydration, particularly due to its low water-to-binder (w/b) ratio and high cement content [8]. Ineffective control of this shrinkage might result in structural issues like cracking, increased permeability, and loss of durability [31, 32]. Numerous studies have investigated the effectiveness of incorporating pre-saturated LWAs in LUHPC to mitigate autogenous shrinkage by providing internal curing [7, 11, 14, 17, 22, 23, 29]. LWAs possess the ability to release the absorbed water progressively during the cement hydration process. This release of water facilitates internal curing and helps maintain a higher internal relative humidity, effectively mitigating autogenous shrinkage [14]. Moreover, water released from LWAs can contribute to the formation of calcium-silicate-hydrate (CSH) phases, increasing solid volume surrounding aggregates and counteracting shrinkage [11].

In terms of mitigating autogenous shrinkage in LUHPC, Guo et al. [17] reported a 47% reduction in autogenous shrinkage with 100% replacement of saturated LWAs, indicating effective mitigation of self-desiccation by providing internal curing. Additionally, Valipour et al. [22] observed significant reductions in autogenous shrinkage when saturated LWAs were utilized. Specifically, a LUHPC mixture containing 60% saturated LWAs exhibited early expansions followed by 295 μm/m shrinkage [22].

Besides LWAs, air-entraining agents and SCMs have been employed to reduce autogenous shrinkage in LUHPC. The porous structure of air-entraining agents act as an internal water reservoir, while SCMs lower water demand, capillary porosity, and matrix density. Encouraging results have also been achieved in controlling autogenous shrinkage in LUHPC with the use of shrinkage-reducing admixtures (SRAs) [23]. Teng et al. [23] found that saturated LWAs and SRA reduced the 28-day autogenous shrinkage of LUHPC by 20% due to lower capillary pore pressure and LWA internal curing. However, the inclusion of PCMs in LUHPC exhibited negative results in controlling autogenous shrinkage [19]. Ren et al. [19] observed that the inclusion of microencapsulated PCMs led to an increase in autogenous shrinkage due to the creation of additional pores, which accelerated the propagation of cracks and deformation.

In general, the inclusion of saturated LWAs, SCMs, and SRA in LWUHPC mixtures has been successful in reducing autogenous shrinkage. By utilizing LWAs for internal curing alongside SCMs and SRA, it is possible to decrease autogenous shrinkage significantly. Table 2 presents a comprehensive summary of autogenous shrinkage data for LUHPC, providing further insights. It is important to

3.3 Carbon Footprint

Currently, the escalating levels of CO_2 emissions present a pressing environmental challenge. Notably, Portland cement manufacturing stands out as a prominent sector that significantly contributes to the escalation of CO_2 emissions [33]. Improving the sustainability performance of LUHPC involves the utilization of SCMs, waste, and recycled materials. Zaid et al. [5] demonstrated that incorporating palm oil fuel ash (POFA) as SCMs and Lytag as LWAs significantly reduced CO_2 emissions by decreasing the Portland cement content and substituting normal aggregates with sustainable alternatives. Integrating waste tire steel fibers into the LUHPC has emerged as an effective method for utilizing waste materials, resulting in decreased CO_2 emissions and landfill waste. These fibers not only enhance the durability and mechanical properties of concrete mixtures but also extend the lifespan of structures, making a significant contribution to the sustainability of the building sector [5].

Moreover, the incorporation of glass microspheres and polyethylene fibers (PE) into LUHPC mixtures led to a reduction in CO_2 emissions and energy usage when compared to the reference mixtures. Specifically, the use of glass microspheres resulted in a 26% reduction in CO_2 emissions, while the substitution of steel fibers with PE fibers led to a 15% decrease. Additionally, the integration of glass

microspheres reduced energy consumption by 22%, while the substitution of steel fibers with PE fibers led to a 24% decrease. The aforementioned reductions in CO_2 emissions and energy consumption underscore the environmental benefits associated with incorporating sustainable materials in the manufacturing of LUHPC [17].

4 Conclusions

This study offers a comprehensive examination of LUHPC with a specific focus on its fresh properties and carbon footprint, illustrating its potential for sustainable construction practices. Employing a comprehensive methodology that incorporates a thorough examination of existing literature and meticulous analysis of experimental data, several significant findings about LUHPC emerged.

The assessment of LUHPC's carbon footprint underscores the potential of substantial environmental advantages through the inclusion of sustainable materials and additives. CO_2 emissions and energy consumption of LUHPC can substantially be reduced by substituting Portland cement with SCMs and incorporating waste or recycled materials. Additionally, the utilization of sustainable materials, such as glass microspheres and PE fibers, offers further opportunities for enhancing sustainability while maintaining or improving mechanical performance. These findings underscore the importance of considering the environmental implications of construction materials and emphasize the necessity of adopting comprehensive strategies for sustainable design and construction methods.

1 Introduction

In the global effort to mitigate greenhouse gas emissions, the cement and concrete industry has dedicated to reducing CO_2 emissions and increasing CO_2 sequestration through the carbonation process. Research indicates that the manufacture of one ton of Portland cement emits approximately 0.87 tons of CO_2 [1], contributing to 8–10% of global CO_2 emissions. In past years, the production of blended Portland cement

has been considered an effective method for reducing CO_2 emissions by decreasing the use of cement clinker [2, 3]. It is well-known that industrial slags have significant potential for partially replacing cement clinker [4–6].

In recent years, global focus on the use of hydrated cement powder, derived from recycling concrete waste, as an alternative to cement in concrete products has increased significantly [7, 8]. Studies have demonstrated that the type and content of waste hydrated cement influence the fresh properties and compressive strength of the resulting concrete products. Hence, it is crucial to enhance the properties of waste hydrated cement through effective treatment methods; so that a higher value-added material and improved performance could be realized.

Mineral carbonation, also known as accelerated carbonation, has been recognized as a promising method for improving the mechanical properties of cementitious materials, including blended cement waste, as well as for capturing CO_2 [9–11]. In the carbonation process, CO_2 can react with alkaline silicate minerals to form calcium carbonate ($CaCO_3$) and amorphous gel, as described in Eqs. (1) to (4).

$$Ca(OH)_2 + CO_2 \rightarrow CaCO_3 + H_2O \quad (1)$$

$$3CaO.2SiO_2.3H_2O + 3CO_2 \rightarrow 3CaCO_3 + 2SiO_2.3H_2O \quad (2)$$

$$2CaO.SiO_2 + (2-x)CO_2 + yH_2O \rightarrow xCaO.SiO_2.yH_2O + (2-x)CaCO_3 \quad (3)$$

$$3CaO.SiO_2 + (3-x)CO_2 + yH_2O \rightarrow xCaO.SiO_2.yH_2O + (3-x)CaCO_3 \quad (4)$$

In fact, the natural carbonation process of cementitious binders is an extremely slow reaction. However, the reaction time can be accelerated by increasing the CO_2 concentration in the reaction environment. Previous studies have also revealed that the carbonation reaction rate depends on operating parameters such as relative humidity [12], carbonation time [13, 14], temperature [15], pressure [16], and CO_2 concentration [17].

For decades, ground granulated blast furnace slag (GGBS) has been extensively used as a partial substitute for cement in concrete production, in line with efforts to mitigate CO_2 emissions in the construction industry. Consequently, it is expected that a significant portion of waste hydrated cement, discarded at the end of concrete's life, contains a specific proportion of GGBS. The objective of this study is, therefore, to enhance the cementitious properties of hydrated blast furnace slag cement powder (BSCP) via moisture carbonation method for re-use in new cement paste. To achieve this, hydrated BSCP containing 70% Portland cement and 30% blast furnace slag, cured under water for 90 days, was prepared, and subjected to carbonation curing for 28 days. The microstructure of uncarbonated and carbonated BSCP was studied using thermal analysis (TG-DTG), X-ray diffraction (XRD), and Fourier-transform infrared spectroscopy (FTIR) techniques. Furthermore, the feasibility of using carbonated BSCP as a partial replacement of cement (at 0%, 15%, and 30% by mass) and its effect on flowability and compressive strength of new blended cement paste were investigated.

2 Materials and Experiments

2.1 Raw Materials

An Ordinary Portland cement (OPC; CEM I 42.5 N) and ground granulated blast furnace slag (GGBS) were used in this work to prepare the "model hydrated blast furnace slag cement." The chemical and mineralogical composition of raw materials was analyzed by X-ray fluorescence (XRF), as given in Table 1.

2.2 Preparation and Carbonation of Hydrated Blast Furnace Slag Cement Powder

In this study, the manufacturing process of uncarbonated (U) and carbonated (C) hydrated blast furnace slag cement powder (BSCP) comprises three main steps. First, a blended cement paste containing 70% OPC and 30% GGBS with a water-to-cement ratio (w/c) of 0.3 was mixed for 3 min, cast into 40 mm-cubic molds, and subsequently covered with a plastic sheet for 24 h at a room temperature of 20 ± 1 °C. Following demolding, the blended paste samples were cured in a water tank at 20 ± 1 °C for 3 months. In the next step, the 90-day hydrated samples were pulverized using a ball mill for 20 min to produce the BSCP samples (sized <75 μm). Finally, to examine the impact of carbonation on the microstructure of hydrated BSCP, powders were subjected to carbonation curing (with a CO_2 concentration of 20%, relative humidity of 65 ± 5%, and temperature of 20 ± 1 °C) (referred to as "CBSCP") for 28 days, while natural air curing (temperature of 20 ± 1 °C and relative humidity of 65 ± 5%) (referred to as "UBSCP") was used for comparison.

2.3 Use of Carbonated BSCP as a Cement Substitute

To examine the effect of carbonation on the cementitious properties of BSCP, particularly on the compressive strength and flowability of cement paste, various rations of CBSCP (0%, 15%, and 30% by mass of binder) were incorporated as partial replacements for cement in newly prepared cement paste. In this investigation, different mix proportions of blended cement paste were prepared with a constant water-to-binder ratio of 0.3. Subsequently, the freshly prepared blended

Table 1 Chemical composition (wt.%) of main raw materials determined by XRF

Component	CaO	SiO_2	Al_2O_3	Fe_2O_3	MgO	SO_3	Ignition loss
OPC	64.31	22.01	4.47	3.45	2.45	2.45	1.27
GGBS	38.24	32.65	14.14	9.74	0.75	0.09	–

cement pastes containing CBSCP were poured into 40-mm cubic molds and maintained at room temperature (20 ± 1 °C) for 1 day. Afterward, the samples were removed from molds and cured in water (20 ± 1 °C) for 3, 7, and 28 days.

2.4 Test Methods

Thermal Analysis Both thermogravimetric analysis (TG) and differential thermogravimetric (DTG) tests were used to determine the contents of calcium hydroxide ($Ca(OH)_2$) and calcium carbonate ($CaCO_3$) of UBSCP and CBSCP specimens. For the characterization tests, first, the hydration of the samples was halted by immersing crushed UBSCP and CBSCP in isopropanol solution for 4 days, followed by transfer to a vacuum oven for drying (40 °C) for an additional 5 days. Finally, the dried crushed samples were ground to prepare a powder with particle size below 5 μm for examination. The thermal analysis was performed using a Thermo Plus EV02 TG with a heating rate of 10 °C/min and under a flow of 30 ml/min of N_2 gas. About 15 ± 1 mg of powdered sample was subjected to heating from 30 °C to 1000 °C.

Microstructure Analysis To evaluate the effect of carbonation on the microstructure of BSCP, the phase composition of carbonated and uncarbonated BSCP samples was studied using X-ray diffraction (XRD) and Infrared spectrum (FTIR) techniques. The powder samples were characterized using a an X'Pert MPD PRO diffractometer (D8 Advance Bruker, Germany), featuring a CUKα X-ray radiation source (with a scanning range of 10°-70° 2θ and a step size of 0.02°). For the FTIR test, powder samples were inserted into a Thermo Scientific IS10 infrared spectrometer, and the spectra were recorded for wavenumbers ranging from 400 cm^{-1} to 4000 cm^{-1}.

Flowability The flowability of cement pastes made with various replacement ratios of carbonated BSCP (0%, 15%, and 30% by mass) was measured in accordance with the GB/T 2419–2005 standard. In this measuring method, the freshly prepared blended cement paste was placed into a slump cone mold. The paste sample was then dropped 25 times on a flop table and the average spreading diameter in four directions was reported as the flowability diameter.

Mechanical Properties The compressive strength of blended cement paste containing CBSCP was determined at 3, 7, and 28 days of hydration based on Chinese Standard GB/T 17671–1999, using a Fengzhi YAW-300 compression machine with a loading rate of 2.4 kN/s. The paste strength was determined by recording the average compressive strength values from three specimens. Additionally, the strength activity index (SAI) of the CBSCP-cement paste samples at 3, 7 and 28 days of hydration (t) was calculated according to Eq. 5:

$$\text{SAI}\ (\%) = \frac{(\text{compressive strength of cement paste containing CBSCP})_t}{(\text{compressive strength of control sample})_t} \times 100 \tag{5}$$

3 Results and Discussion

3.1 Characterization of BSCP upon Moisture Carbonation

To evaluate the impact of carbonation on the microstructure of hydrated blast furnace slag cement powder, thermal, XRD, and FTIR analysis of BSCP cured under CO_2 and natural air environment were investigated and compared, as depicted in Figs. 1, 2, and 3, respectively.

Thermal Analysis TG-DTG testing was employed to estimate the contents of hydration and carbonation products in the BSCP sample before and after carbonation. In this study, the contents of hydrated bound water (BW), $Ca(OH)_2$, and $CaCO_3$ were calculated based on the weight loss of BSCP specimens within the temperature ranges of 70–540 °C, 400–500 °C, and 540–950 °C, and they are given in Eqs. (6)–(8), respectively [3]:

$$\%\mathrm{BW} = \frac{(\mathrm{W}_{70\,^\circ\mathrm{C}} - \mathrm{W}_{540\,^\circ\mathrm{C}})}{\mathrm{W}_{950\,^\circ\mathrm{C}}} \times 100 \tag{6}$$

$$\%\mathrm{Ca(OH)_2} = \frac{(\mathrm{W}_{400\,^\circ\mathrm{C}} - \mathrm{W}_{500\,^\circ\mathrm{C}})}{\mathrm{W}_{950\,^\circ\mathrm{C}}} \times \frac{74.09}{18.01} \times 100 \tag{7}$$

$$\%\mathrm{CaCO_3} = \frac{(\mathrm{W}_{540^\circ\mathrm{C}} - \mathrm{W}_{950^\circ\mathrm{C}})}{\mathrm{W}_{950^\circ\mathrm{C}}} \times \frac{100.09}{44.01} \times 100 \tag{8}$$

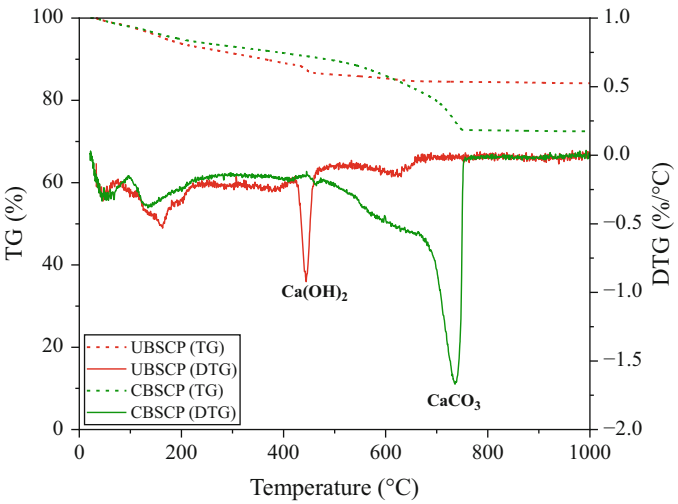

Fig. 1 TG-DTG curves of BSCP samples after 28 days of natural air (UBSCP) and carbonation (CBSCP) curing

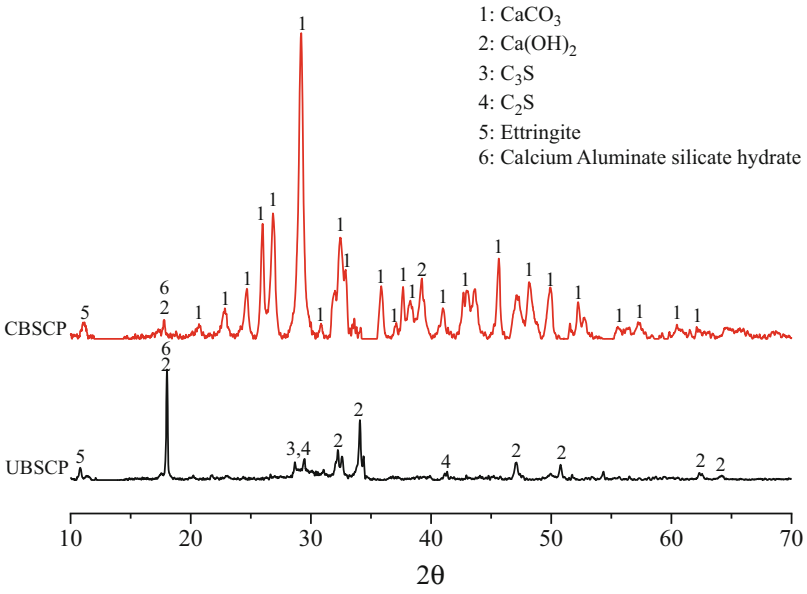

Fig. 2 X-ray diffraction patterns of BSCP samples after 28 days of natural air (UBSCP) and carbonation (CBSCP) curing

As seen in Fig. 1, BSCP cured under natural air demonstrates a peak within 100–200 °C, which can be related to dehydration of the hydrated calcium silicate phase (C-S-H gel) and ettringite (AFt), followed by a larger peak (weight loss of 0.33%) in the temperature range of 400 °C to 500 °C due to decomposition of Ca $(OH)_2$. In comparison to the UBSCP sample, the thermal analysis results for the BSCP sample cured under CO_2 rich condition (CBSCP) indicated a gradual decrease in weight of the sample upon heating up to 680 °C until a significant weight loss of 1.67% appeared from 700 to 800 °C, corresponding to decarbonation of $CaCO_3$.

According to the thermal results given in Table 2 (based on Eqs. (6)–(8)), the total amount of precipitated $CaCO_3$ in the structure of UBSCP and CBSCP samples was 5.49% and 50.91% by weight, indicating a significant amount of $CaCO_3$ has formed in CBSCP sample. This can be associated with an increase in the diffusion rate of CO_2 into the structure of CBSCP during the accelerated carbonation process compared to the natural air carbonation process, which led to heightened CO_2 reaction with calcium-based phases in the samples.

XRD Analysis Microstructure analysis, employing both XRD and FTIR techniques, was performed to further explore the impact of moisture carbonation on the precipitation of $CaCO_3$ in the BSCP sample. As marked in the XRD analysis (Fig. 2), the UBSCP sample consists of $Ca(OH)_2$, a small amount of ettringite (AFt), and unreacted calcium silicate-based phases of cement (C_2S and C_3S), whereas calcium carbonate ($CaCO_3$, calcite) predominates as the main carbonate phase in

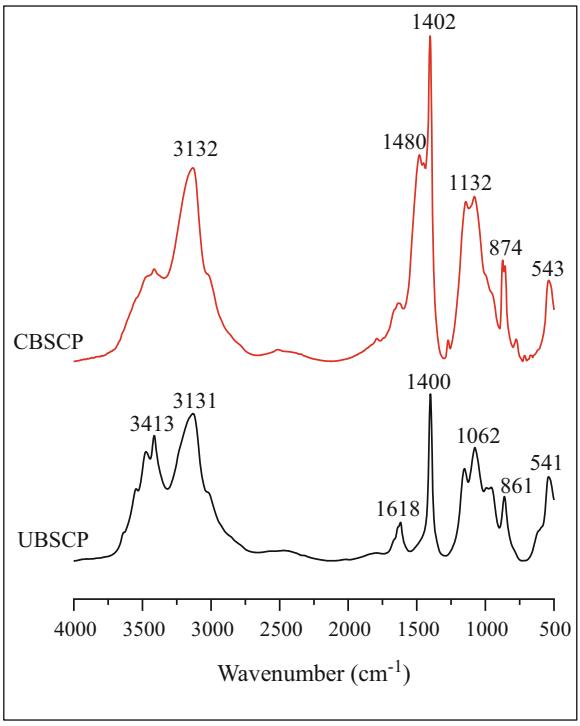

Fig. 3 FTIR spectra of BSCP samples after 28 days of natural air (UBSCP) and carbonation (CBSCP) curing

the structure of CBSCP sample. In other words, during the carbonation process, the distinctive peaks of C_2S, C_3S, and $Ca(OH)_2$ in the structure of BSCP specimens were significantly reduced due to the reaction between CO_2 and the mentioned components. This interaction led to the formation of $CaCO_3$ polymorphs, consistent with the TG-DTG curves shown in Fig. 1.

FTIR Analysis The infrared spectroscopy technique was also used to study the amorphous gel formed within the structure of BSCP during the carbonation process. The FTIR spectra of carbonated and uncarbonated BSCP are presented in Fig. 3. It can be observed that vibration bonds appeared at 1618 cm^{-1} and 3413 cm^{-1} in the UBSCP sample, corresponding to the O-H stretching bond in hydrated water molecules of hydration products and portlandite ($Ca(OH)_2$), respectively. However, this bond disappeared after the carbonation process, as evident in the FTIR spectra of the CBSCP sample. Conversely, new vibration peaks of CO_3^{2-} were formed at 874 cm^{-1} and 1480 cm^{-1} after the carbonation of BSCP, indicating the formation of $CaCO_3$ in the structure of the carbonated BSCP sample. Moreover, it is observed that the asymmetric stretching vibration of Si-O bond in the chain structure of C-S-H gel shifted to the higher wave number (from 1062 cm^{-1} to 1132 cm^{-1}) following the carbonation of the BSCP sample. This result is attributed to the decalcification of the C-S-H gel phase and an increase in the degree of polymerization. So, it can be

Table 2 The contents of hydration and carbonation products in uncarbonated and carbonated BSCP (% by weight)

Component	UBSCP	CBSCP
BW	15.19	13.88
$Ca(OH)_2$	13.71	2.60
$CaCO_3$	5.49	50.91

Table 3 Flowability of blended cement paste samples containing carbonated BSCP

Sample	Binder (wt.%)		Flowability (mm)
	OPC	CBSCP	
CBSCP-0 (control sample)	100	0	175
CBSCP-15	85	15	142.5
CBSCP-30	70	30	105

concluded that the carbonation of hydrated blast furnace slag cement powder leads to an increase in silica gel amorphous content in the structure of BSCP. The bond at 3131 cm^{-1} belonging to (Si,Al)-OH bond of water molecule remained unchanged after carbonation of BSCP [11]. The FTIR spectra results are in alignment with the XRD findings (Fig. 2) and thermal results (Fig. 1 and Table 2).

3.2 Performance of Carbonated BSCP as a Cement Substitute

To assess the impact of carbonation on the cementitious reactivity of BSCP, carbonated BSCP with a particle size below 75 μm was used to replace the Portland cement at 0%, 15%, and 30% by mass of binder in the preparation of cement paste.

Flowability (Water Requirement) Table 3 presents the flowability of fresh blended cement paste incorporating different CBSCP contents. As shown in this table, regardless of the cement replacement ratio, the flowability of paste samples containing carbonated BSCP was notably lower compared to that of pure cement paste (CBSCP-0). The reduced flowability of cement pastes containing CBSCP could be mainly attributed to the differences in the porosity and specific surface area of CBSCP samples compared to cement particles (caused by $CaCO_3$ formation), which led to increased water requirement and a subsequent decrease in workability. Moreover, the flowability of freshly blended cement pastes is found to decrease as the CBSCP content in the mix proportion increases. This result can be mainly due to the higher specific surface area of CBSCP compared to cement particles, resulting in greater water demand for CBSCP and contributing to a further reduction in the flowability of the cement paste.

Compressive Strength The effect of CBSCP content on the compressive strength of blended cement paste was investigated. As depicted in Fig. 4 and supported by strength activity index results presented in Table 4, replacing 15% of cement with

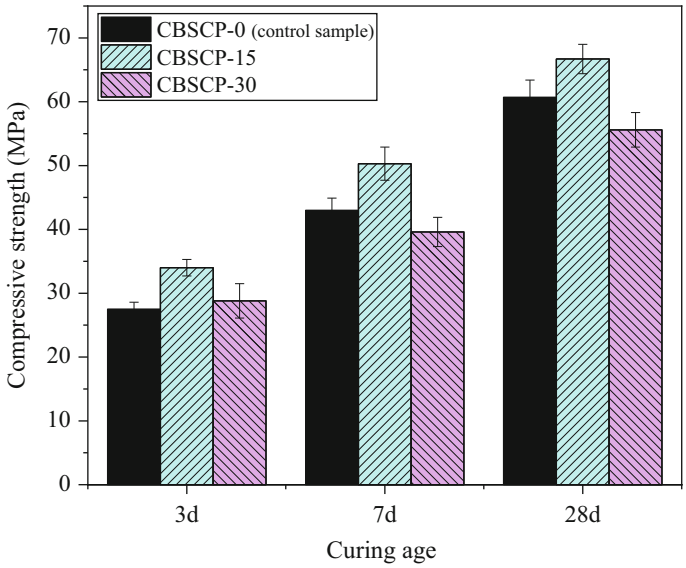

Fig. 4 Compressive strength of blended cement paste containing carbonated BSCP at different curing ages

Table 4 Strength activity index (SAI) of blended cement paste samples

Sample	SAI (%)		
	3 days	7 days	28 days
CBSCP-0 (control sample)	100	100	100
CBSCP-15	123.6	117.0	109.9
CBSCP-30	104.7	92.1	91.6

CBSCP resulted in a notable increase in the compressive strength of paste by 23.6%, 17.0%, and 9.9% for 3, 7, and 28 days of hydration, respectively. The enhanced compressive strength of blended cement pastes containing CBSCP could be mainly attributed to the increase in heterogeneous nucleation sites for cement hydration provided by $CaCO_3$ in carbonated BSCP, along with the stabilization of the ettringite phase [3]. However, the beneficial effect of CBSCP on the strength enhancement of the blended paste became less pronounced when the volume of cement replaced with CBSCP was increased to 30%. This might be attributed to the high water requirement of the paste sample prepared with 30% CBSCP compared to the control sample, resulting in a decrease in hydrated water and a delay in cement hydration, which led to a reduction in the compressive strength of the blended cement paste.

4 Conclusions and Future Perspective

The study investigated the effect of carbonation on the microstructure alteration of hydrated blast furnace slag cement powder (BSCP) as a pozzolanic waste material. To understand the feasibility of re-using BSCP in cementitious products, the study also examined the flowability and compressive strength of blended cement pastes containing 0%, 15%, and 30% of carbonated BSCP (CBSCP) as a cement replacement. The microstructural changes (analyzed by XRD and FTIR tests) and thermal analysis (TG-DTG) revealed that calcium hydroxide is the main crystalline phase of uncarbonated BSCP, while CBSCP samples consist mainly of calcium carbonate ($CaCO_3$) with approximately 50.91% by weight. Moreover, the carbonation increased the silica gel amorphous content in the structure of BSCP samples. The finding also indicated that replacing cement with carbonated BSCP decreased the flowability of cement paste due to the high water absorption of the CBSCP sample compared to cement particles. Furthermore, an increase in the replacement ratio (from 15% to 30% by mass) of cement with CBSCP caused a significant decrease in the flowability of the cement paste. Despite the adverse effect of CBSCP on the flowability of cement paste, substituting 15% of cement with CBSCP enhanced the compressive strength of paste samples at 3, 7, and 28 days. Therefore, it can be concluded that carbonated BSCP can be used as a cement substitute (up to 30% replacement) in the production of cement-based materials, without a significant compromise to mechanical performance.

As a new emerging binder, BSCP can be used as a CO_2 sink and to produce low-carbon cement-based materials with acceptable mechanical performance. The proposed treatment method (moisture carbonation) for improving the pozzolanic reactivity of waste hydrated cement powders demonstrates promising potential for industrial applications. However, scaling up the carbonation process from laboratory scale to industrial scale remains a challenge due to the long carbonation time (28 days). Hence, optimizing moisture carbonation parameters, such as CO_2 concentration, humidity, BSCP particle size, and carbonation temperature, is necessary to reduce carbonation time and enhance the efficiency of the carbonation process for real industrial applications. Additionally, investigating the long-term durability of construction materials incorporating CBSCP is critical to ensure their reliability over time. Conducting a comprehensive life cycle assessment of the carbonation of CBSP and the utilization of carbonated CBSCP as a cement substitute compared to Ordinary Portland cement production methods is also required to assessing the potential environmental benefits of the proposed method and its impact on reducing CO_2 emissions in the construction industry.

1 Introduction

The use of Portland cement in the construction and building industry led to serious environmental challenges, such as the depletion of natural resources, the release of greenhouse gases, and the generation of waste materials [1]. Researchers and scientists are actively exploring alternatives to cement-based materials either partially or fully using wastes or abundant resources [1, 2].

Metakaolin (MK), originating from the calcination of kaolin clay, stands out as a highly reactive pozzolanic material extensively utilized in the production of high-performance concrete and mortar [3]. Alkali-activated or geopolymer (GP) is a cement-free construction product manufactured by activating alumina or silica-rich binders such as metakaolin, fly ash, slag, or perlite, with a sodium or potassium-based alkaline solution [4, 5]. The poly-condensation of silica and alumina

oligomers creates dense crystalline and amorphous polymer structures that harden at ambient temperature with durability and mechanical properties comparable to alternative cement-based materials [6]. GP is successfully used in a variety of niche applications such as retrofitting of damaged structures, repair and strengthening works requiring superior bond and attrition resistance, soil injection to reduce seepage, insulating infill used in lightweight sandwich panels, and refractory materials possessing improved resistance to fire and elevated temperature [7]. Recent applications showed that GP could be successfully used as masonry plasters exhibiting shorter settings and higher bonding without the need for moist curing normally required than cement-based plasters [5].

The construction of marine and underwater structures such as dams, bridges, and tunnels requires viscous materials to mitigate washout loss and prevent water penetration into the matrix during placement and curing [8]. As a result, geopolymers have proven to be excellent alternatives to cement-based counterparts due to their higher plastic viscosity and yield stress rheological properties [9]. Favier et al. [10] presented evidence that the increased plastic viscosity of MK-based GP is linked to the high viscosity of alkaline sodium hydroxide and sodium silicate solutions that surpass water by 10–100 times. The negligible colloidal interactions among MK particles suggest that hydrodynamic dissipation of the highly viscous alkaline solution predominantly influences the rheological behavior. Regarding durability, several studies highlighted the superior resistance of GP to degradation by aggressive ions present in marine and wastewater environments such as sulfates, chlorides, and acids [11, 12]. The GP maintained a dense microstructure even after a 30-day immersion in a 5% acid solution with a limited weight loss of 7%, while traditional cement-based concrete experienced about 35% loss under similar conditions [13].

The primary aim of this chapter is to produce MK-based GP mortars intended for underwater casting. Two flowability levels of 16 and 22 ± 1 cm along with three different binder-to-sand ratios of 1:3, 1:1.85, and 1:0.8, are investigated. The sodium-based alkaline solution is adjusted to attain the specified flowability. The washout loss and residual 28-day compressive strength of mortars were determined under dry and submerged casting conditions. The investigation delves into the effects of varying alkaline solution-to-binder and binder-to-sand ratios on the overall performance of GP mortars.

2 Experimental Work

2.1 Materials

Artificial or manufactured MK derived from the calcination of kaolinite clay was utilized to produce the GP. The alumina-silica-rich binder possessed a specific gravity, median particle size (d_{50}), and BET surface area of 2.2, 6.1 μm, and 19,000 m^2/kg, respectively. Figure 1 presents the particle size distribution of MK

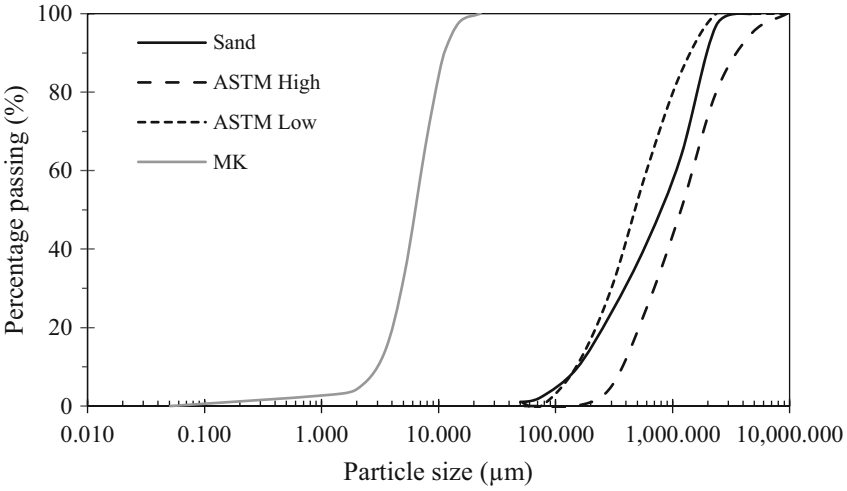

Fig. 1 Particle size distribution of MK and sand

ranging between 0.05 and 22.80 μm. Its chemical composition comprised 55% SiO_2, 39% Al_2O_3, 1.8% Fe_2O_3, 0.35% CaO, 0.25% MgO, and 1.5% TiO_2, with a 1% loss on ignition. Sodium hydroxide pellets (SH) and sodium silicate (SS) with SiO_2-to-Na_2O ratio of 3.25, both supplied by Sigma-Aldrich, were employed to activate the MK.

A well-graded siliceous sand was used; it had a water absorption of 0.91%, fineness modulus of 2.40, and bulk specific gravity of 2.62. Additional water was introduced into all mixes to offset the water absorption of the sand. The particle size gradation of the sand (Fig. 1) conformed to ASTM C33 [14] standard defined by the lowest and highest limits for aggregate gradation.

Tap water was utilized in the production of MK-based mortar. Sea water was not used as it resulted in a slight decrease in the compressive strength of MK-based geopolymer mortar, as zeolite formation was inhibited with increasing sea water concentration [15].

2.2 Mix Design

Six mortars were prepared to assess the impact of flowability and sand content (i.e., binder content) on GP performance. Two different flowabilities (i.e., 16 and 22 ± 1 cm) and three binder-to-sand ratios (i.e., 1:3, 1:1.85, and 1:0.8) were tested. Two flow values, 16 and 22 ± 1 cm, were chosen to evaluate the influence of flowability and alkaline solution content on the performance of MK-based geopolymer mortar in underwater applications. This selection was made to assess a range of flowability conditions and alkaline solution concentrations, which are

Table 1 Mix design of MK-based GP mortar

Mix designation	Binder-to-sand	SH molarity	SS-to-SH	Flow (cm)	AAS-to-binder
B:S(1:3) F(16)	1:3	10	2	16 ± 1	1.37
B:S(1:1.85) F(16)	1:1.85	10	2	16 ± 1	1.24
B:S(1:0.8) F(16)	1:0.8	10	2	16 ± 1	0.78
B:S(1:3) F(22)	1:3	10	2	22 ± 1	1.83
B:S(1:1.85) F(22)	1:1.85	10	2	22 ± 1	1.31
B:S(1:0.8) F(22)	1:0.8	10	2	22 ± 1	0.83

critical factors affecting the behavior of mortar underwater. The volume of sand was systematically increased until a maximum loss of strength between the dry and submerged samples reached 50%.

The mix design for all formulations is provided in Table 1; each mix is designated as *B*:*S*(*X*) *F*(*Y*), where *X* represents the binder-to-sand ratio values and *Y* represents the flow in centimeters.

2.3 Sample Production

The alkali-activated solution (AAS) was prepared 1 day before mortar production to ensure the complete dissipation of heat generated during the preparation of SH and by mixing SH with SS. Initially, tap water was blended with SH pellets to achieve the desired molarity of 10; after that, the SS and SH were mixed at SS-to-SH ratio of 2. This specific molarity and ratio were chosen to attain the desired setting time for underwater placing [9].

The mortar production involved mixing the MK and siliceous sand for 2–-3 minutes. Subsequently, the AAS and additional water required to account for sand water absorption were gradually added, and the mixture was blended for another 2 minutes. After a 30-second rest period, mixing was resumed for an additional 3 minutes.

2.4 Testing Procedure

The fresh mortar properties were assessed based on the initial flow, setting time, plastic viscosity, and washout loss. The flowability and setting time of mortars were measured using the mini-slump cone and the Vicat needle in accordance with the ASTM C1437 and ASTM C191, respectively [16, 17]. The average of four diametrical readings was used for determining the flow of mortar without vibration. The plastic viscosity (□) was determined using a four-bladed slotted vane connected to Anton Paar rheometer [9]. The washout loss (*W*3) of investigated mortars was determined using an adapted version of the CRD C61 test, as described in the

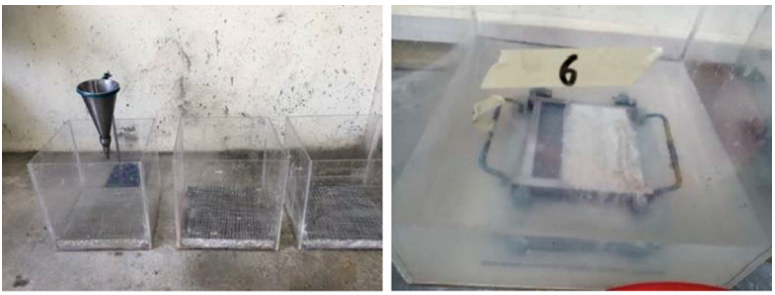

Fig. 2 Casting methods for placing Geopolymer (GP) mortars underwater: (**a**) on concrete slabs and (**b**) inside molds

referenced research study [9]. This consists of measuring the mass of the freshly mixed material placed in a perforated basket before and after dropping it in a 1-m tube filled with water following three drops.

For strength testing, the fresh mortar was poured into prismatic molds measuring 4 × 4 × 16 cm, both in dry and submerged water conditions. In the dry condition, the mortar was poured without vibration and cured in a plastic bag. In the submerged condition (Fig. 2a, b), the molds were positioned in a large container filled with water to a depth of 30 cm. A March funnel cone with an outer diameter of 11 mm, positioned approximately 1 cm above the surface of the molds, was utilized to pour the mortar without any vibration. The specimens remained submerged in water at 21 ± 3 °C until the testing time. The ambient temperature during both mixing and placing varied around 21 ± 3 °C. The compressive strengths of dry $f'c$ (dry) and submerged $f'c$ (submerged) mortars were characterized based on the 28-day compressive strength values. This was measured following the EN 196/1 Test Method, with the average of four readings taken into consideration [18]. Each measurement was obtained from two halves of prisms, resulting in a total of four samples tested for compressive strength.

3 Results and Discussion

3.1 Slump Flow and Alkaline Solution Content

Table 1 summarizes the AAS-to-binder ratio employed in each mix to attain the targeted flowability of 16 and 22 ± 1 cm. Evidently, the rise in the binder-to-sand ratio (i.e., higher binder content) led to a reduced amount of alkaline solution to achieve the desired flow. The AAS-to-binder ratio for mixes with a B:S(1:3) composition increased significantly by 33.5%, rising from 1.37 to 1.83. In contrast, the ratio for mixes produced with B:S ratio of 1:0.8 experienced a modest increase of 6.41%, increasing from 0.78 to 0.83. These adjustments were made to attain flow

measurements of 16 and 22 ± 1 cm, respectively. This can be attributed to the higher inter-particles links and internal friction between the fine aggregates and mortar paste [19].

As expected, a lower demand for liquid solution was required for mixes having a flowability of 16 ± 1 cm compared to counterparts having 22 ± 1 cm flow. In the former, the AAS-to-binder ratio increased only from 0.78 to 1.37; in the latter, it increased from 0.83 to 1.83. This phenomenon is directly related to the thickness of the water film surrounding the fine aggregates [20]. The increase in AAS content results in an increase in water film thickness followed by an increase in particles cohesion and a reduction in yield stress that hinders the ease of flow and deformation of fresh mortar [20].

3.2 Setting Time

The final setting times are presented in Table 2. Generally, the setting of different GP mortars hovered between 270 and 470 minutes, which is about half than cement-based countertypes reported in [9]. This suggests that the use of MK-type GP can be relevant to speed up underwater construction, simultaneously enhancing the resistance toward scaling and erosion during the initial phases of casting [21]. It is worth noting that the setting times increased with a decrease in binder content and mixtures possessing higher flow values. Figure 3 shows the relationship between setting and the AAS-to-binder ratio, having a strong correlation coefficient (R^2) of 0.86. Similar findings were observed elsewhere, indicating that the increase in AAS-to-binder content prolongs the setting time of fly ash-slag-based screed mortar [22].

3.3 Plastic Viscosity

Figure 4 illustrates the plastic viscosity of tested mortars, which ranged between 15.6 and 26.3 Pa.s. Comparing these values with values of cement-based counterparts, MK-based mortar possessed higher plastic viscosity, mainly attributed to the higher

Table 2 Fresh and hardened properties of MK-based GP mortar

Mix designation	Setting (min)	□ (Pa.s)	*W*3 (%)	*f'c* (dry) (MPa)	*f'c* (submerged) (MPa)
B:S(1:3) F(16)	355	24.3	3.27	50.8	28.3
B:S(1:1.85) F(16)	320	25.7	2.78	51.1	28.3
B:S(1:0.8) F(16)	270	26.3	1.93	44.8	22.6
B:S(1:3) F(22)	470	15.6	7.52	23.4	17.7
B:S(1:1.85) F(22)	400	19.5	7.02	39.3	24.6
B:S(1:0.8) F(22)	310	24.6	2.78	47.2	25.3

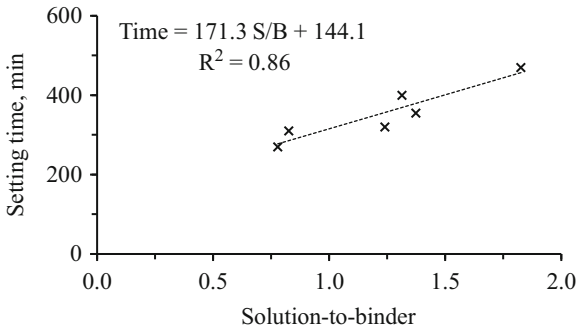

Fig. 3 Correlation between the setting time and the solution-to-binder

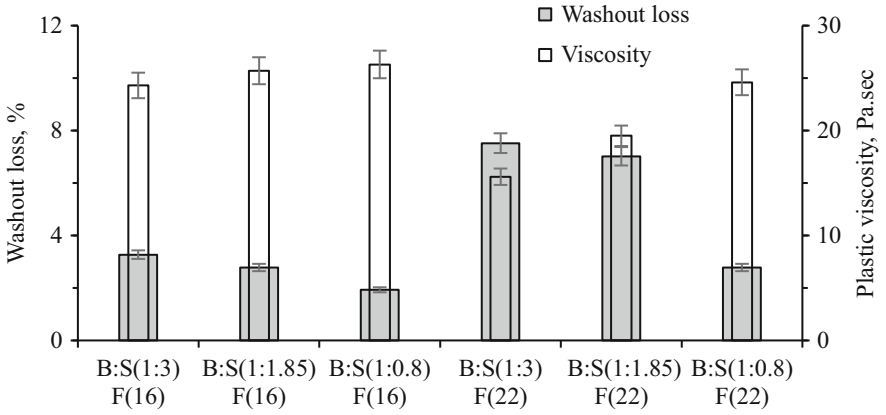

Fig. 4 Plastic viscosity and washout loss values of tested mortars

viscosity of AAS compared to tap water [9]. The plastic viscosity was observed to increase with increased binder content (i.e., lower sand content) and with lower flow values. The rise in stickiness with an increase in plastic viscosity was felt during mortar production and is mainly owed to the drop in AAS content. Similar findings were reported by Alnahhal et al. [23], where the plastic viscosity of GP paste decreased with an increase in the AAS solution, which was attributed to the reduction in the volume fraction of solids in the suspended fluid.

3.4 Washout Loss

The washout loss of tested mortars is presented in Table 2. Compared to cement-based mixtures that normally exhibit between 5% and 20% washout loss [9], all MK-based mortars demonstrated higher resistance against washout with percentages ranging between 1.93% and 7.52%, thus reflecting the suitability of geopolymers for

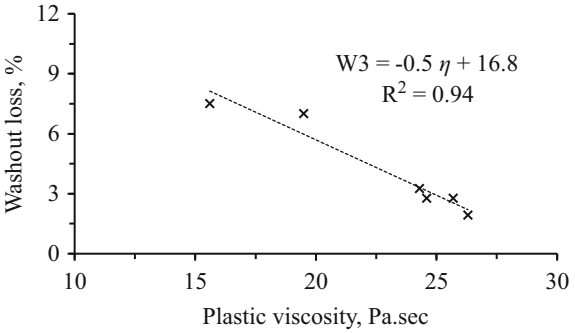

Fig. 5 Correlation between the plastic viscosity and washout loss

underwater applications. This is evidenced in Fig. 2b where the mold remained visible even after pouring the mortar into the water.

Regardless of the flow level, mortars prepared with higher binder-to-sand ratios exhibited higher washout loss, which can be related to the lower plastic viscosity of samples with lower binder content. For example, the washout loss varied from 1.93% to 3.27% when the binder-to-sand ratio changed from 1:0.8 to 1:3, respectively, in mixtures possessing 16 ± 1 cm flow. Such variations ranged from 2.78% to 7.52% for mixtures having 22 ± 1 cm flow. In fact, washout loss was observed to be directly influenced by the plastic viscosity of the produced mortar. The linear correlation of Fig. 5 demonstrates that the increase in viscosity is directly associated to higher resistance against washout loss, which would decrease the material proneness toward dilution upon underwater casting [9].

3.5 Compressive Strength

The 28-day compressive strengths of GP mortars cast in different conditions are illustrated in Fig. 6. Clearly, the effect of underwater casting led to reduced mechanical properties, which can be directly attributed to the water infiltration inside the material coupled with the washout of the MK-based paste [9]. Hence, the 28-day compressive strengths varied from 23.4 to 50.8 MPa and from 17.7 to 28.3 MPa when casting was made in dry or underwater conditions, respectively.

The impact of binder content varied for mixtures produced with different flowability and/or amount of alkaline solution used. Hence, the 28-day compressive strength values of mortars having a flow of 16 ± 1 cm dropped from 50.8 to 44.8 MPa with the increase in binder-to-sand ratio from 1:3 to 1:0.8. Meanwhile, in the other group of mixes having a flow of 21 ± 1 cm, the strength increased from 23.4 to 47.2 MPa. In general, it is common to observe a strength increase with higher paste volume due to a denser paste matrix and improved interfacial transition zone between the paste and aggregates [24, 25]. Similarly, a decrease in the binder-to-sand ratio from 1:3 to 1:7 resulted in a substantial drop in strength, approximately 87%, for fly ash and slag-based geopolymer screed produced with crushed limestone

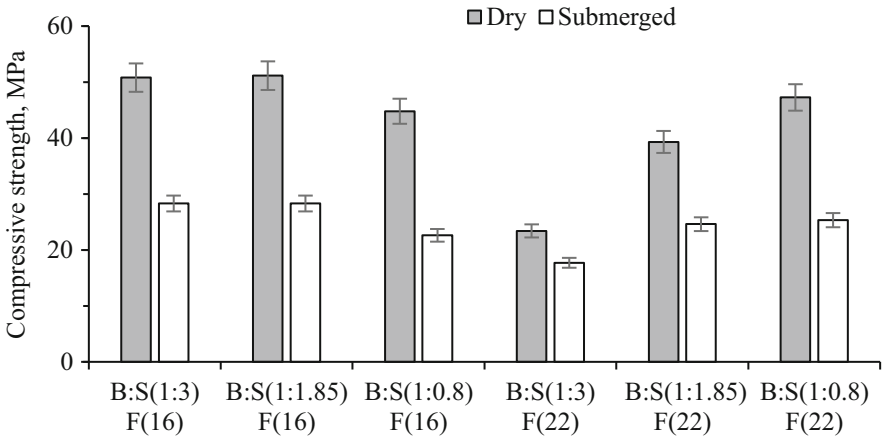

Fig. 6 28-day compressive strength values

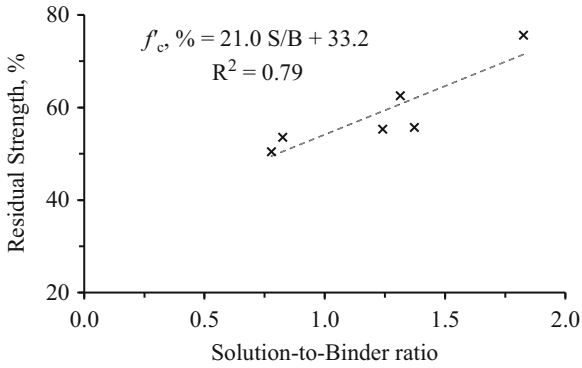

Fig. 7 Correlation between the solution-to-binder ratio and residual strength

sand as fine aggregates [22]. However, it appears that the amount of AAS added to the first group of mixes having 16 ± 1 cm flow was insufficient for the activation of MK particles, which resulted in a drop in strength. This becomes apparent when comparing the strength values of B:S(1:0.8) F(16) and B:S(1:0.8) F(22), where the strength increased from 44.8 to 47.2 MPa with an increase in AAS-to-binder ratio from 0.78 to 0.83 (Table 1). Similar findings were found elsewhere [22]; the maximum strength values of fly ash and slag-based geopolymer mortar produced with dune sand were achieved with an alkaline solution-to-binder ratio of 0.60.

Figure 7 presents the relationship between the residual compressive strength and alkaline solution-to-binder ratio, with an acceptable R^2 of 0.79. Hence, the higher the solution content, the better the residual compressive strength of GP mortars. This phenomenon is attributed to the high viscosity of the solution, which may act as a barrier preventing water penetration and dilution of the mortar matrix at early age casting.

4 Conclusions

This research focused on the formulation of MK-based alkaline-activated GP mortars intended for underwater applications. The impact of different flowability, alkaline solution content, and binder-to-sand ratios on setting time, plastic viscosity, washout loss, and compressive strength was assessed. From the foregoing, it can be concluded that the setting times increased with a decrease in binder content and mixtures possessing higher flow values. The washout loss was well correlated to the plastic viscosity of the mortar, wherein the increase in sand content and decrease in alkaline solution content (i.e., lower flowability) resulted in greater resistance against washout loss. The difference in compressive strengths of mortars placed in dry and submerged conditions decreases with the increase in the alkaline solution, which worked as a barrier for water intrusion inside the mortar matrix. Such data are quite promising for advancing the adoption of GP materials in underwater construction practices, ultimately contributing to a more sustainable and eco-friendly built environment.

1 Introduction

The pursuit of sustainable practices in the construction industry has led to the exploration of alternative materials that can reduce environmental impact while maintaining or even enhancing performance. Calcium sulphoaluminate (CSA) cements have emerged as a promising substitute for ordinary Portland cement (OPC) due to their inherent advantages, including reduced CO_2 emissions and lower energy requirements during production [1, 2]. These attributes align closely with the objectives of sustainable development, driving efforts to integrate eco-friendly materials into construction practices.

Around 2.01 billion tons of municipal solid waste (MSW) are generated globally each year [3]. With urbanization on the rise, leading to a surge in MSW production, urgent steps must be taken for sustainable waste management. A prevalent solution involves the incineration of these MSW where some by-products are generated such

as fly ashes. In way with circular economy and sustainability, different types of industrial wastes and alternative materials have been extensively studied as raw materials in the production of clinkers [4–7], and the municipal solid waste incineration fly ashes (MSWI FA) have garnered attention as a potential resource within the construction sector. Their incorporation into building materials offers an avenue to improve performance and minimize dependence on traditional raw materials so they have been evaluated as a supplementary cementitious material [8], as a precursor material in geopolymers [9], in asphalt mixtures [10], and as a raw material to produce ordinary portland clinker [11] and CSA cements [12].

Several studies have demonstrated the viability of producing CSA clinker utilizing MSWI FA through analyses of various factors such as clinkering temperature [12], kiln residence time, and different formulations of raw meal modules [13], microstructure [14] and durability [14, 15]. However, MSWI FA have a distinctive condition in their chemical and mineralogical compositions such as the presence of some chlorides and trace metals. The potential impact of these constituents on the formation of cementitious phases during clinkering and consequently their influence on the hydration process of the resulting products have not yet been studied in detail.

This research aims to explore the feasibility and effects of using MSWI FA as a raw material in the production of CSA clinkers and evaluate its effect on the development of cementitious phases and hydration products. This study contributes to a broader discourse on waste management practices and the development of innovative building materials that align with sustainability and circularity goals in the construction industry.

2 Materials and Methods

2.1 Materials

The raw meal used in the production of CSA clinker consists mainly of a calcium source such as calcium carbonate ($CaCO_3$), gypsum ($CaSO_4{\cdot}2H_2O$) as a source of sulfur and calcium, fly ash as a source of silicon and iron, and a source of aluminum. The chemical composition of the raw materials was determined by X-ray fluorescence (XRF) and is shown in Table 1. The MSWI FA is sourced from the municipal solid waste incineration plant located in San Andres Island, Colombia. The MSWI FA shows as a source of calcium, sulfur, and silicon, with the presence of chlorine and some trace elements shown in Table 2.

2.2 Mix Designs and Samples Preparation

The mix designs for preparing the raw meal were standardized across all formulations, ensuring consistency in key parameters. The substitution levels of MSWI FA varied at 10%, 20%, 30%, and 40% in the raw meal composition and each

formulation maintained an alkalinity modulus (Cm) of 1.05, an alumina–sulfur ratio (P) of 3.0, and an alumina–silica ratio (N) of 2.5 [13]. Table 3 shows the raw mix composition of each formula.

All raw meals underwent the same burning conditions. The clinkering process involved heating from room temperature to 800 °C at a rate of 15 °C/min holding the temperature at 800 °C for 30 minutes to ensure decarbonation, followed by heating from 800 °C to 1250 °C at a rate of 7 °C/min. The temperature was then held at 1250 °C for 45 minutes. Subsequently, the samples underwent thermal shock to prevent phase retrogradation post-burning.

2.3 Test Methods

2.3.1 X-Ray Diffraction (XRD)

The copper anode was used for the test, operated at 45 kV/40 mA, collecting data from 5° to 69.9° (2θ) with steps of 0.017 °2θ and an accumulation time of 59.7

seconds in continuous mode at 25 °C. For qualitative identification of the crystalline phases and quantitative analysis by Rietveld, refinement was carried out using the software X'Pert-HighScore Plus, ensuring an Rwp (Weighted R Profile) value close to or below 20 and a goodness of fit close to 1.

2.3.2 Thermal Analysis (TGA–DSC)

Thermogravimetric analysis and differential scanning calorimetry (TGA–DSC) was carried out on a TA Instruments brand SDT 650 simultaneous thermogravimetric equipment under an inert nitrogen atmosphere from room temperature to 1250 °C with a heating ramp of 15 °C/min up to 800 °C where the temperature was constant during 30 min, then the heating ramp was adjusted at 7 °C/min until reaching 1250 °C. These conditions were established in order to coincide with the clinkering conditions.

2.3.3 Isothermal Microcalorimetry

Tam Air Thermostat 90/3116-1 isothermal conduction microcalorimetry equipped with admix ampoules was used to study the samples. 1.43 g of raw meal as a solid part was mixed with 1.00 g of water to guarantee a w/c = 0.70 was tested at 25 °C. The mixing was carried out at a speed of 55 rpm for 150 seconds.

3 Results and Discussions

3.1 Mineralogic Development

The XRD patterns of CSA clinkers are show in the Fig. 1 and the mineralogical quantification of clinkers by Rietveld refinement in the Table 4. The proposed formulation for CS0 clinker (blank), with an alumina–silica ratio (N) of 2.5, aimed to achieve a ye'elemite to gehlenite ratio close to 1:1 [16] allowing for the assessment of MSWI FA's impact on phase development. Rietveld quantification revealed 19.3% ye'elemite and 19.9% gehlenite in the sample. Additionally, the blank sample exhibited the highest anhydrite content at 11.9% and showed the presence of calcium dealuminate, suggesting incomplete ye'elemite formation and development.

CSA1 clinker is characterized as the sample with the lowest percentage of anhydrite (3.9%) and belite (27.2%), alongside the presence of ternesite, a phase that can sometimes be associated with the ye'elemitic–belitic system [9, 10]. Ternesite typically forms in systems characterized by low temperature and short residence time, where the reaction between belite and anhydrite is facilitated [17], hereby accounting for the low amounts of these phases in the clinker. A total of 10% MSWI (CS1) shows to encourage ye'elemite development and anhydrite

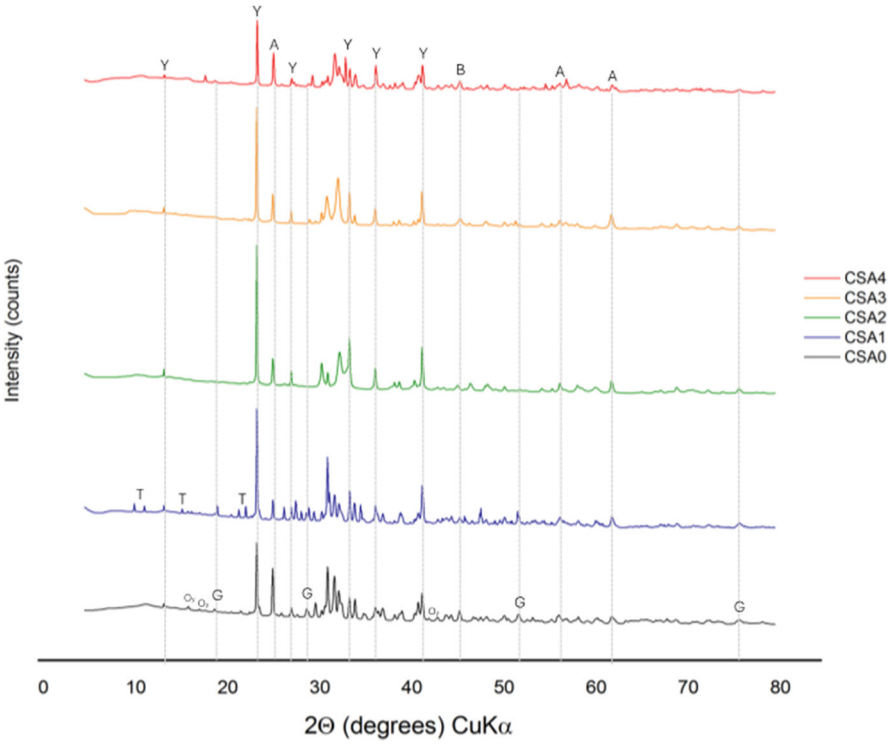

Fig. 1 XRD pattern of CSA clinker. Y: Ye'elimite, Oy: Orthorhombic Ye'elemite, A: Anhydrite, G: Gehlenite, B: Belite, T: Ternisite

Table 4 Mineralogical quantification of clinkers

		CSA0	CSA1	CSA2	CSA3	CSA4
Ye'elemite	$C_4A_3\check{S}$	19.3	27.0	38.7	30.9	18.3
Anhydrite	$C\check{S}$	11.9	3.9	9.8	6.7	11.6
Belite	C_2S	41.5	27.2	51.4	56.9	55.8
Gehlenite	C_2AS	19.9	14.2	0.2	–	–
Calcium dialuminate	CA_2	7.4	–	–	–	–

Merwinite	C_3MS	–	–	–	–	–
Alite	C_3S	–	–	–	5.5	–
Wadalite	$C_{x(y)}S_z{\cdot}Cl$	–	–	–	–	14.3

consumption compared to the blank sample; however, ternesite formation evidences a low phase development process.

The main phases identified in the CSA2 (20% MSWI) clinker are ye'elemite with 38.7%, belite with 51.4%, and to a lesser amount anhydrite with 9.8% and gehlenite with 0.2%. This composition makes CSA2 the clinker with the best phase

development. CSA3 (30% MSWI) composed of 56.9% belite, 30.9% ye'elemite, 6.7% anhydrite, and 5.5% alite, which has three important characteristics: it boasts the highest belite content among all the clinkers analyzed, the second highest ye'elemite content and the only one where alite was identified. This means that in contrast to 10% MSWI FA, with 20% and 30% of MSWI FA, the ash acts as a mineralizer, promoting the reaction kinetics during clinkerization and also suggests a stabilizing effect possibly due to the contribution of trace metals.

Wadalite was identified in CSA4 (40% MSWI) clinker, a calcium chloride silicate phase. It is important to identify this phase because it shows the possibility of stabilizing chlorine in the CSA cement structure. The stabilization of this phase is due to the fact that by increasing the amount of MSWI FA in the raw meal formulation, so does the amount of magnesium, which is necessary to distort the structure of the calcium silicates in formation and stabilize the chlorine in it [18]. The high MSWI FA content leads to the decomposition of ye'elemite releasing SO_3 forming anhydrite, while the available calcium is stabilized in the form of belite.

Thereby, it is possible to observe a notable variation in the compositions of the main phases across the different CSA clinkers. CSA2 exhibits the highest proportion of ye'elemite at 38.7% followed by CSA3 at 30.9%. All samples show a higher ye'elimite development compared to CSA0, whereas CSA4 having the lowest content with 18.3%, only 1% lower than the blank (19.3%). CSA1 stabilizes ternesite, CSA3 alite with a high belite content, and CSA4 wadalite.

The presence of alite in CSA3 and the effects evidenced in the clinkers suggest that MSWI FA acts as a flux and mineralizer which promotes the development of phases at low temperatures, and that in adequate proportions it acts as a stabilizer of phases of interest such as alite or wadalite. Furthermore, employing MSWI FA obviates the need to augment the alumina–silica ratio (N) in the raw meal formulation to prevent gehlenite formation.

3.2 Thermal Analysis of Raw Meal

Figure 2 shows the TG, DTG, and DSC curves of raw meals CSA0, CSA2, and CSA3 treated up to 1250 °C. Up to 800 °C all the raw meals show a similar behavior as the temperature increases. The first endothermic peak associated to dehydration of gypsum takes place at ~120 °C. Near to ~350 °C, an exothermic effect appears corresponding to the phase transition of γ-$CaSO_4$ into β-$CaSO_4$ form [19]. For CSA2 and CSA3, the decarbonation occurs ~35 °C earlier than the CSA0 blank likely due to the flux effect of the MSWI FA over the system, where the low melting point of chlorides (NaCl + KCl) around 650 °C [20] and high ionic mobility decrease the activation energy required for the decarbonation reaction.

After the full decarbonation of the calcium carbonates, a second endothermic peak related to liquid phase formation appears at 890 °C for the CSA3 raw meal, at 905 °C for the CSA2, and at 980 °C for the blank [21]. This shows again a fluxing effect of the MSWI FA decreasing the formation temperature of the liquid phase as

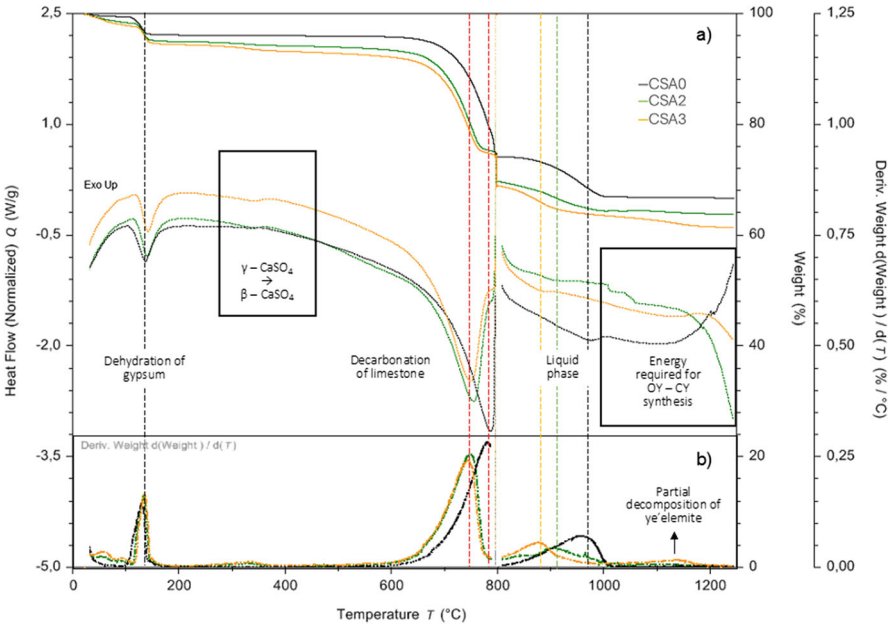

Fig. 2 Thermal analysis of CSA0, CSA2, and CSA3 raw meal. (**a**) TGA-DSC curves (**b**) Derived weight loss curves

the amount of MSWI FA increases. Above 1000 °C, the phase transformations associated with the formation of ye'elemite take place. The energy needed for orthorhombic ye'elemite (OY) synthesis is higher than for cubic ye'elemite (CY), evidenced by a more pronounced endothermic transition in OY, requiring a higher energy flux during the transition to become ye'elemite [22]. This suggests that in the CSA0 clinker, orthorhombic ye'elemite (OY) synthesis is favored, while the samples utilizing MSWI FA promote the formation of cubic ye'elemite (CY). Figure 1 allows to discern this distinction via the XRD patterns between the two polymorphs of ye'elemite, orthorhombic for the CSA0 sample and cubic for CSA2 and CSA3 [23]. This phenomenon is likely attributed to the trace metals within MSWI FA, which act as mineralizers, facilitating the formation of phases with lower energy requirements. During this process, CSA3 exhibits a weight loss near 1150 °C, possibly associated with a minor decomposition of the ye'elemite already formed [22].

3.3 Early Hydration of Cement Paste

The early hydration at 3 days of the clinkers was studied by isothermal microcalorimetry at a water–cement ratio of 0.70 (see Fig. 3). In the curves, four peaks are

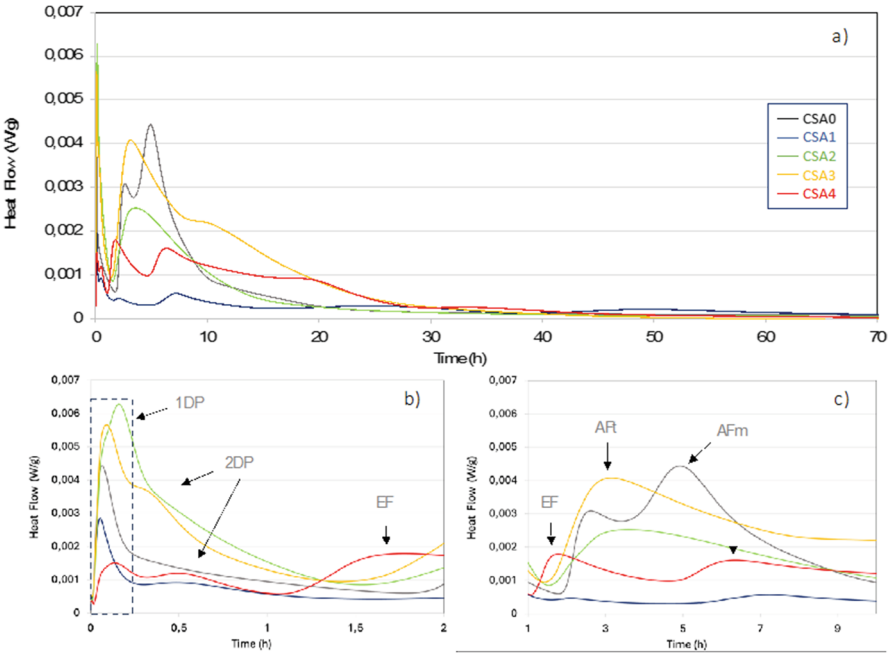

Fig. 3 Heat flow development of clinkers with w/c= 0.70 to: a) 0–70 h, b) 0–2 h, and c) 1–10 h. 1DP (First dilution peak), 2DP (Second dilution peak), EF (early formation)

mainly identified. The first of them occurs in the first 15 minutes of hydration and corresponds to the induction stage, where the dissolution of ye'elemite and C-S-H gel formation occurs. A secondary peak, discernible as a shoulder in the curves, corresponds to the dissolution of anhydrite [24]. These initial two peaks occur before the first hour of hydration, giving way to the dormant period. CSA4 represents the first clinker to break the dormant period, which, in its case, is nearly nonexistent. The peak manifests around 1.5 hours into hydration and correlates with the formation of Friedel's salts stemming from the hydration of calcium chloride aluminosilicate [17, 25]. For the remaining phases, the third peak, indicative of the hydration and precipitation of ettringite and AFt phases [26], typically emerges around the 3-hour mark, while the fourth peak, associated with AFm phases, occurs between 5 and 6 hours. In the case of the blank (CSA0), there's a preference for the formation of AFm phases over AFt attributable to sulfate depletion, as indicated by the absence of the second dissolution peak of anhydrite (2DP) [27]. However, due to the orthorhombic polymorph ye'elimite, a notable formation of AFt phases, surpassing even that of the CSA2 clinker.

CSA2 and CSA3 exhibit the highest heat flux released during the first and second dissolution peaks. Both clinkers share an approximate dormant period of one hour before entering the acceleration stage. Then, only a peak is observed within the AFt range, indicating an efficient sulfate consumption for the ettringite formation. Once sulfate is depleted, the formation of AFm phases ensues. The sluggish and low

reaction kinetics observed in CSA1 clinker can be attributed to the significant presence of ternesite in its composition. Ternesite is noteworthy due to its intermediate reactivity, serving as a link between the rapid reaction of ye'elemite and the delayed reaction of belite [28]. However, ternesite exhibits reactivity solely in the presence of aluminum phases like $Al(OH)_3$, $C_{12}A_7$, or C_3A, facilitating the formation of AFm-type phases [17]. Additionally, the low anhydrite content contributes to decreased hydration kinetics of the clinker. The third outstanding peak in the CSA4 at about 6 h aligns with the formation of AFm phases. This occurrence is possibly promoted by the fact that being the clinker produced with the highest percentage of MSWI FA, there is an inhibition in the dissolution of some phases such as anhydrite due to the impurities present, causing a sulfate depletion during hydration and promoting the formation of AFm phases [6].

Figure 4 shows the DTG plots of all hydrated clinkers at w/c = 0.70 after 3 days. The first set of peaks are identified approximately at 100–120 °C, mainly due to the dehydration of C-S-H and the release of water molecules from ettringite [19, 20]. Second set of peaks between 200 and 250 °C correspond to the dehydration of AFm-type phases [29] and at ~270 °C the dehydroxilation of aluminum hydroxide gel $Al(OH)_3$. The non-presence of portlandite decomposition at ~450 °C may suggest that after 24 h in the absence of calcium sulfate and ye'elemite [30, 31], portlandite reacts with aluminum hydroxide to produce more AFm phases [32]. CSA2 shows to be the clinker with greater C-S-H and AFt as hydration products, which is consistent with the mineralogy identified by XRD, while the CSA0 clinker shows a greater decomposition of AFm-type phases and aluminum hydroxide. The dehydration of Friedel's salt is identified around 280 °C [33, 34].

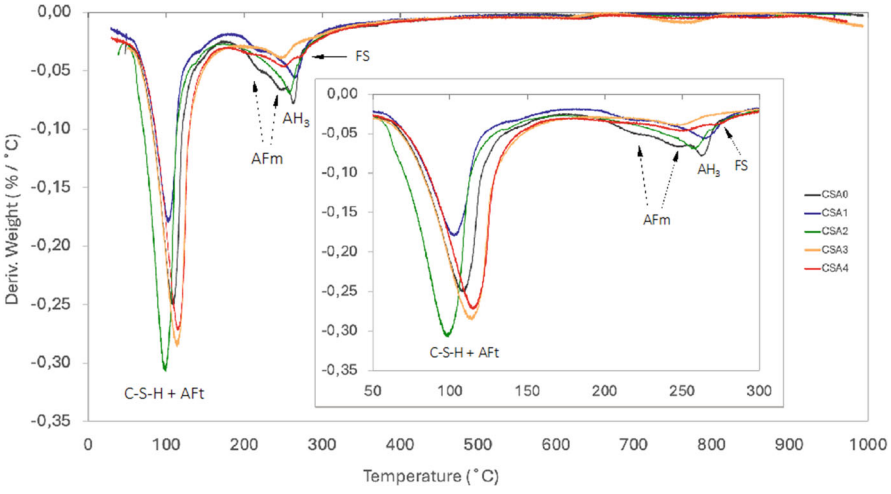

Fig. 4 Thermogravimetric curves of clinkers with w/c = 0.70 to 3 days

4 Conclusions

Utilizing MWSI FA as a raw material for CSA cement production enhances the formation of key phases such as ye'elemite and belite, while also stabilizing alite, owing to its fluxing, mineralizing, and stabilizing attributes derived from its chemical and mineral composition. In this study, incorporating 20 wt% MWSI FA into the raw meal formulation resulted in an improved clinker composition. However, increasing the usage to 30% demonstrates even more favorable effects on phase development.

Employing MSWI FA avoids the need to augment the alumina–silica ratio (N) in the raw meal formulation to prevent gehlenite formation. This is significant, particularly considering one of the drawbacks of CSA cements compared to OPC lies in the availability of aluminum, a resource in limited supply and extensively sought after in other industrial sectors.

The utilization of MSWI FA as a raw material triggers reaction kinetics at lower temperatures and fosters the formation of phases requiring less energy, which occurs in the decarbonation or the liquid phase formation. This implies a potential melting and mineralizing effect exerted by the incineration ash.

In future research, it is essential to assess the distinct impact of the components within MSWI FA, particularly focusing on chlorinated compounds and trace elements.

challenges. The cement and concrete industry is now the world's largest producer of carbon emissions. To achieve the goal of net zero carbon emissions by 2050, researchers, engineers, and the industry have invested heavily in research and development of materials and equipment and other strategies to reduce carbon emissions and indirectly reduce the payments of carbon tax [1, 2]. As the global steel industry has continued to flourish in recent years, steel has become an indispensable and significant industrial material. In particular, the increased demand in engineering fields, such as high-rise buildings and bridges, has strengthened the utilization of steel materials. Recycled steel waste has increased as reinforced steel and steel materials have been produced at higher rates [3, 4]. Over the past few years, electric arc furnace oxidizing slag (EAFOS) has become the primary recycling material due to the recycling industry's requirements. For a long time, EAFOS reuse has troubled the relevant engineering units. The industry strongly advocates that resources should be recycled and reused, and how to use EAFOS is the research focus at this stage [5, 6]. The EAFOS waste was a typical solid waste with high iron content and hardness, making it unsuitable for grinding into powder for reuse. Reprocessing EAFOS also led to high production costs. This treatment option contributed significantly to alleviating the shortage of natural aggregates by using crushed EAFOS as a direct substitute for aggregates [7, 8]. However, using EAFOS instead of natural aggregation has led to problems with expansion and cracks on the surface of the concrete because of the effect of free calcium oxide (f-CaO) or magnesium oxide (f-MgO) [9]. Therefore, the development of stabilization technology to replace natural aggregates with EAFOS is an essential task at this stage.

The use of EAFOS as aggregates was subject to the requirement of volume stability. In the past, alkali-activated technology was used as the test procedure for the stabilization of EAFOS [10, 11]. Although using such alkali-activation technology to reuse EAFOS was feasible, practical application required the addition of chemical agents, which also increased the cost. It was found in the literature that EAFOS should be able to be successfully used in cement mortars to replace fine aggregates in combination with other industrial by-products such as copper slag and coal bottom ash [12, 13]. Past studies have shown that recycled aggregates have the potential to be precoated to enhance recyclability and adaptability [14, 15]. The same precoated technology can be applied directly to EAFOS, verifying its feasibility and achieving EAFOS stabilization. In this study, EAFOS was selected as an industrial by-product to replace the natural aggregates and to improve the recycling efficiency of the waste. The paste mixing process provided EAFOS with a precoated layer of cement, ground granulated blast furnace slag (GGBS), or fly ash. It verified the most suitable precoated material and the best aggregate replacement ratio for precoated EAFOS. The volumetric stability of the precoated EAFOS mortar has also been continuously verified to verify the stabilizing effect of this solution on EAFOS particles.

2 Test Programs

2.1 Materials

The precoated materials used in this study consisted of Portland Type I cement, GGBS, and fly ash. The specific gravities of the three precoated materials were 3.15, 2.88, and 2.72, respectively. The fineness of the three precoated materials was 3690 cm^2/g, 5850 cm^2/g, and 10,500 cm^2/g, respectively. EAFOS was sourced from Tung Ho Steel Enterprise Corporation in Taiwan. EAFOS conducted tests in the range of fine aggregate gradations to replace the natural aggregates in the mortar specimens. EAFOS had a modulus of fineness of 3.90, water absorption of 3.80%, and a specific gravity of 3.60. Results of the EAFOS sieve analysis tests are shown in Fig. 1. It was found that EAFOS aggregates were significantly coarser than fine aggregates, and their grading curves deviated from ASTM requirements. Subsequent tests were performed to improve the particle size distribution of EAFOS using paste-precoated technology.

2.2 Paste-Precoated Method

Three types of binders (cement, GGBS, and fly ash) were used as paste-precoated materials in this test. Different water-to-binder ratios (w/b) were used as variables. The test procedure was to mix the paste-precoated materials into a paste specimen at a specified w/b. And the next procedure was to mix the paste with EAFOS using a mixer for 5 min to perform the subsequent procedures. The precoated EAFOS was then allowed to cure in the air for 7 days and tested by sieve analysis. The test procedure is to set the No. 4 (4.75 mm) sieve passing rate to 85% of the paste-precoated group, which was regarded as the test group that met the requirements. The test variables included two parameters, namely the amount of paste-precoated (20%, 25%, 30%, 35%, and 40%) and w/b (0.20, 0.25, 0.30, 0.35, 0.40, 0.45, and 0.50).

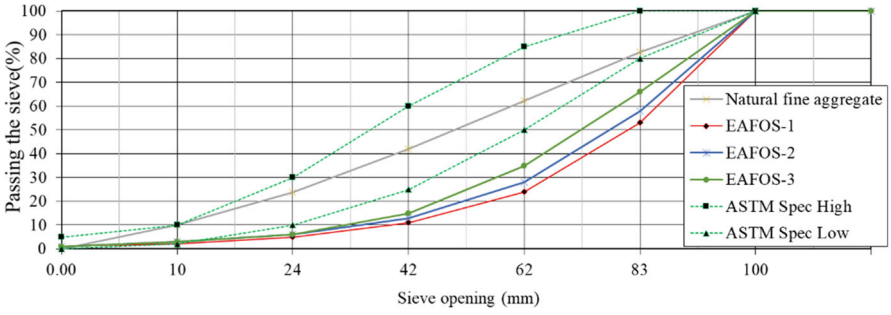

Fig. 1 Results of the EAFOS sieve analysis tests

Table 1 Mix design of control group (kg/m^3)

Water	Cement	Fine aggregates
288.1	523.8	1440.5

2.3 Mix Design

The mix design for the control group is shown in Table 1, and the w/b was fixed at 0.55. EAFOS was used to replace 10–50% of fine aggregates in 10% increments. The ratio of cement to aggregates was 1:2.75.

2.4 Testing Methods

The sieve analysis of natural fine aggregates and EAFOS particles was carried out according to ASTM C136 specification. The specific gravity and water absorption of natural fine aggregates and EAFOS particles were tested with reference to the ASTM C128 specification. The compressive strength tests of mortar specimens were conducted by referring to ASTM C109. The specimen size for compressive strength was 50 × 50 × 50 mm. The dry shrinkage tests of mortar were conducted with reference to ASTM C596, and the size of the specimen was 25 × 25 × 285 mm. The measurement of length change was mainly based on the observed value on the first day as the zero point (reference point), and the measurement values for each age were the observed values. Scanning electron microscope (SEM) observations were conducted in accordance with the recommended procedures of the ASTM C1723 specification. The specimens were selected after compressive strength tests from broken specimen fragments (size less than 3 × 3 × 10 mm).

3 Results and Discussion

3.1 Precoated Properties of EAFOS Particles

EAFOS was mixed with three types of binder using the paste precoated technique and cured for 7 days, and the test groups that passed 85% through a No. 4 sieve (4.75 mm) are listed below. For the cement group, the passing percentages were 83%, 89%, and 86% for the precoated EAFOS with a paste amount of 30% and w/b of 0.35, 0.30, and 0.25, respectively. Aggregates with 35% and 40% paste content showed a less than 15% passing percentage. This means that the EAFOS particles in the fine grades have jumped to the coarse grades due to excessive precoated pastes. For the GGBS group, the passing percentages were 86% and 87% for the precoated EAFOS with a paste amount of 30% and w/b of 0.35 and 0.30, respectively. The same trend was observed in the GGBS group. When the amount of precoated was

Table 2 Specific gravity and water absorption of different types of precoated EAFOS

Indicators	Precoated EAFOS					
	–	Cement	GGBS	GGBS	Fly ash	Fly ash
Parameters for w/b and precoated amount	–	0.35	0.35	0.30	0.40	0.35
	–	30%	30%	30%	40%	40%
Specific gravity	3.60	3.30	3.20	3.28	3.29	3.25
Absorption (%)	3.80	8.80	7.53	4.82	3.39	3.01

20% and 25%, although its passing percentage met the requirement of more than 85%. It can be observed from the external observation of the precoated EAFOS particles that there is insufficient precoated paste. For the fly ash group, the passing percentages were 92% and 92% for the precoated EAFOS with a paste amount of 40% and w/b of 0.40 and 0.45, respectively. Insufficient precoated pastes were also observed in groups with less than 35% precoated content. From the relevant studies, it can be found that these surface coatings were beneficial to forming surface hydration layers on the EAFOS particles to achieve the effect of particle stabilization [16, 17].

Table 2 summarizes the specific gravity and water absorption of EAFOS particles, cement-precoated, fly ash-precoated, and GGBS-precoated EAFOS (curing at room temperature for 7 days). The lower specific gravity of the coated particles compared to the EAFOS particles demonstrates the lower weight for the same volume. The GGBS and fly ash precoated group had a lower specific gravity than the cement group (cement had a higher specific gravity of 3.15 compared to the two binders). In addition, the water absorption of the coated particles was higher than that of the original EAFOS particles. The cement group had the highest water absorption. On the contrary, the GGBS and fly ash groups showed significantly lower water absorption than the cement group. It was evident that the pozzolanic reaction led to an increase in compactness and a decrease in water absorption. Such a trend is consistent with the findings of previous studies [18, 19].

3.2 Compressive Strength

Development curves of EAFOS utilization against compressive strengths for non-precoated group are shown in Fig. 2. The compressive strength was negatively affected by EAFOS doping without paste precoated, and the strength began to decrease significantly at 40% replacement. In addition to being coarser than natural fine aggregates, EAFOS aggregates are distributed in approximate section grades. Large amounts of EAFOS resulted in grain size grades deviating from ASTM specifications. This significantly reduced the strength of the mortar. For the cement-precoated group, a precoated amount of 30% with a w/b of 0.35 was used as a parameter. The development of compressive strength with the corresponding

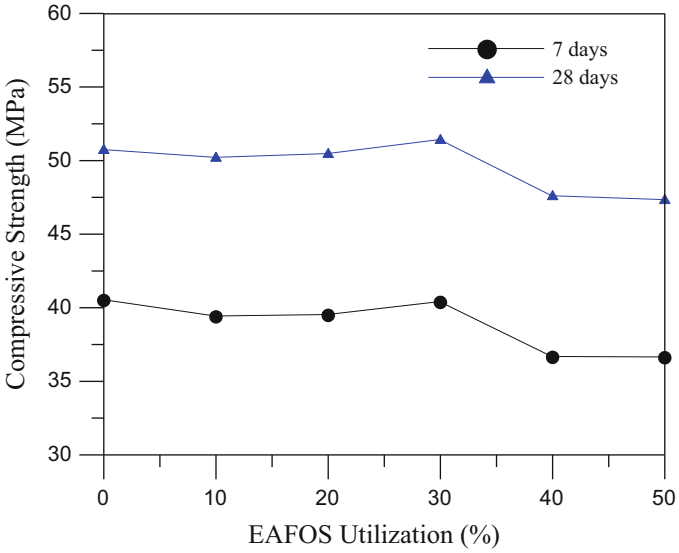

Fig. 2 Development of EAFOS utilization against compressive strengths (non-precoated)

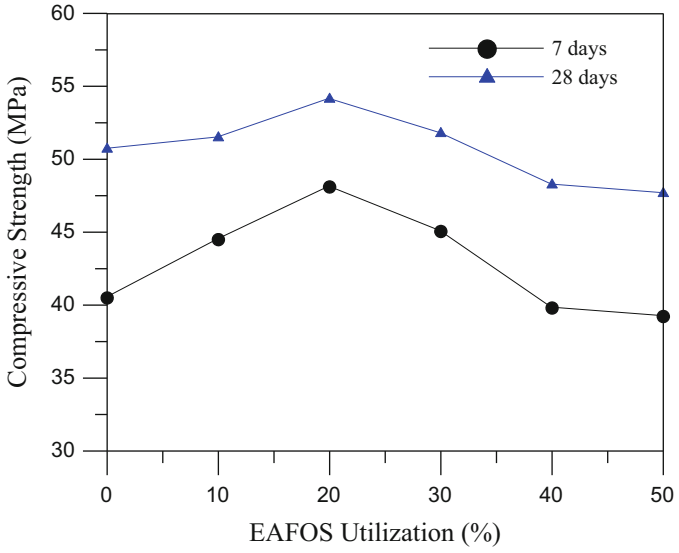

Fig. 3 Development of EAFOS utilization against compressive strengths (cement-precoated)

EAFOS replacement is shown in Fig. 3. Cement-precoated specimens increased their compressive strength, with the maximum compression strength of 20% EAFOS being substituted. Compressive strength has also increased significantly with the

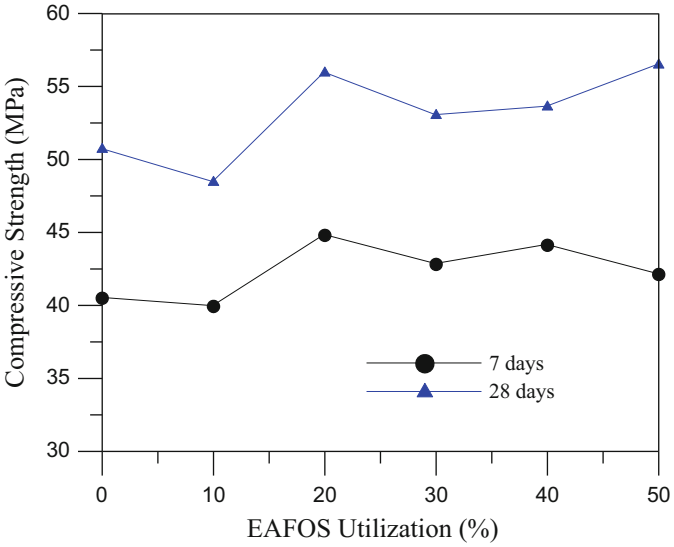

Fig. 4 Development of EAFOS utilization against compressive strengths (GGBS-precoated)

increase in EAFOS replacement. It is clear that the paste-precoated technology contributed to the improved suitability of EAFOS aggregates. Prior to the production of mortar specimens, the paste precoated EAFOS aggregates were allowed to cure for 7 days. To further increase the strength of the specimens, it is recommended to increase the curing time to 28 days.

For the GGBS-precoated group, a precoated amount of 30% with a w/b of 0.30 was used as a parameter. The development of compressive strength with the corresponding EAFOS replacement is shown in Fig. 4. GGBS was slightly more potent than the cement group, and the optimum substitution was also 20%. The maximum strength of the GGBS group (20% EAFOS) was up to 55.92 MPa. Under the same curing conditions, GGBS had a better pozzolanic reaction and a better interfacial transition zone between aggregates and pastes. There was an improvement in the compactness of the paste and an increase in strength [16]. For the fly ash-precoated group, a precoated amount of 40% with a w/b of 0.35 was used as a parameter. The development of compressive strength with the corresponding EAFOS replacement is shown in Fig. 5. Because of the high fluidity of fly ash, a precoated amount of 40% was required. The fly ash-coated specimens were not significantly stronger due to the long curing times required for fly ash to develop the reactive properties required for pozzolanic materials. The maximum strength (47.97 MPa) of the fly ash-precoated specimens was achieved with 30% EAFOS replacement. In conclusion, coated EAFOS particles helped to increase the compressive strength of the mortar. GGBS as paste-precoated materials provided superior compressive strength. Compared to previous findings [8, 20], such paste-

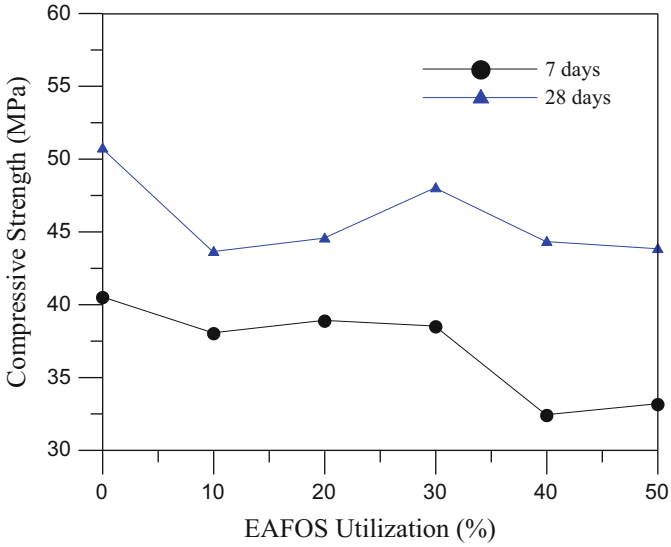

Fig. 5 Development of EAFOS utilization against compressive strengths (fly ash-precoated)

precoated technology provided an effective solution for replacing aggregates with EAFOS and offered superior compressive strength and a cost-effective treatment process.

3.3 Length Variations

Length variations of mortar specimens with different precoated methods are illustrated in Fig. 6. The w/b of cement, GGBS, and fly ash paste-precoated materials were 0.35, 0.30, and 0.35, respectively, for 20% EAFOS replacement (based on better strength considerations). Observing the length variations within 28 days, it was found that the length variations of the paste-precoated materials were similar to those of the un-precoated specimens. The precoated method contributed to the control of the expansion behavior of the specimens. Compared with the results of compressive strength, the paste-coating method is favorable for increasing strength and utilization. This treatment solution contributed to the high-volume reuse of EAFOS and achieved industrial waste reuse efficiency. The appearance of the specimens immersed in 90-degree water for 28 days after demolding is shown in Fig. 7. From the appearance of the specimens, it can be found that there were no abnormalities such as cracking and swelling in the various proportions.

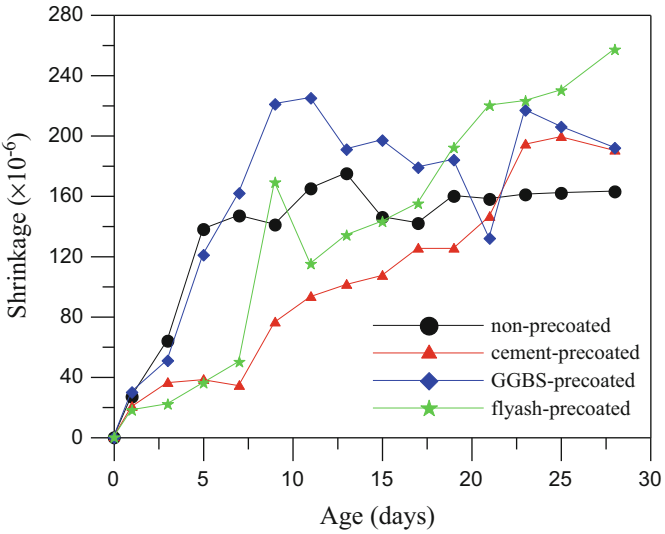

Fig. 6 Length variations of mortar specimens with different precoated methods

Fig. 7 Appearance of specimens immersed in water at 90° for 28 days

3.4 SEM Observations

SEM photographs of the three paste-precoated materials are shown in Figs. 8, 9, and 10. The w/b of cement paste-precoated materials was 0.35, GGBS paste-precoated materials was 0.30, and fly ash paste-precoated materials was 0.35. The replacement rate of EAFOS was fixed at 30%. Significant inter-crystalline gaps were found in the microstructure of cement paste-precoated materials. AFt and calcium hydroxide were also observed, and hydrates filled the remaining voids. The microstructure of

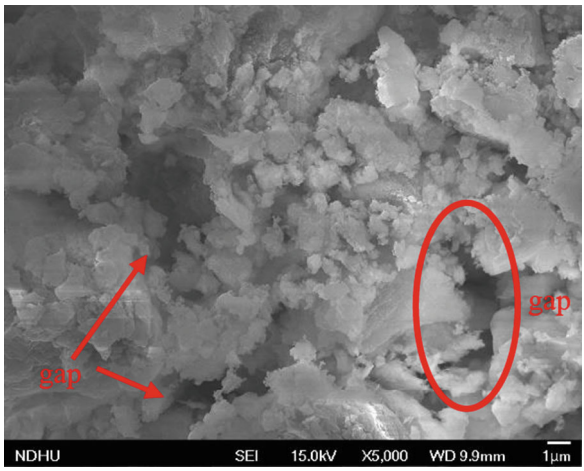

Fig. 8 SEM photo for cement-precoated specimen

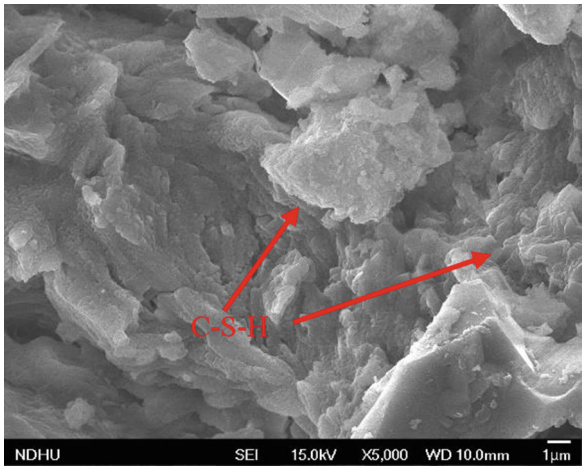

Fig. 9 SEM photo for GGBS-precoated specimen

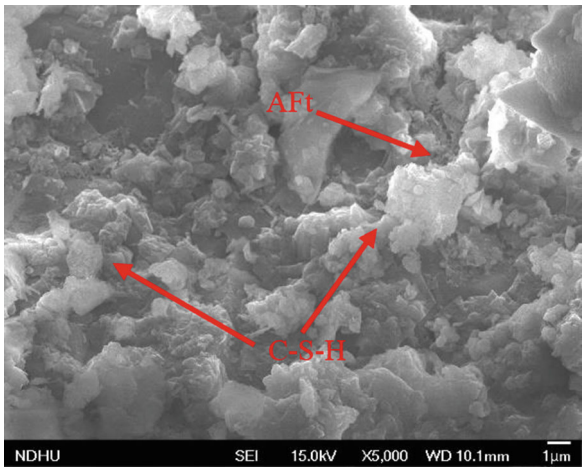

Fig. 10 SEM photo for fly ash-precoated specimen

GGBS paste-precoated materials had fewer pores than cement paste-precoated materials, the surface was significantly smoother and denser, and the amount of AFt and sodium hydroxide was reduced considerably. This is the main reason that GGBS paste-precoated materials possess better compressive strength than other compositions. The microstructure of the fly ash paste-precoated materials showed noticeable unreacted fly ash particles, AFt and calcium hydroxide, with smaller gaps between the crystals and a smoother surface. The surface had fine hydrates but required continuous curing to facilitate hydration reaction.

4 Conclusions

The results are summarized as follows:

1. The compressive strength of natural aggregates replaced by uncoated EAFOS in mortar specimens did not increase significantly with increasing amounts of aggregate. Strength began to deteriorate at 30% replacement.
2. The paste-precoated method benefited the compressive strength of EAFOS mortars, and the optimum replacement was between 20% and 30%. The precoated specimens also maintained excellent volume stability.
3. Among the three paste-precoated materials, GGBS-precoated showed the highest compressive strength (55.92 MPa at 20% EAFOS replacement).
4. The paste-precoated method should pay attention to the amount of precoated and the w/b of the binders; the optimal amount of precoated was 30–40%, and the w/b was 0.30 ~ 0.35.
5. This paste-precoated technology provided an effective solution for replacing aggregates with EAFOS and offered superior compressive strength and a cost-effective treatment process.

1 Introduction

The rapid growth of industrialisation and urbanisation has made the construction industry greater than ever. The global construction volume is expecting a 3.2% yearly increase in the next decade [1]. However, the production process of Ordinary Portland Cement (OPC) is energy intensive. It is reported that the construction sector is responsible for ~39% of the Global greenhouse gas emission [2]. In order to achieve net-zero, alkali-activated material (AAM) has gained increasing attention due to its comparable mechanical properties to OPC and environmentally friendly nature [3]. AAM is produced via the activation of the solid aluminosilicate precursors by the activator solution, where polycondensation takes place and the main hydration product C-(A)-S-H is produced. The most commonly used base materials are ground granulated blast furnace slag (GGBS), Class-F fly ash and metakaolin, while the alkaline activator often consists of one or more chemicals such as sodium

hydroxide (NaOH), sodium silicate ($Na_2O{\cdot}2SiO_2$) or sodium carbonate (Na_2CO_3) aqueous solution [4]. Depending on the geographic location, the availability of base material and the alkali activator may vary. Depending on the raw materials used, the cost and energy of manufacturing alkali-activated binder can save up to 45% and 75%, respectively, in comparison to OPC [5].

Properly designed AAM mixes can have superior engineering properties. Literature [6] suggests that when using 8% sodium silicate by the weight of slags, it has an amazing compressive strength of 80.9 MPa at 28 days. When similar amounts of Na_2CO_3, NaOH, and $Na_2O{\cdot}2SiO_2$ are used as a sole activator for slag cement, the 28-day compressive strengths are 33.0 MPa, 55.9 MPa and 64.7 MPa, respectively [7]. Despite the outstanding mechanical performance of AAM, it still has many shortcomings, such as hazardous chemicals, flash setting and high drying shrinkage, which are mainly linked to the activator material [8]. At the current stage, the most widely used activator is NaOH, which is very environmentally and user-unfriendly due to its caustic nature. Besides, high temperature ranging 1100–1200 °C is required during the NaOH production process [9]. All of the mentioned problems impede the wide application of AAM. Recently, it has been found that using Na_2CO_3 as a sole activator can solve most of the short comings. However, longer setting times and lower mechanical strengths were seen due to its low alkalinity nature. These two problems limit Na_2CO_3-activated GGBS concrete as a main construction material [5].

Therefore, efforts have been made to enhance the early-day mechanical properties of Na_2Co_3-activated GGBS concrete. For example, the use of MgO and nucleation seeding have been proven effective, which could triple the 28-day compressive strength [8]. So far, no study has considered to utilise graphene as a seeding material in AAM, although graphene has demonstrated outstanding performances on traditional cementitious material due to the nano-filler and nucleation effect [9]. The large surface area of graphene will provide additional nucleation sites between the cement particles. Hence, a denser structure can be achieved.

This study is focusing on the role of graphene on setting time, early-day mechanical strength and working mechanism at the microstructural level of Na_2CO_3-activated GGBS concrete. The aim of this study is to find out the key effects of graphene in AAM systems by quantitative measurement of the changes. This study first tested the 3-day compressive strength performances. Afterwards, the scanning electron microscope (SEM) was employed to observe the microstructure changes. Finally, X-ray diffraction (XRD) was used to analyse the formation of hydration products.

2 Materials and Methodology

2.1 Materials

The graphene powder used in the experiments was PureGRAPH 50 supplied by First Graphene (UK) with an average particle diameter of 50 μm and tapped density of

0.395 g/cm^3. GGBS of this research (density of 2.4–3 g/cm^3) was obtained from Conserv (UK), in line with BS EN 15167-1:2006. The sodium carbonate (Na_2CO_3) was obtained from Fisher scientific (UK). The activator is in a powdered form and the purity is ≥99.5%. Ordinary river sand and coarse aggregates (up to 10 mm) were used in the concrete samples. Note that mechanical test samples were prepared with aggregates while samples for setting time tests and microstructure imaging were prepared in paste form without aggregates to avoid contamination. The composition of GGBS concrete used was Na_2CO_3/GGBS = 0.08 and water/binder ratio = 0.375.

2.2 Sample Preparation

Graphene solutions, by the process of ultrasonification, were prepared in five different concentrations (0%, 0.005%, 0.0075%, 0.01% and 0.02% by weight of GGBS), denoted as 0G, 0.005G, 0.0075G, 0.01G and 0.02G, respectively. The Na_2CO_3 alkali activator was added into the graphene solution (graphene powder and water), dispersed using Cole-Parmer Ultrasonic homogeniser for 1 h around 20 ± 3 °C (20 s dispersion with 3 s break at amplitude of 35%). The graphene/Na_2CO_3 solution was then added into the cement drum mixer first, followed by GGBS powder. Sand was added until the GGBS paste reached a smooth consistency (the operation took about 2 min). Coarse aggregates were then added and the mixing process lasted 3 min. Finally, the concrete mix was casted into moulds, placed on vibration table for 60 s and cured at 20 ± 3 °C exposed to air until the day of testing.

2.3 Characterisation

Compressive strength measurement was carried out using Controls C56Z00 compression frames, with specimen size of 50 × 50 × 50 mm. The tests were carried out in line with EN12390-3 [10] standard. Five repeat tests were performed for each mix. Setting time measurements, on the paste form of GGBS only, were obtained using Vicatronic E044N, according to EN 480-2 [11].

Scanning electron microscope (SEM) images were obtained by TESCAN MIRA3 FEG-SEM, the accelerating voltage used was 10 kV. Both secondary and backscattered modes were used to observe surface changes and the distribution of unreacted GGBS.

XRD was recorded on Bruker Autochanger using Cu K_α radiation with 40 kV and 30 mA. Calcium fluoride was used as an internal standard. The scanning rate is 0.04° 2Θ/step from 5° to 70° 2Θ. This was used to identify the composition and crystallinity of different phases.

3 Results

3.1 Setting Time

The initial and final setting times of Na_2CO_3− activated GGBS pastes are shown in Fig. 1. The number on the y-axis indicates the percentage of graphene by the weight of GGBS. The control sample (0 wt.%) has a relatively long setting period with an initial and final setting times of 2.93 and 6.67 h. This long setting time is related to the low alkalinity of the pore solutions. The setting time has an inverse relationship with the dosage of graphene. When 0.02 wt.% graphene is used, the initial and final settings are reduced by 1 and 0.7 h, respectively. The reduction on both initial and final setting times shows that graphene influences both the dissolution and hardening stages of GGBS formation. This finding is in line with other graphene-modified traditional cementitious materials. The shortened setting time is related to the nucleation effect of graphene.

3.2 Compressive Strengths

The compressive strengths of specimens with various amounts of graphene are presented in Fig. 2. Clearly, the presence of graphene has an overall positive effect on compressive strength. This finding is consistent with other studies conducted on traditional cementitious materials [9], due to graphene acting as a nucleation site for hydration products to grow on. However, the strength gained is not always proportional to the graphene added. In other words, there is an optimal level of graphene content. As shown in Fig. 2, when 0.005 wt.% graphene is added into the mix, the

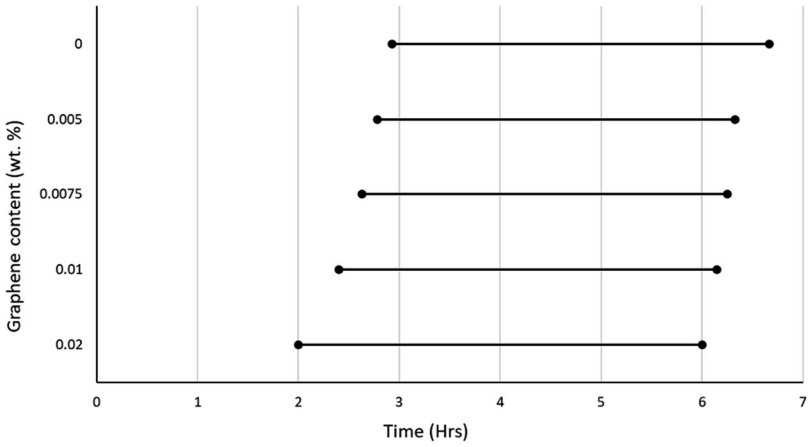

Fig. 1 Initial and final setting times of the samples

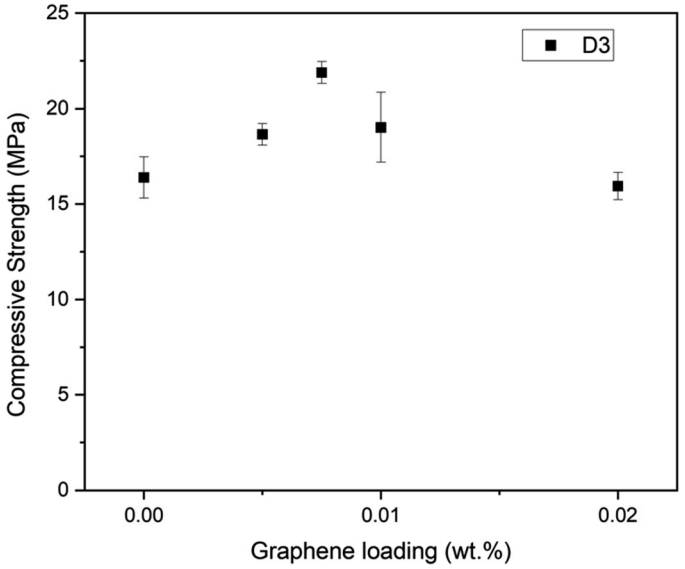

Fig. 2 3-day compressive strength with various graphene loadings

strength increased by 13.8%. When 0.0075 wt.% graphene is added, the increase of compressive strength is around 31%. After reaching the optimum levels, the increases in compressive strength of concrete are much less. Based on these sets of results, the optimum level of graphene content is about 0.0075 wt.% for 3-day compressive strength.

In fact, adding more graphene may lead to a reduction in concrete compressive strength compared with control sample. The observation is that there is an optimal level of graphene content. This suggests that in addition to the beneficial effect of graphene nucleation, incorporating graphene introduces a competing mechanism. Due to the nature of graphene, agglomeration of graphene will often occur at higher dosage, thus reducing the number of nucleation sites, leading to reduced increase in compressive strength. Furthermore, the smaller number of larger nucleation sites may introduce some weakness in concrete, this is attributed to the uneven hydration products formation through the matrix. This can lead to a reduction in concrete strength compared to the specimen without graphene [9, 12].

3.3 SEM Analysis

Figure 3 presents SEM images of undamaged concrete mixes after 3-day curing for different graphene contents. Obviously, the addition of graphene can cause significant microstructure changes. For the control sample, unreacted GGBS particles are often surrounded by large gaps or cracks, due to the 'slow reaction' nature of

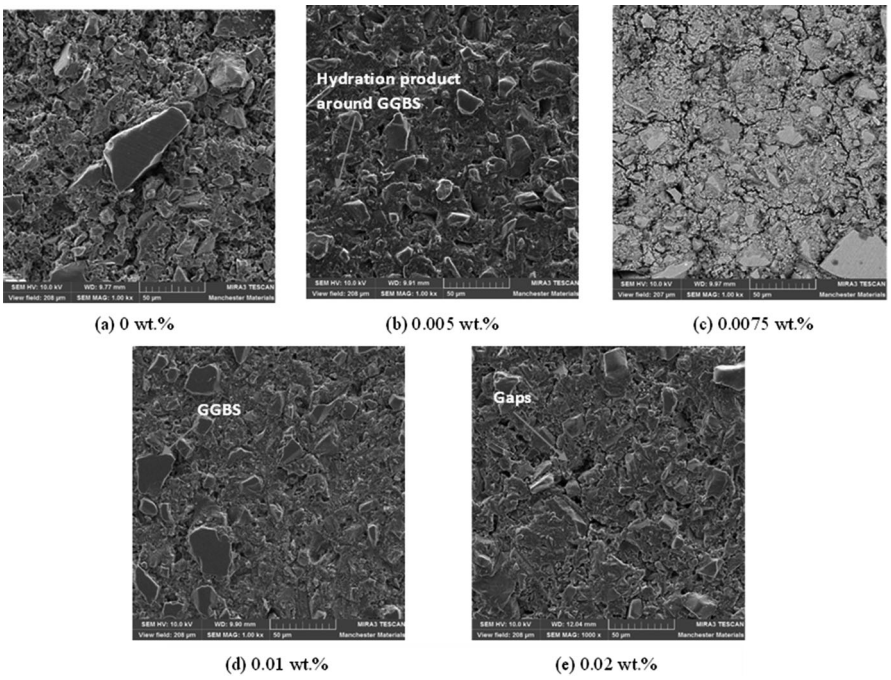

Fig. 3 SEM image for various 3-day samples (**a**) 0 wt.% (**b**) 0.005 wt.% (**c**) 0.0075 wt.% (**d**) 0.01 wt.% (**e**) 0.02 wt.%

Na_2CO_3 with GGBS as shown in Fig. 3a. When graphene content increases from 0 to 0.005 wt.%, the microstructure of the concrete changes from the control sample having a very porous microstructure with uneven distribution of unreacted GGBS particles (large grey shapes), to much more compact and dense microstructures. The same effect appears in other samples with graphene. With the addition of graphene, there are much less unreacted GGBS particles owing to more nucleation sites enabling more reactions. These can be seen by hydration products covering GGBS particles. Furthermore, the big pores observed in the sample without graphene are spilt into many small micro pores, which is attributed to the nano-filler effect of graphene.

However, when the graphene content increased from 0.01 to 0.02 wt.%, the gaps around the GGBS particles became larger and the overall structure became more porous. The reason might be that higher dosages of graphene lead to agglomeration, resulting in less nucleation site as mentioned in previous paragraph [13]. Moreover, the larger nucleation sites will likely introduce some weakness in concrete. Hence, identifying an optimum graphene level for GGBS concrete design is crucial. Based on the SEM observation, the optimum level remains around 0.005 wt.%, which is in line with the 3-day compressive test results.

An additional beneficial effect of graphene in cementitious material is that graphene makes any crack development in concrete become more tortuous (as shown in the red highlighted lines) [14]. For example, Fig. 4 compares cracks

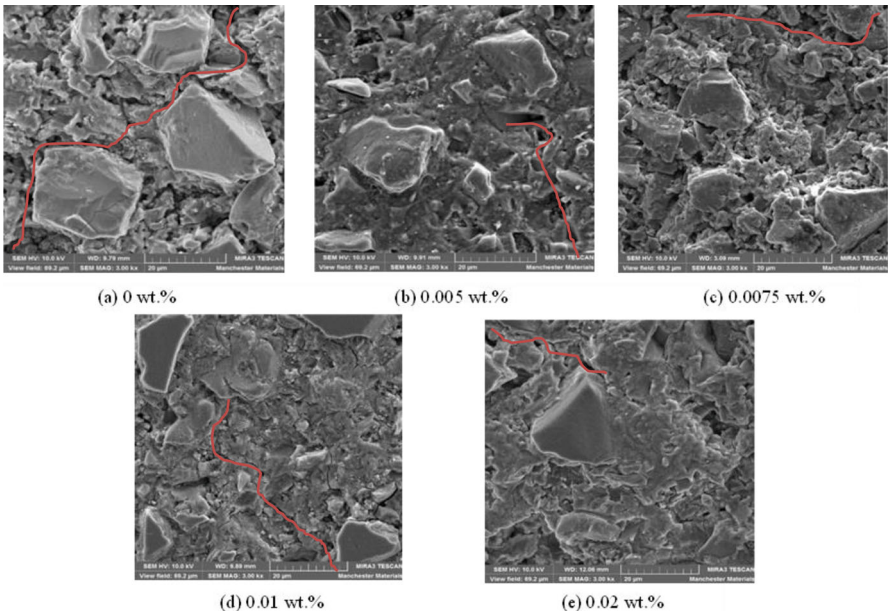

Fig. 4 Cracks propagation in the 3-day samples (**a**) 0 wt.% (**b**) 0.005 wt.% (**c**) 0.0075 wt.% (**d**) 0.01 wt.% (**e**) 0.02 wt.%

in concrete samples without graphene and with 0.005% graphene after mechanical testing at 3 days. The cracks in the control sample without graphene are almost straight, whereas the graphene-modified sample has several finer and discontinued cracks with occasional branching off. When graphene content increased to higher dosages, the propagation of cracks is stilled being control without competing effect of 'agglomeration'. This can be directly observed from the mechanical strength test. The mechanical strength has an inversely proportional relationship with the size of the cracks. As the graphene dosages increase, the cracks have been mitigated. Hence, the overall compactness has been increased, which leads to an increase in the overall strength. Once the optimum dosage has been reached, the effects of graphene on the cracks decreased. Therefore, the overall compactness is slightly weakened compared to the optimum level. Which explains the decreased strength gains.

3.4 XRD Analysis and Associated Chemical Reactions

The proposed 3-day chemical reaction is listed as follows. In Eq. (1), when the moment activator is added into the dry precursor. The CaO from slag reacts with water leads to an increase in the alkali environment. The reaction product (Ca^{2+}) is a key component in the reaction process, as Ca^{2+} initialises the following reactions (i.e., Eqs. (2) and (3)). In Eq. (2), the activator itself contains Na+ and CO_3^{2-}, the Ca^{2+} is from the reaction in Eq. (1), which is the reaction in between CaO from slag

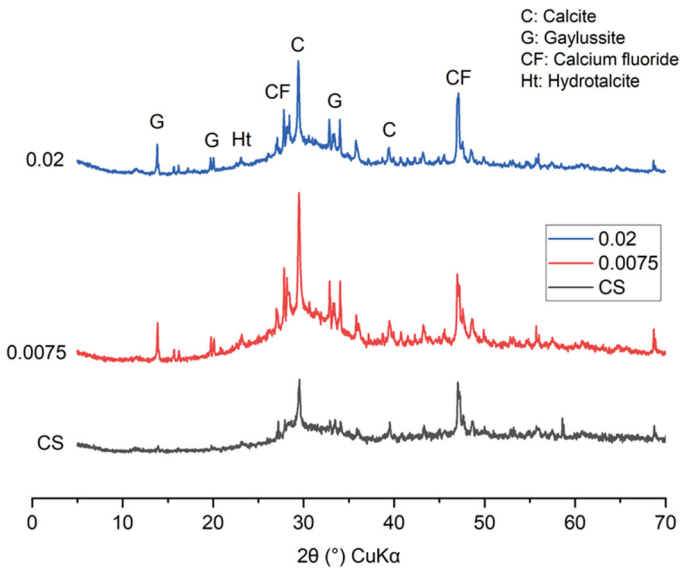

Fig. 5 XRD phases comparison of the 3-day samples

and the water added. Due to the weak bonding in between O and Ca. The O-Ca bond breakage can be carried out in a low alkalinity environment without any additional environment requirements (such as evaluated temperature) [8]. Therefore, the following Eq. (2) will take place to form gaylussite. Afterwards, gaylussite will quickly free ions to form calcite in Eq. (3).

$$CaO + H_2O \rightarrow Ca^{2+} + 2OH^- \tag{1}$$

$$5H_2O + 2Na^+ + Ca^{2+} + 2CO_3^{2-} \rightarrow Na_2Ca(CO_3)_2 \cdot 5H_2O \text{ (gaylussite)} \tag{2}$$

$$Ca^{2+} + CO_3^{2-} \rightarrow CaCO_3 \tag{3}$$

Figure 5 shows the combination view of the XRD patterns of CS, 0.0075 wt.% and 0.02 wt.% graphene samples, it suggests that when graphene is added into the sample, the peaks are constantly sharper and higher than the control sample. Calcium fluoride was included as the internal standard in this test. The main hydration phases are gaylussite ($Na_2Ca(CO_3)_2 \cdot 5H_2O$; PDF #01-072-8410) and calcite ($CaCO_3$; PDF #01-071-3699), which identified via using Highscore. It suggests that the formation of calcite phase increase by 22% when 0.0075 wt.% graphene added. The optimum level has been reached at this point, the reason being that the formation of calcite reduced to 15% increase when 0.02 wt.% graphene added. This finding is closely linked to the mechanical strength test. Figure 2 shows the compressive strength test results, it indicates that the addition of 0.0075G leads to greater than 30%

compressive strength performance at 3 days curing. The 30% increase is related to the amount and crystallinity of phases formed in the sample. The reason being that gaylussite ($Na_2Ca(CO_3)_2{\cdot}5H_2O$; PDF #01-072-8410) and calcite (CaCO3; PDF #01-071-3699) are the main strength providers during the 3-day reactions. Hence, the mechanical performance is directly linked to the amount of these two hydration phases formed.

With the addition of graphene added into the system, the peaks do not change, the only difference is the intensities of all phases are constantly higher than the plain sample. As shown in Fig. 5, the shapes of all peaks in each sample are the same. When 2θ at 13°, 20°, 30°, 33°, 35° and 40°. The identical peaks suggest that no new crystalline chemical phases were found, and graphene only takes account of the physical reactions. This finding is similar to the findings from others in traditional cementitious material. Which the addition of graphene only will change the shapes of the humps and peaks. In other words, graphene will only have an impact on the crystallinity of the phases. The sharper the peak is, the higher the crystallinity will be.

Overall, a higher degree of formation of all phases are observed in samples with addition of graphene in the system. The intensity increases in calcite and other crystalline phases is due to the nucleation effect of graphene. Due to the nano-size nature, graphene will fill in the macro pores and split the big pores into small micropores. Hence, a much-compacted structure was seen, leading to increased compressive strength. Also, promotes nucleation leading to increased reactions.

4 Conclusions

This paper has presented the results of a research study to investigate the effects of graphene on the 3-day compressive strength and setting time of Na_2CO_3-activated GGBS concrete. Various microstructure analyses were obtained to explain the fundamental mechanisms of the effects of graphene. Graphene can be used as an effective additive to increase early-day compressive strengths of Na2CO3-activated GGBS concrete, increasing the 3-day result by up to 33% at the optimal level of graphene dosage of 0.0075% in weight of GGBS. The improvement on setting time due to the incorporation of graphene is modest, achieving about 20-min reduction in setting time at the optimal graphene dosage (i.e. 0.005% by weight of GGBS). The effects of graphene on Na_2CO_3-activated GGBS concrete are controlled by two main mechanisms: nucleation effect (which promotes nucleation leading to increased reactions) and nano-filler effect (which fills in the macro pores and split the big pores into small micropores). Hence, a much-compacted structure was seen, increased compressive strength. Moreover, graphene will not change the chemical reactions during the hydration process, it will affect the amount of hydration products formed in the process. It is found that the inclusion of 0.0075% graphene will lead to 22% and 11% increase in the formation of calcite and gaylussite, respectively. This finding is in line with the compressive strength test results.

1 Introduction

With the development of bioinspired green solutions for sustainable construction, Microbially Induced Calcium carbonate Precipitation (MICP), which uses microbial metabolic processes for biocementation to improve the durability of concrete and masonry materials, has received a lot of attention in different sectors [1–5]. This approach has several advantages over traditional methods that use Portland cement: MICP's embodied energy is 43–95% less than that of conventional cement as it occurs at ambient temperature [6]; the carbon footprint from the MICP process is about 18–49.6% lower than traditional cement [6, 7]; due to the relatively low viscosity of the cementation solution and bacterial suspension, they can flow easily through the pores of the concrete, leading to better permeability [8]; and bacteria's small dimensions (<10 μm) compared to cement particles (<40 μm) lead to higher efficacy of MICP for holes as small as 6 mm [9]. Each of the mentioned benefits

represents a significant advancement in the development of a low-carbon construction material and contributes to the achievement of net-zero construction.

In this context, the literature extensively discusses the mechanism of biocementation for a large spectrum of microorganisms, from bacteria and cyanobacteria to fungi and microalgae and even the enzymes isolated from them [1–5]. The latter is not discussed here for the sake of brevity. Bio-cementation is an intricate process that is influenced by various factors. The quantity and quality of $CaCO_3$ precipitation are influenced by various factors, including the type and conditions of microorganisms (such as live bacteria, bacterial fractions, or isolated enzymes), the method of application (e.g., mixing, spraying, injection, and percolation), and environmental conditions like pH, temperature, and nutrition media, as well as the availability of nucleation sites for bacterial growth [10–12].

While experimental characterization of the bio-cementation has advanced significantly at the laboratory scale, the feasibility of scaling up this technology to the building site and field scale has yet to be thoroughly investigated. This considerable limitation is primarily due to the complicated nature of the process, which occurs on several temporal and dimensional scales and involves interrelated biological, chemical, hydraulic, and mechanical processes [12]. In this respect, numerical models that predict ideal environmental conditions and application processes, while taking into account interrelated elements, might pave the way for optimization and scalability of the technology. However, compared to the experimental characterization of bio-cementation, computational modeling of this phenomenon has not made as much progress [13]. Only a few studies have been devoted to the computational modeling of bio-cementation, which mainly focused on the application process parameters rather than simulating the effects of the environmental conditions [14, 15]. Sharma et al. [14] developed a simplified model to simulate the kinetics of the bacterial ureolysis, the dynamic balance between the liquid–gas interface and the supersaturation of ions, as well as the kinetics of formation of calcite. Qin et al. [15] utilized PHREEQC software to simulate the development of biofilm, the introduction of nutrition media, and the formation of calcium carbonate under various injection flow rates at pore scales ranging from 18 to 400 μm. Undoubtedly, Paassen [16] has conducted one of the most comprehensive experimental and analytical investigations in the literature, providing physical and chemical models for various influential factors that impact bio-cementation.

The first step in optimizing bio-cementation involves establishing the optimal environmental conditions that promote the highest level of urease activity in microorganisms. In this regard, a computational model able to predict the outcome of bio-cementation influenced by environmental conditions can shed light on maximizing the effectiveness of bio-cementation exploitation. Among the environmental variables (e.g., pH, nutrition supply, temperature, etc.), pH has the most significant impact on microorganisms' metabolic processes, as the by-products of $CaCO_3$ precipitation induce a fluctuation in the pH of the environment, which in turn continuously affects the urease activity in microorganisms [11, 16, 17]. This results in a loop between the urease activity rate and pH variation.

This chapter focuses on the impact of environmental conditions (urea and calcium concentrations) on the urease activity of the most studied bacterium, *Sporosarcina pasteurii*, with a particular emphasis on the effect of pH level variation in the environment over time. First, the theoretical foundation of the bio-cementation phenomena, including environmental variables influencing urease activity and controlling biochemical reactions, is described. Next, the computational model structure in COMSOL Multiphysics® is systematically elucidated. Subsequently, the simulation's prediction for $CaCO_3$ concentration, pH fluctuation over time, and electrical conductivity under certain experimental conditions are compared with the experimental outcomes to assess the model's accuracy. Last but not least, a parametric analysis of the effect of the initial pH of the environment on the final pH is presented.

2 Theoretical Background

2.1 Influential Parameters

The rate of urea hydrolysis is mostly influenced by the enzyme type and population, the environmental conditions, storage, hydrolysis, and precipitation [10, 16, 18]. Among these parameters, environmental factors, including urea and calcium content in the system, pH, and temperature, substantially impact on urease activity [12, 16, 18]. The ideal environmental conditions for bio-cementation differ depending on the microorganism or isolated enzyme type, as each microorganism or enzyme has a distinct optimal pH and temperature for its enzymatic activity [12]. Furthermore, these ideal conditions vary once again depending on whether the microorganism or isolated enzyme is used [12]. As this study specifically examines the impact of pH and considers the hydrolysis of urea at a constant temperature (of 25 °C), the effect of temperature variation is not taken into account.

The effect of urea concentration on the hydrolysis rate of urea (R) is known to follow Michaelis–Menten kinetics (Eq. 1) [14–16], where R_{max}, K_{m_ur}, and C_{ur} are the maximum hydrolysis rate, urea concentration at which the reaction rate is half of R_{max}, and urea concentration, respectively.

$$R = R_{max} \times \frac{C_{ur}}{K_{m_ur} + C_{ur}} \tag{1}$$

On the other hand, calcium concentration affects the urease activity following the exponential equation shown in Eq. (2), where the coefficient K_{iCa} is the concentration at which the urease activity is reduced to 37% of its original value [16, 18].

$$R = R_{max} \times e^{-C_{Ca}/K_{iCa}} \tag{2}$$

The impact of ambient pH, however, is deeply convoluted. As previously stated, each microorganism or enzyme has distinct ideal environmental conditions for its growth. Similarly, these organisms also experience particular environmental conditions that permanently hinder their enzymatic activity. This impediment, also known as denaturation, is the result of the enzyme undergoing structural modifications and losing its functionality. Therefore, urease activity declines within a specific pH range, both below and above the optimal pH range, generating a bell-shaped inhibition curve that can be represented using the expression (Eq. 3) proposed by Batstone [19], where pH_{LL} and pH_{UL} represent the minimum (lower limit) and maximum (upper limit) pH values, respectively, at which the hydrolysis rate is decreased by 50%.

$$R = R_{max} \times \frac{1 + 2 \times 10^{0.5(pH_{LL} - pH_{UL})}}{1 + 10^{(pH - pH_{UL})} + 10^{(pH_{LL} - pH)}} \tag{3}$$

It is crucial to emphasize that the values of parameters R_{max}, K_{m_ur}, K_{iCa}, pH_{LL}, and pH_{UL} vary not only between different microorganisms but also between a microorganism and the enzyme extracted from it [16, 19]. In addition, the parameter K_{iCa} is also influenced by the type of calcium source (e.g., calcium chloride, calcium nitrate, or soluble calcium) utilized as a nutritional medium [16, 19]. The K_{m_ur}, pH_{LL}, and pH_{UL} values for the *Sporosarcina pasteurii* bacteria were determined to be 10 (mM), 5, and 9.7, respectively, at a constant temperature of 25 °C [16, 18]. The value of K_{iCa}, on the other hand, which depends on the calcium source, was considered 0.6 mol/l for calcium chloride [16, 18].

Figure 1 depicts the normalized hydrolysis rate (R/R_{max}) of *Sporosarcina pasteurii*, described in Eqs. (1)–(3), as functions of urea and calcium concentrations

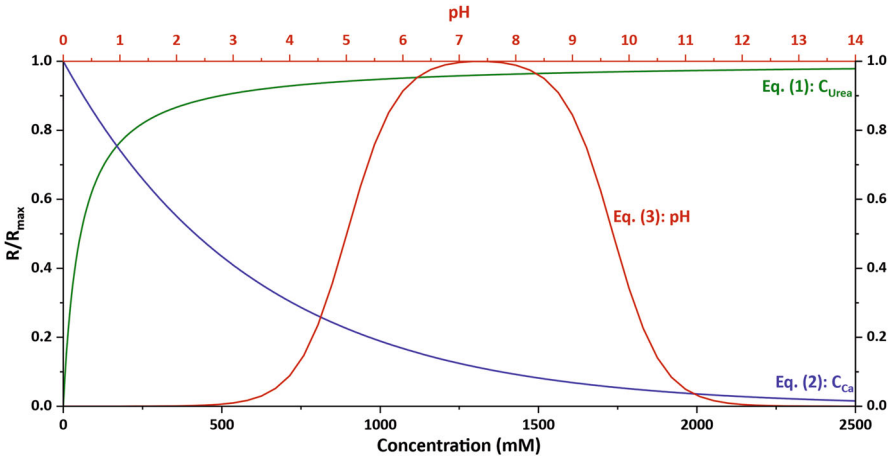

Fig. 1 The effect of urea concentration (green), calcium concentration from calcium chloride source (blue), and environmental pH (red) on *Sporosarcina pasteurii* hydrolysis rate

(from calcium chloride source) and the pH of the environment. As seen in this figure, the hydrolysis rate exhibits a substantial rise as the urea content in the solution increases up to about 1 M; beyond this concentration, the rate stabilizes at a nearly constant level (green line). In contrast, an increase in calcium content up to about 2 M results in a decrease in the rate of hydrolysis, while at higher concentration it does not cause any significant change (blue line). Regarding the impact of pH, the enzyme responsible for bio-cementation in *Sporosarcina pasteurii* denatures at pH levels below 3.5 and at pH above 12 [12]. Although it has been reported that the bacterium can remain alive up to a pH of 13.6, the enzyme essential for bio-cementation is denatured at a pH above 12; hence, no precipitation occurs under these conditions [12]. The bacteria exhibit optimal precipitation performance within a pH range of 6–8.75, where the hydrolysis rate, as influenced by the environmental pH, reaches 90% of its maximum rate (red line).

2.2 Chemical Reactions in Microbially Induced Calcium Carbonate Precipitation

Bio-cementation is an intricate process involving an array of biochemical reactions in which microorganisms, through the activity of the enzyme urease, catalyze the hydrolysis of urea, leading to the precipitation of calcium carbonate. First, urease catalyzes the decomposition of urea into ammonium (NH_4^+) and carbonate (CO_3^{2-}) through hydrolysis, which is an irreversible reaction (Eq. 4).

$$CO(NH_2)_2 + 2H_2O \longrightarrow 2NH_4^+ + CO_3^{2-} \tag{4}$$

Then, the presence of carbonate and ammonium in the aqueous solution triggers a series of reversible acid–base reactions within the medium until the system reaches equilibrium (Eqs. (5)–(13)). The equilibrium of each of these subsequent acid–base reactions is expressed by the pK_a value, which represents the acid dissociation constant on a logarithmic scale [20].

In more detail, under neutral pH conditions, bicarbonate (HCO_3^-) is the primary species in the system rather than the carbonate ion (CO_3^{2-}). This leads to an increase in pH in order to maintain a balanced charge; consequently, ammonium undergoes dissociation into ammonia (NH_3) until a state of equilibrium is achieved between NH_4^+/NH_3 and HCO_3^-/CO_3^{2-} (Eqs. (5)–(10)).

$$H_2O \leftrightharpoons OH^- + H^+ \ (pK_w = 14) \tag{5}$$

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \ (pK_a = 6.1) \tag{6}$$

$$H_2CO_3 \rightleftharpoons HCO_3^- + H^+ \ (pK_a = 6.35) \tag{7}$$

$$HCO_3^- \leftrightharpoons CO_3^{2-} + H^+ \ (pK_a = 10.33) \tag{8}$$

$$CO_2 + OH^- \rightleftharpoons HCO_3^- \ (pK_a = 7.64) \tag{9}$$

$$NH_4^+ + OH^- \rightleftharpoons NH_3 + H_2O \ (pK_a = 9.25) \tag{10}$$

On the other hand, calcium ions (Ca^{2+}) engage in interactions with other compatible species in the system, including carbonate ions that yield calcium carbonate, which is soluble in water (Eqs. (11) and (13)) and eventually precipitates as calcium carbonate crystals (Eq. 14). The equilibrium between the solid and aqueous calcium carbonate and its ions in the system is presented by the solubility product (K_{sp}).

$$Ca^{2+} + H_2O \rightleftharpoons CaOH^+ + H^+ \ (pK_a = 12.78) \tag{11}$$

$$Ca^{2+} + CO_3^{2-} + H^+ \rightleftharpoons CaHCO_3^+ \ (pK_a = 3.22) \tag{12}$$

$$Ca^{2+} + CO_3^{2-} \rightleftharpoons CaCO_3 \ (pK_a = 11.44) \tag{13}$$

$$CaCO_{3\,(solid)} \rightleftharpoons CaCO_3 \ \left(K_{sp} = 3.36 \times 10^{-9}\right) \tag{14}$$

3 Structure of the Numerical Model

COMSOL Multiphysics® 6.1 was used for the numerical modeling of the system. A one-space dimension with a time-dependent analysis was considered for this model. Figure 2 shows a diagram outlining the arrangement of inputs and workflow of the numerical model in relation to the described theory. The model was defined using two physics: reaction engineering, which accounts for chemical reactions in the system, and electrophoretic transport, which considers the balance of electrical charges of the medium's species in acid–base equilibria. The "thermodynamics" of a "vapor–liquid system" with an ideal solution and gas was added as a subnode to

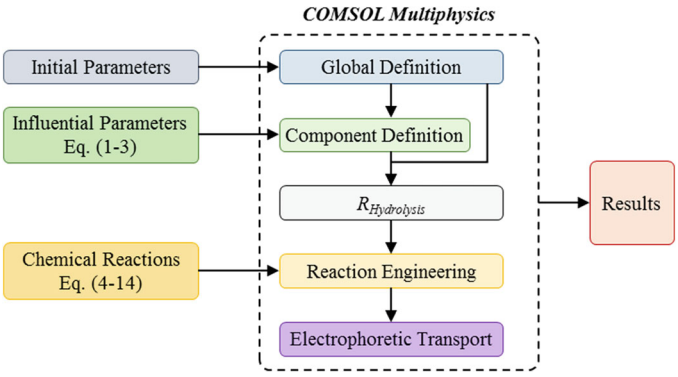

Fig. 2 Schematic representation of the inputs and workflow within *COMSOL Multiphysics*®

"Global Definition," recalling three species: ammonia (NH_3), carbon dioxide (CO_2), and water (H_2O).

The value for R_{max} was considered 40 (mM/h) at 25 °C [16, 18]. The effect of urea and calcium concentration, as well as the pH of the environment, on the activity of the enzyme urease was defined as three separate variables as described by Eqs. (1)–(3) under the "component definition" subnode. The urea concentration (C_{ur}) for Eq. (1) was defined as the variation of urea over reaction time. The pH value for Eq. (3) was defined as the logarithmic function of hydrogen ion concentration over time ($pH(t) = -\log [H^+(t)]$).

A new function ($R_{Hydrolysis}$) has been created that incorporates the rate dependency on urea and calcium concentrations, as well as pH (Eqs. (1)–(3)) with conditional statements to obtain a time-dependent reaction rate that changes as the parameters that affect urease activity change over time. Under the assumption that each function is independent of the other two parameters, $R_{Hydrolysis}$ alters the hydrolysis rate by integrating the values from all three functions in the following manner:

1. If the pH of the environment causes denaturation of the enzyme (pH <3.5 or pH >12), no precipitation occurs, and hence the hydrolysis rate is null.
2. If the pH falls within the permissible range of 3.5–12 and the normalized hydrolysis rate (R/R_{max}) from the effect of pH is above 0.5 and the one from the effect of calcium concentration is above 0.67, the hydrolysis rate is mainly affected by the urea concentration, which triggers the reactions.
3. If one of these conditions is not satisfied, an average value of normalized hydrolysis rate R/R_{max} from the three functions will be taken into consideration.
4. When the system reaches charge equilibrium for all species and the concentration of urea is significantly low to trigger ureolysis, the process comes to a conclusion.

A total of 11 chemical reactions were defined in the reaction engineering node: one irreversible reaction for urea hydrolysis (Eq. 4), nine reversible reactions for acid–base equilibrium in the system, considering the acid dissociation constant (pK_a) for each pertinent reaction (Eqs. (5)–(13)), and one reversible reaction for the solubility of calcium carbonate in an aqueous solution (Eq. 14).

The reaction rate for urea hydrolysis (Eq. 4) has been redefined as denoted function $R_{Hydrolysis}$. Initial concentrations of urea (C_{ur}), calcium (C_{Ca}), water (C_{H2O}), hydrogen ions ($C_{H}{}^{+}$), and hydroxide ($C_{OH}{}^{-}$) have been considered according to the experimental conditions presented in the literature in the "initial values" subnode.

The electrophoretic transport module utilized the predetermined solvent, water. The initial potential was set to zero. Urea was defined as a protein subnode with a neutral average charge (zero). CO_2, NH_3, and $CaCO_3$ were defined as uncharged species. $NH_4{}^+$ was specified as a weak acid with monoprotic donation and the pK_a from Eq. (10). H_2CO_3, on the other hand, was defined as a weak acid with polyprotic donation and two dissociation stages, with the first and second ionization constants reported in Eqs. (7) and (8), respectively. Both $CaOH^+$ and $CaHCO_3{}^+$ were defined as weak bases with monoprotic donation and relevant pK_a from Eqs. (11) and (12).

OH^-, H^+, Ca^{2+}, and CO_3^{2-} were defined as fully dissociated species with the relevant electrical charge. The concentration of all species in the electrophoretic node was determined by analyzing the variation in time of the relevant species resulting from reaction engineering. A time increment of 1 min was used to simulate the process over a period of 20 h. The data obtained from the simulation's global outputs comprised the evolution of species concentration in the system as determined by the reaction engineering module and the electrical conductivity derived from the electrophoretic module over time.

4 Results and Discussion

The first step of validating the numerical methodology outlined in this work involves comparing the simulation results with existing experimental data found in the literature. Figure 3 illustrates the comparison between the simulated concentrations of the main reactants (urea and calcium) and the resulting product (precipitated calcium carbonate) and by-product (ammonium) for a 0.5 mol/l concentration of urea and calcium and an initial pH of 6.67 obtained from calcium chloride and the experimental findings presented by Paassen [16].

The model accurately predicts both the final concentrations of reactants and products, as well as the evolution of these species' concentrations over time. Since the initial pH (6.67) falls within the ideal pH range of *Sporosarcina pasteurii's* urease during the early stage of the reaction, the rate of hydrolysis is maximized, resulting in a rapid occurrence of the reaction. Simultaneous consumption of equal quantities of urea and calcium results in the precipitation of an equivalent amount (1:1) of calcium carbonate. The ratio of ammonium production to reactant consumption is twice that of calcium carbonate precipitation, as expected. The reactions continue

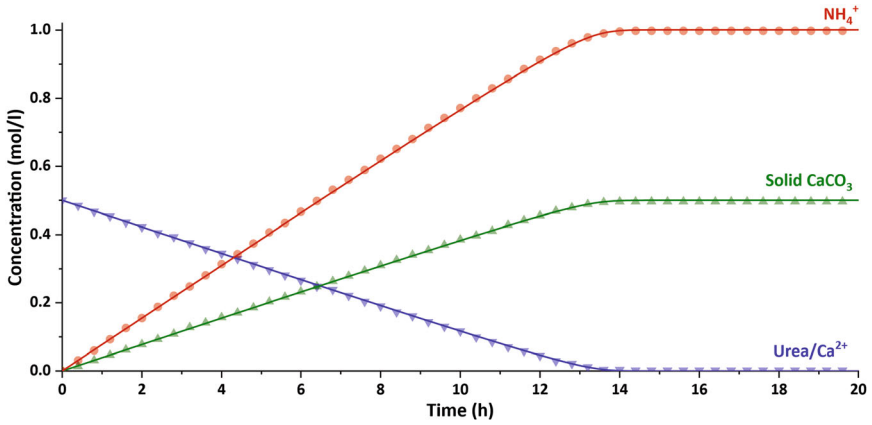

Fig. 3 Main species concentration evolution with time: comparison between this work numerical modeling (continuous lines) and data from Paassen [16] (symbols)

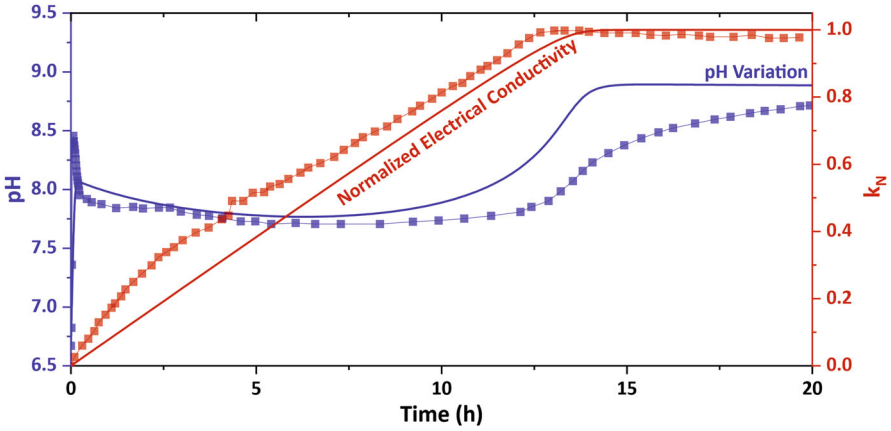

Fig. 4 pH (blue) and normalized electrical conductivity (red) variation during the precipitation process: a comparison between this work's numerical modeling (continuous lines) and data from Paassen [16] (symbols)

at a steady rate for approximately 13.5 h, during which time almost all of the urea and calcium in the system are consumed. After 14 h, the pace began to change and eventually leveled off.

Figure 4 presents the predicted pH variation and the normalized electrical conductivity ($k_N = \left(\frac{k - k_{min}}{k_{max} - k_{min}}\right)$) of the species in the system, compared to the experimental results reported by Paassen [16] for the same experimental setting described in Fig. 3. The numerical model and experimental data show substantial agreement for both the pH fluctuation and normalized electrical conductivity.

In relation to pH variation, during the initial phases of reactions (the first 5 min), the pH increases rapidly (from 6.67 to 8.75) upon hydrolysis of a small amount of urea, when the amount of carbonate produced exceeds the solubility product, leading to the precipitation of calcium carbonate. Then, the pH rapidly decreases, primarily due to the balance between unbound calcium and the calcium bicarbonate complex, which is the most prevalent dissolved inorganic carbon compound during the early stages of the process, when calcium levels are still elevated. When almost 50% of the calcium and urea initially present have been used (approximately 7 h (Fig. 3)) and the pH is still within the optimal range (R/R_{max} from Eq. (3) >0.9), the pH starts to steadily increase due to the acceleration of the hydrolysis rate, which is influenced by the calcium concentration (see Eq. (2) and Fig. 1). Eventually, after 14 h, when nearly all of the calcium and urea have been consumed and equilibrium between the reactants, products, and by-products has been reached, the reaction ends and the pH remains stable. The discrepancy between the computational model and experimental results for pH after 10 h of hydrolysis time is attributable to overlooked influencing factors, such as the decrease of urease activity caused by bacterial cell lysis [16].

As for the normalized electrical conductivity (curve and symbol in red), it is worth noting that both model and experimental data demonstrate an anticipated

increase over time. Even though there is a disparity, particularly at the beginning of the process, the model is able to predict the overall trend adequately. Given that electrical conductivity in this scenario is affected by various factors, such as the presence of additional ions in the system, which can lead to a different pattern, as reported in the literature [14], any discussion on this subject necessitates a more comprehensive experimental analysis.

Once confirming the ability of the numerical model to well predict the evolution of calcium carbonate concentration and pH over time, the model was exploited to obtain information regarding the optimal environmental conditions for improving the calcium carbonate precipitation process. For instance, Fig. 5 depicts a parametric analysis of pH evolution based on the starting pH value for the same amounts of urea and calcium considered in Figs. 3 and 4.

When the initial environmental pH values are below 3.5 or above 12 (the threshold of denaturation of the enzyme responsible for bio-cementation), the hydrolysis rate is zero; hence, a horizontal line with no change in pH may be anticipated. At these pH levels, because the enzyme does not initiate the hydrolysis process, all of the subsequent chemical reactions ranging from Eq. (5) to Eq. (14), with the exception of Eq. (11), are not triggered. At these specified pH ranges, the only by-product that may be generated is $CaOH^+$ (Eq. 11), which is formed as a consequence of the charge balance between the different calcium (calcium chloride in this case) species in the solution. Therefore, in an acidic environment (pH <3.5), there is not any change in pH. Conversely, in a basic environment (pH >12), the system attempts to achieve charge balance between calcium species within the first 1 or 2 min, leading to an instant fall of about 0.9 in pH. This aspect may be confirmed by an additional parametric analysis of the concentration of by-product species, which is not included here for brevity.

For an initial pH ranging from 4 to 7, during the early phase of urea hydrolysis (first 10–15 min), there is a significant and rapid increase in pH, as already

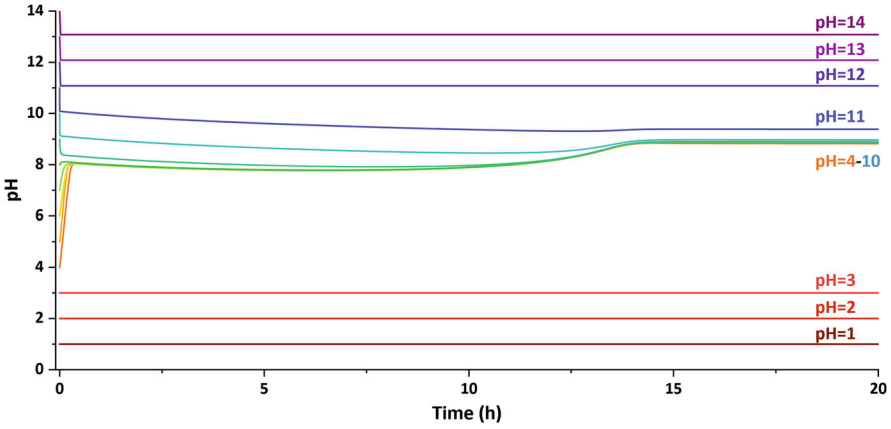

Fig. 5 Parametric analysis of pH evolution estimation in time as a function of the initial pH

commented above (Fig. 4). This phenomenon aids processes that begin at lower pH levels, which may not be ideal for bacterial enzymatic activity, to rapidly rise to higher levels where the normalized hydrolysis rate as a function of pH is greater than 0.9. This prediction aligns with the experimental study performed by Lai et al. [17] on the pH evolution over time influenced by initial environmental pH values ranging from 4 to 8.75, which is not reported here for brevity.

For initial pH levels ranging from 8.75 to 11, as the precipitation of $CaCO_3$ proceeds the pH increase causes a decrease of normalized hydrolysis rate (Fig. 1). The pH drop at the early stage is the result of superposition of decrease of pH by reactions' by-products and increase of pH due to urea hydrolysis. Thus, the overall variation of pH for this range of initial pH is little.

5 Conclusion

The present research provided a concise overview of the theoretical foundation of influencing factors in biochemical processes related to microbially induced calcium carbonate precipitation. A step-by-step procedure has been described for using COMSOL Multiphysics® to develop a computational model for prediction of calcium carbonate precipitation and the variations in environmental conditions during the bio-cementation process. A function has been introduced to define bacterial urease activity based on the real-time influence of three independent environmental parameters: urea and calcium concentrations and the initial pH of the environment. This function controls the urease hydrolysis rate during the process, depending on the current conditions. The comparison between experimental data available in the literature and the numerical model prediction presented in this study resulted in the following conclusions:

- The defined model accurately predicts the trend and amount of consumption of the primary reactants (urea and calcium), as well as the generation of the subsequent products (precipitated calcium carbonate) and by-products (ammonium). It can also forecast the quantity of all other minor by-products, which are not mentioned here for brevity.
- The model can estimate the system electrical conductivity evolution and how the environmental pH fluctuates over time as a result of the bio-cementation process.
- The parametric analysis results suggest the most favorable initial pH range for the precipitation of calcium carbonate and pH variation over time, using *Sporosarcina pasteurii* for bio-cementation, is between 4 and 10. This applies to the specific concentrations of urea and calcium derived from calcium chloride used in this investigation.

However, it is important to note that the model can predict the outcome and serve as a useful tool for optimizing ideal bio-cementation under varying concentrations of primary reactants, different calcium sources, or changes in the type of bacterium or enzyme isolated from a bacterium or plant, as long as the intrinsic parameters for the

process mentioned in Eqs. (1)–(3) are known. For future developments, it would be beneficial to use a systematic coding program (e.g., MATLAB) to integrate the introduced hydrolysis rate function ($R_{Hydrolysis}$) with other influential parameters simultaneously. This will result in a more sophisticated and comprehensive computational model.

1 Introduction

The world is becoming more vulnerable to climate change and its associated impacts than ever before, and many attempts are being made toward mitigation initiatives. CO_2 is one of the key factors highlighted in here. Actions are being taken to achieve net-zero CO_2 emissions globally by 2050 to avoid the worst impacts of climate changes [1]. Moreover, the majority of CO_2 emissions associated with the

construction industry result from the combination effect of cement production and transportation that involves concrete. This eventually ascribes up to approximately 6–8% of greenhouse gas emissions globally per annum [2], which directly contributes to the effects related to global warming and climate changes [3]. The manufacturing of low-carbon concrete holds significant potential for reducing CO_2 emissions associated with the construction industry. This involves various options such as utilizing alternative SCMs, optimizing mix designs, employing different types of carbon capture techniques, developing new materials, conducting life cycle assessments, and improving energy efficiency. In this context, the exploration of sustainable alternatives to partially replace traditional cement-based materials, and the development of low-carbon construction materials are becoming attractive hot topics in the construction industry nowadays. Achieving sustainability within the construction industry is one of the most challenging goals as the demand for new infrastructures continues growing unabated worldwide.

SCMs are materials that contribute in enhancing the properties of hardened concrete through hydraulic or pozzolanic activity or both [4]. Pozzolans and slags are generally categorized as SCMs or mineral admixtures or additives. SCMs such as ground granulated blast furnace slag (GGBFS), various forms of fly ash (FA), silica fume (SF), metakaolin (MK), limestone (LS), and natural pozzolans including calcined shale and metakaolin are well-known SCMs in this field [3]. In addition to these, there are a number of other SCMs presently being investigated to discover enhanced performances. Many of their effects on concrete are well understood, and most recent research is being focused on areas like exploring new SCM materials, increasing the replacement amount of additives to improve properties, etc. [4].

From various studies conducted about the suitable percentage of replacement of cement, 10% is acceptable for all types of SCMs [4]. Generally, the replacement levels of cement by weight with SCMs like GGBFS, FA, SF, MK, and LS range from 40% to 80% [3], 15% to 35% (some instants up to 50%) [5], 3% to 10%, 5% to 10%, and 5% to 20%, respectively [3, 5]. Moreover, SCMs show a range of performances in different replacement percentages based on various factors like the water demand, fines and shape of particles, and specific density [5]. Most of the research works are mainly directed toward using a single type of SCM and forming a binary mixture. However, current studies are targeting the utilization of a combination of two or three SCMs instead. The main goal of such interest is to use high replacement percentages of cement and take advantage of the synergy to overcome the shortfalls of binary binders. There are some negative effects observed like high demand for water and on the other hand poor mixing with water, hence making the optimization of such binder formulations tedious. However, having a good comparative perspective to estimate the behavior of different SCMs when used in several combinations is an interesting area to study [6]. Moreover, recent research focuses on exploring new SCM materials and optimizing their performance, including investigating increased replacement percentages and using different combinations [7].

One such material of interest is SiMn slag, a by-product of SiMn alloy production [8]. Worldwide production of SiMn alloy is increasing relentlessly and 1.2–1.4 tons

of SiMn slag generated during the production of 1.0 ton of alloy [9]. Norway shares the fourth place in the world in this industry [10]. Despite its abundance, SiMn slag remains underutilized, primarily relegated to landfilling. However, there is a growing potential to incorporate SiMn slag into concrete production as a high-volume cement replacement SCM [11]. Hence, it is more important to aim at exploring the feasibility of utilizing SiMn slag in various proportions to develop low-carbon binders with high cement replacement rates.

The objective of the study is to develop a low-carbon composite binder by incorporating SiMn slag in various combinations attempting to replace the maximum amount of cement possible. Previous researchers have identified the high feasibility of the usage of SiMn slag in granulated glassy or even in crystalline hard stone form within the field of SCMs and geopolymer concrete. Accordingly, there is a potential to modify the properties of SiMn slag resembling granulated blast furnace slag (GGBFS) in order to utilize it more effectively. GGBFS is used as a promising early strength gain SCM to verify the possibility of developing a ternary binder. Initially, to develop high-volume replacement binary binder, 30%, 50%, 70%, and up to 90% of cement was replaced with SiMn slag. For ternary binder, 50%, 70%, and up to 90% of cement were replaced with a combination of varied SiMn slag with 20% of GGBFS.

2 Experimental Procedure

2.1 Materials

The experiment utilized INDUSTRISEMENT, CEM I 52,5 R conforming to NS-EN 197-1:2011 standards as the primary cement, sourced from a cement producer in Norway. Various proportions of this cement were replaced with SiMn slag supplied from ERAMET-Norway and GGBFS obtained by Merox AB-Sweden as provided, which served as SCMs in the experiment.

Prior analyses, including particle size distribution and BET-surface area analysis, were conducted on the same materials to assess their characteristics. Accordingly, SiMn slag used in this experiment has a mean particle size of D50 as 24.5 μm in dry analysis and 23.0 μm in wet analysis. The related values of D50 for GGBFS are 13.7 μm in dry analysis and 14.4 μm in wet analysis, respectively. Potable tap water was used in the mixture, and an admixture based on modified acrylic polymers (Dynamon SX-N by MAPEI), was added to ensure consistency throughout the experiment.

The X-ray fluorescence (XRF) analysis data are presented in Table 1. SiO_2, CaO, and Al_2O_3 are the main components of the two types of slags comprising together approximately 85% of the total composition, similar to cement. They have the potential of improving the binding performances. SiMn slag and GGBFS have MgO content of 3.38% and 7.75%, respectively. While SiMn slag contains MnO at a higher percentage of 8.72% of total composition when compared with 0.8% of

Table 1 XRF results of cement and SCMs used in the experimental setup

Material (weight %)	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	Na_2O	K_2O	MnO	TiO_2	SO_3	BaO	P_2O_5	SrO_2
Cement	23.59	5.05	3.84	59.14	0.0	0.0	2.01	0.10	0.25	5.51	0.06	0.35	0.09

GGBFS. However, the composition of CaO in SiMn slag is 24.38%, which is lower than that of cement and GGBFS.

2.2 Mixture Proportions and Preparation of Specimens

To explore the feasibility of developing high-volume cement replacement composite binders using SiMn slag and GGBFS as SCMs, a comprehensive experimental setup was designed. This included a control series, consisting of four types of binary binders and three types of ternary binders. These binders are aimed to partially replace cement by weight basis. The replacement percentages of cement were systematically varied: 30%, 50%, 70%, and 90% by weight of the total binder content to assess the maximum achievable cement replacement. Both binary and ternary binder series were investigated. Within the ternary binders, GGBFS accounted for 20% of the total binder weight, with the percentages of SiMn slag being fine-tuned to match the partial replacement levels found in the binary mixes. Notably, no ternary binder was proposed with 30% replacement utilizing GGBFS, as the objective was to evaluate the high cement replacement potential of SiMn slag alongside the use of GGBFS to enhance the strength gain properties of the mixture.

In line with the findings from preliminary trials, a fixed water-to-binder ratio of 0.35 was maintained throughout the study for targeting a high level of compressive strength after the 28-day period. Additionally, a superplasticizer was added at 1% of the binder weight to ensure consistent workability. The superplasticizer dosage was determined based on observations of mini-slump flow, aiming to maintain a minimum flow table diameter of 200 mm through several trials. Control specimens (C), containing only cement without any replacements, were also prepared for comparative analysis. Specimens were labeled according to the type of binder (control, binary, or ternary) and the percentage of replacement (ranging from 30% to 90%). For example, the designation "B1" referred to binary set 1, replacing 30% of the cement, while "T2" indicated ternary set 2, replacing 50% of the cement with a combination of 30% SiMn slag and 20% GGBFS. The specific mixture proportions are shown in Table 2.

2.3 Casting, Curing and Testing of Specimens

The procedures for casting, curing, and testing were carefully carried out to ensure an accurate assessment of the specimens' properties and are detailed below.

Mixing Process All cement binders were mixed using a desktop Hobart mixer with a bowl volume of 4.73 liters, operating at a speed setting of 139 RPM. In order to obtain a homogeneous mixture, dry materials were first gently hand-mixed in the bowl, followed by a 2-min dry mixing process at low speed. Potable tap water was

Table 2 Mixture Quantities for 5 liters

Binder ID	% Replaced	Material requirement/(g)				
		Cement	SiMn slag	GGBFS	Water	Admixture
Control—(C)	0	2610	–	–	913.5	26.1
Binary-1 (B1)	30	1825	785	–		
Binary-2 (B2)	50	1305	1305	–		
Binary-3 (B3)	70	785	1825	–		
Binary-4 (B4)	90	260	2350	–		
Ternary −1 (T2)	50	1305	785	520		
Ternary −2 (T3)	70	785	1305	520		
Ternary −3 (T4)	90	260	1830	520		

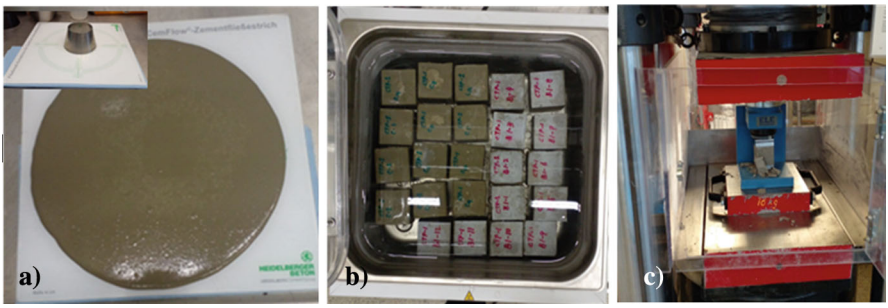

Fig. 1 (**a**) Mini flow table test, (**b**) Curing of specimens, and (**c**) Compressive strength test

then added to the mixing vessel, and wet mixing continued for another 2-min to obtain a uniform paste. While the mixer was running, the admixture was slowly added and mixing continued for an additional 2-min [12].

Slump Test and Casting After mixing, consistency tests were performed using a mini-flow table. The mini-slump cone was placed on a flat, nonabsorbent mini-flow board. After filling the binder to the top of the cone, it was carefully lifted vertically to allow the paste to spread out and settle as shown in Fig. 1a. The average diameter of the slump was measured. Subsequently, the paste was poured into oiled three-gang cube molds measuring 50 × 50 × 50 mm in size in two lifts, with 32 hand compressions applied to each lift using a steel tamping rod to ensure complete filling without voids. The top surface of the paste was leveled, and the specimens were placed under ambient conditions while covered with polythene to prevent moisture loss.

Curing and Compressive Strength Testing After 24 h of initial curing under ambient room conditions, the molds were carefully de-molded, and the specimens were stored fully submerged in water to ensure 100% relative humidity [13] inside a curing chamber as shown in Fig. 1b at a constant temperature of 23 °C until subjected to testing. Subsequently, the specimens were removed and allowed to dry at room temperature for 1 h before testing. The average compressive strength

was calculated from the results of three samples each at intervals of 3, 7, 14, and 28 days using an automatic compressive strength machine, (UCS test machine, Toni Technik, 300 kN) with a loading rate of 0.5 MPa/s, as shown in Fig. 1c. Here, the compressive strengths of all 3-day specimens were measured using a UCS test machine (Zwick-Roell, 50 kN). The NS-EN 12390-3:2019 is the test standard followed in here.

Microstructural Analysis Microstructural analysis was conducted on samples collected after the 28 days compressive strength test using scanning electron microscope (SEM) (Zeiss Supra 35VP field emission gun scanning electron microscope coupled with an EDS detector of EDAX Octane Elite 25) at University of Stavanger. Small representative samples from the selected test specimens were used for SEM analysis. The specimens selected were coated with sputtering using palladium to get rid of charging effects. Thereafter, samples were crushed and ground into powder for XRD analysis using a Bruker-AXS micro-diffractometer D8 ADVANCE equipped with a CuKα radiation source [8]. Measurement range used was $2\theta = 3$ degrees–70 degrees.

Isothermal Hydration Tests Monitoring of the progress of the hydration process after mixing the binder materials with water was carried out using an isothermal calorimeter [12] to identify the involvement and effect of SCMs in the hydration process compared to the control. The tests were performed at 23 °C to examine the heat generation rate and degree of reaction of SCMs, especially at early ages, using separately mixed small samples of paste (approximately 10 g). The temperature of 23 °C was selected to represent the curing conditions adopted during the test. The rate of heat evolution during the reaction was measured using an eight-test channel isothermal conduction calorimeter (TAM Air, thermometric AB).

3 Results and Discussion

3.1 Effects of SCMs on Compressive Strength

Figure 2 displays the average compressive strength of the binder samples at different ages, including the control specimens consisting of industrial cement without any replacement with SCMs. The compressive strength of all specimens exhibited an increasing trend with time. According to Fig. 2, binary specimens except the B4 category achieved beyond a strength of 60 MPa at 28 days. Out of them, B1 and B3 categories developed higher strengths of 9.4% and 13.1%, respectively, higher than the control. The B3 category achieved a strength of 9.1% lower than the control specimen's strength. The B4 category showed a comparatively lower strength development during the test period and ended up with 61.9% reduced strength compared to the control specimens.

Similarly, a trend of increasing strength with time is observed in ternary binders as shown in Fig. 2. The T2 category exhibits a slightly greater strength development

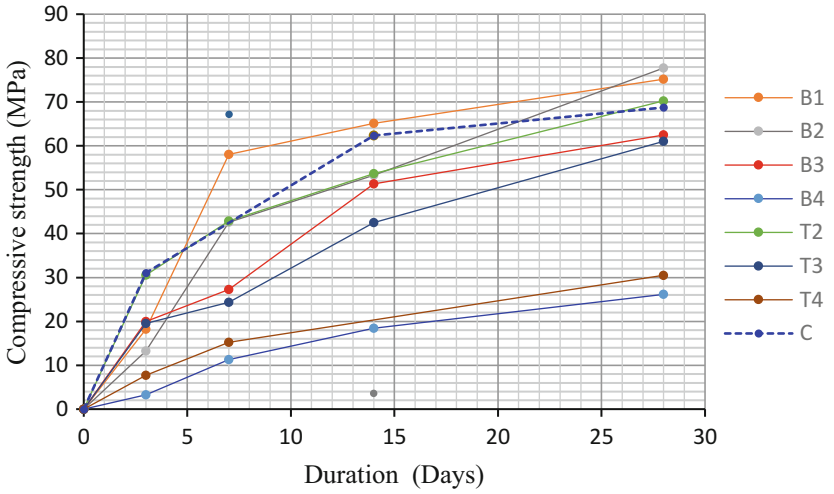

Fig. 2 Compressive strength test results of control, binary, and ternary specimens

when compared to the control, which is 2.2%. Except for T2, the rest of the two categories' strength developments fall at lower value ranges compared to the controls by 11.2% and 55.6%, respectively. However, T2 and T3 have developed strengths over 60 MPa, indicating the capability of developing high strength similar to the binary binders in the same experiment. These binders exhibited the potential for further modification to attain the development of even better high-strength composite binders.

Out of all the binder types investigated, T2 showed a similar strength development pattern at initial and later stages resembling that of the control specimens. This is in agreement with the previous research findings demonstrating the achievement of increased early and later-stage strengths of the binder paste by adding GGBFS in right proportion at about 20% [14]. This result implies a good indication of the capability of utilizing the properties of SCMs to develop new binders with enhanced strength and other desired properties effectively.

The relative compressive strength of all the proposed binders based on average compressive strength results together with respect to those of control specimens are presented in Fig. 3. It demonstrates the gradual development of strengths of the proposed binders from an early stage (3 days) up to later stage (28 days) in terms of the percentage deviations to the control specimens. The common tendency of these proposed binders is starting with low early strength (except T2), gradual development of strength less than the control and achieving a higher later strength (except B4 and T4). On the other hand, these results can be attributed to the low heat of hydration generation at the initial stage which improves durability aspects associated with the heat of hydration process in general practice, especially with high-strength concrete works.

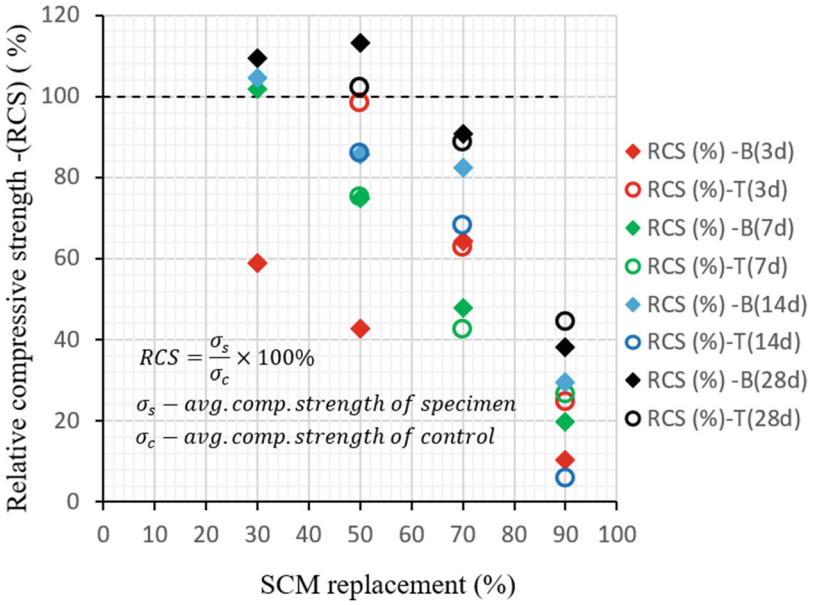

Fig. 3 Variation of relative compressive strength with replacing percentage of SCM

3.2 Isothermal Conduction Calory Meter Studies

The heat evolution curves have been obtained by the isothermal conduction calory meter of the samples at 23 °C for 72 h as shown in Fig. 4. The first peak at time starts from 0, representing where it starts the collection of data and is being assigned to the preinduction stage occurring due to wetting and initial dissolution of particles [15]. This occurred due to the procedure adopted, as the mixing was done outside the instrument and the paste was then introduced to the instrument soon after 2–3 min of mixing. Then the gelation process has taken place, and the second peaks were observed. The next peak(s) can be attributed to the precipitation of C-S-H gel with time. This result is correlated with the compressive strength development of the binders along with the timeline [16]. The resulting curves belonging to binary and ternary testes imply low heat evolution directly correlated to the strength developments. They are clearly matched with the strength development rates of binders compared with the control. Especially, the low peak in the case of B4 after approximately 36 h indicates the very low heat of hydration that took place in that specimen type and less progress of the hydration process particularly at high volume replacement. According to the calculated area under each curve, heat evolution during the reaction periods decreased in the following order: C, B1, T2, B2, B3, T3, B4, and T4. This is correlated to the strength characteristics of the specimens noted in the same order and explains well that the rate of hydration process has taken place with an increasing percentage of replacement with SCMs used.

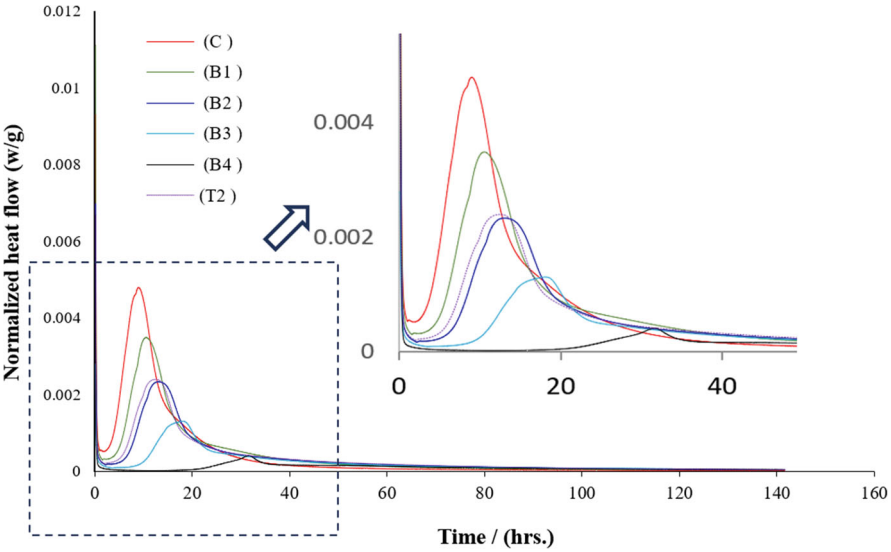

Fig. 4 Time evolution heat production—cement & other binder types

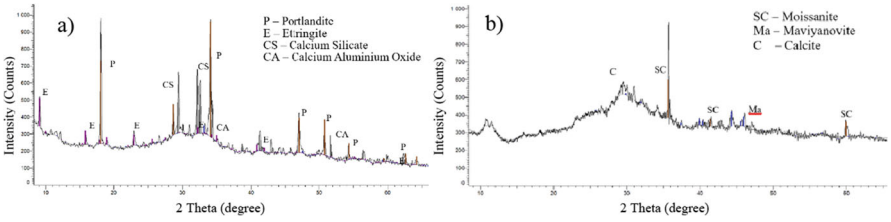

Fig. 5 XRD pattern—(**a**) control specimen (only cement) and (**b**) B4 specimen (90% SiMn slag)

3.3 X-Ray Diffraction Technique (XRD)

XRD was used for the purpose of the identification of crystalline and amorphous phases in raw SiMn slag and cementitious paste after hardening. XRD results of SiMn slag showed Mavlyanovite (Mn_5Si_3), Moissanite (SiC), and Quartz (SiO_2) as the main crystalline components along with amorphous-rich phases. Generally, the amorphous phase is more reactive than the crystalline phase in SCMs. On the other hand, the observations were used to correlate the strength development with time within the binder. When the XRD diffraction pattern of the control specimen at 28 days is compared with that of the B4 specimen at the same duration, the existence of hydration products is clearly identifiable in the control specimen as shown in Fig. 5a. Based on Fig. 5b, the presence of lesser amounts of hydration products and remains of unreacted particles are clearly visible. This evidently displays the difference in the extent of production of cement hydration products with the addition of

SCMs, which on the other hand is also associated with the strength development of the binder. Amorphous components could have contributed to the enhanced strength observed. Diffraction patterns from minor components and trace components cannot be easily determined using XRD due to its limited sensitivity.

3.4 Scanning Electron Microscopy (SEM) Observation

Since XRD results verified the presence of both amorphous and crystalline phases in SiMn slag, a good hydration process followed by strong reaction products associated with cement hydration products can be expected in binary specimens. The comparative examinations of the microstructures of the control specimens, binaries (B1, B2, B3, and B4), and ternary (T2) were conducted after 28 days. An overview of the backscatter electron (BSE) images at similar magnification for selected samples is displayed in Fig. 6. B1, B2, and T2 showed a densified microstructure similar to the control while B3 particularly B4, consists of significantly very loose and unreacted phases within their respective microstructures. B1, B2, and T2, in contrast, showed the formation of ettringite, portlandite, and C-S-H hydrated gel and consequently appear well bonded, supporting the relatively high compressive strengths measured. Partially reacted SiMn slag grains, apparently at an early stage of bond formation on their surfaces, are notable in the microstructure of B4 compared to the control, B1, and B2 at higher magnifications (Fig. 7). Furthermore, in B3 and B4 samples, formation of ettringite looks at a comparatively very low state. The microstructure of B4 is very poor when it comes to the extent of bonding between the different components and at higher magnification levels, it showed the existence of partially unreacted finer grains. In general, the microstructural observations are in good agreement with the 28-days compressive strength results which are increasing with time and decreasing with the addition of progressively higher proportions of SCMs as shown in Fig. 2.

The bond formation mechanism has been studied and compared, and the comparative densifications in the microstructures of C, B1, B2, and B4 as shown in

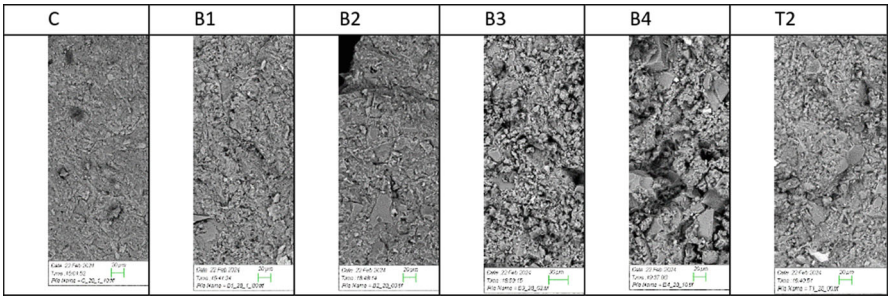

Fig. 6 SEM analysis of microstructures at 500× magnification level

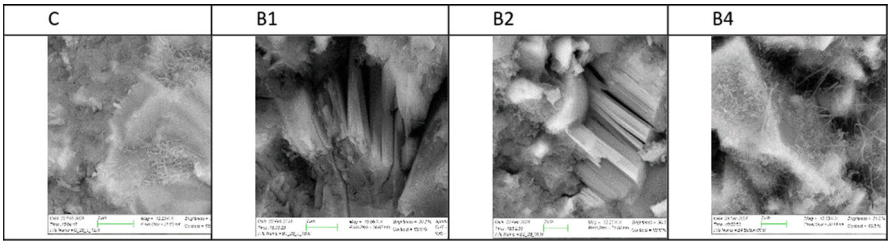

Fig. 7 SEM analysis of microstructures at 15,000× magnification level

Fig. 7. SEM results are also consistent with those acquired from isothermal calorimeter measurements. Mainly, in the B4 specimen, even after 28 days, the smaller grains have not fully entered into the reaction process while other binders have a well densified, good bonding microstructural formations as visible in Fig. 7. Portlandite was presented in every sample at 28 days, which implies further hydration process will take place along the timeline with the possibility of further enhancement in compressive strength with time.

4 Conclusions

The objective of the study is to develop a low-carbon composite binder by incorporating SiMn slag, as well as combinations of SiMn slag and GGBFS, to replace the maximum amount of cement feasible. Based on the experimental investigation, it was found that binary binders (B1 and B2) with SiMn slag replaced cement by 30% and 50%, respectively, and the ternary binder T2 comprised of 30% of SiMn slag and 20% GGBFS, replaced cement by 50%, achieved compressive strengths higher than the control after 28 days. Moreover, utilizing even higher replacement proportions like 70% binary and ternary binders resulted in achieving strengths exceeding 60 MPa after 28 days.

Low strength development has been observed for up to 7 days with the incorporation of SiMn slag, resulting in a reduction in the initial strength of the resultant binder. However, in later stages, this might be outweighted by the pozzolanic characteristics due to the presence of SiO_2 and Al_2O_3, which led to increases in strength. Significant amounts of nonhydrated and isolated particles are observed, and they increased with progressively greater replacement percentages of SCMs. This phenomenon may explain the observed strength loss with increasing SiMn slag replacement percentages.

Studying the characteristics of the binder phase in the initial stage of developing the low-carbon concrete is essential. Based on the results obtained in this experiment, it opens the prospect of exploring and investigating more about the next level of optimal mixing of cement with aggregates in the binder. This exploration aims to obtain higher strength and other desirable performance characteristics. Based on the

strength development observations made, several strength classes can be identified along with different replacement percentage of cement with SiMn slag and GGBFS and their varied combinations in future research.

Acknowledgments The author would like to express gratitude to Leif Hunsbedt and Kjorkleiv Oyvind Karstein of ERAMET, Norway for providing the ground SiMn slag necessary to conduct this study.

1 Introduction

The construction industry is currently grappling with significant environmental challenges, primarily due to its substantial carbon footprint and reliance on non-renewable resources [1]. As one of the main sources of global carbon emissions (39%), the sector is under increasing pressure to adopt more sustainable practices [2]. This includes reducing greenhouse gas emissions using greener materials and energy-efficient construction techniques. Additionally, the industry's heavy consumption of non-renewable resources, such as gravel, sand, and various minerals, raises concerns about resource depletion and environmental degradation [3]. Efforts are being made to address these issues through innovations in material science, recycling, and the adoption of circular economy principles, but the pace of change is a critical factor in mitigating environmental impacts [4]. Bio-based materials offer a

promising solution to the environmental challenges previously mentioned. These materials derived from renewable resources are significant for their sustainability, contributing to a reduced carbon footprint and lower environmental impact compared to traditional construction materials [5]. Bio-based materials, such as bamboo, timber, and hempcrete, not only support the reduction of greenhouse gas emissions but also promote the conservation of non-renewable resources. Their renewable nature and biodegradability position them as a cornerstone in the transition toward more sustainable and eco-friendly construction practices, embodying the principles of circular economy and environmental stewardship [6].

Among the myriad of sustainable materials under investigation, hempcrete has become a prominent choice among the many sustainable materials being researched because of its distinctive properties and potential environmental benefits [7]. Hempcrete, a composite material formed from the mixture of hemp shiv (the woody core of hemp plant), lime-based binder, and water, offers a compelling case for sustainable construction through its low density, high thermal insulation, and inherent carbon sequestration capabilities [8]. Notably, hempcrete's lifecycle embodies a carbon-negative profile, primarily due to the hemp plant's rapid CO_2 absorption rate during its growth phase, a characteristic that distinguishes it from traditional construction materials [7].

This paper presents a rigorous analysis of hempcrete's Global Warming Potential (GWP) through a detailed Life Cycle Assessment (LCA) focused on cradle-to-gate stages. Our study quantitatively evaluates the GWP of hempcrete mixes incorporating varying percentages of hemp (5%, 10%, 20%, 30%, 40%, and 50% by weight), aiming to establish a potential correlation between hemp content in hempcrete and environmental impact. By integrating process-based LCA data for industrial hemp production in the United States with comprehensive reviews of literature for other key components such as hydrated lime, and admixtures, this research offers an in-depth understanding of hempcrete's carbon footprint.

Given the construction industry's growing interest in 3D printing and additive manufacturing for its precision, efficiency, and waste reduction capabilities [9], the potential for integrating hempcrete into this technology represents a significant stride toward sustainable construction methodologies [10, 11]. In conducting this analysis, the paper aims to contribute quantitatively substantiated insights into the sustainability discourse, providing a robust foundation for advocating hempcrete's use in reducing the construction industry's environmental impact. Through this endeavor, we seek not only to advance the scientific understanding of bio-based construction materials but also to influence policy and practice toward embracing more ecologically responsible building solutions.

2 Literature Review

2.1 Need for Bio-Based Construction Materials

The construction sector's environmental footprint is notably marked by its use of traditional construction materials, with Portland cement emerging as a primary concern due to its high carbon intensity [12]. Studies quantifying the environmental impact of construction practices have shed light on the substantial CO_2 emissions attributed to Portland cement production, emphasizing its role in exacerbating global warming [13]. Specifically, the cement industry is responsible for approximately 8% of worldwide CO_2 emissions [13], highlighting the critical need for a paradigm shift toward sustainable construction methodologies [14]. This necessitates exploring innovative materials and practices that can mitigate the industry's environmental impact, emphasizing the urgency of integrating sustainability into the core of construction activities. Bio-based construction materials represent a transformative shift in the building industry [5], offering a path to sustainability that diverges from traditional practices known for their environmental toll [6]. These materials are derived from biological sources such as plants, trees, and other organic matter and have gained prominence for their potential to substantially reduce the construction industry's carbon footprint [6]. The emergence of bio-based materials as sustainable alternatives is driven by their renewable nature, reduced energy consumption in production, and their ability to sequester carbon, thereby contributing to a lower overall carbon footprint of construction projects [5].

A critical aspect of bio-based materials is their potential to be carbon-negative. Carbon-negative materials absorb more carbon during their growth and production processes than is emitted throughout their lifecycle [15]. This characteristic is pivotal for mitigating climate change, as it contributes to the reduction of atmospheric CO_2 levels. Materials such as bamboo, hempcrete, and cross-laminated timber not only offer sustainable building solutions but also help combat climate change by sequestering carbon [16]. The role of bio-based materials in construction is not just an alternative approach but a necessary evolution toward sustainable development and climate resilience.

2.2 Hempcrete as a Sustainable Alternative

Hempcrete is a material that exemplifies the shift toward environmentally conscious construction practices. Composed of hemp fibers mixed with lime and water, hempcrete offers a lightweight, durable, and natural alternative to traditional construction materials [17]. Its distinct composition endows it with excellent thermal insulation properties, moisture regulation, and a high degree of breathability, making it an ideal material for a variety of construction applications [18]. Unlike conventional materials such as concrete, hempcrete's production and application processes

are associated with lower carbon emissions, contributing to its recognition as a carbon-negative material due to its capacity to sequester carbon over its lifespan [19].

The application of hempcrete in construction has been the subject of various research studies, focusing on its thermal performance, mechanical properties, and compatibility with different construction techniques [7, 8, 17, 19]. These studies emphasize hempcrete's potential to significantly improve energy efficiency in buildings, reduce heating and cooling costs, and enhance indoor air quality.

Life Cycle Assessment (LCA) plays a pivotal role in evaluating the environmental impact of building materials, including bio-based options like hempcrete [20]. LCA methodology assesses materials from production to disposal, providing a thorough understanding of their environmental footprint [7]. Previous Life Cycle Assessment (LCA) studies on hempcrete have emphasized its environmental benefits, particularly highlighting its low Global Warming Potential (GWP) and its efficacy in carbon sequestration [7, 19, 20]. For instance, research conducted by Shareef et al. [21] indicated that hemp, a plant with a long history of use, can be effectively employed in load-bearing wall structures and offers a cost advantage over many traditional insulation materials. Research by Salvatore et al. [22] showed that walls made of hempcrete surpassed both hemp-lime blocks and conventional perforated brick blocks with external polystyrene insulation in performance. The study by Yadav et al. [10] emphasized the role of hempcrete in reducing waste, conserving natural resources, and minimizing energy consumption within the building and construction sector. These studies reinforce the position of hempcrete as a material that not only meets the structural and aesthetic needs of modern construction but also advances the industry toward a more sustainable and environmentally responsible future.

3 Methodology

This section outlines the approach applied to evaluate the global warming potential (GWP) of hempcrete mixes and discusses their suitability for 3D printing applications in construction. Our methodology integrates process-based hybrid life cycle assessment (LCA) data of industrial hemp production with literature review data for other ingredients. The objective is to quantify the environmental impact of hempcrete with varying hemp ratios by weight and assess its carbon negativity potential.

3.1 Hemp LCA Data Calculation Using Process-Based Hybrid Approach

To assess the GWP of hemp used in hempcrete, we employed a life cycle assessment approach. This involved collecting primary data on the cultivation, harvesting, and industrial processing of hemp in the United States. The data encompassed inputs such as energy consumption, transportation, and agricultural material usage, alongside outputs like yield and waste. Specifically, inputs such as seeds, fertilizer, lime, and fuel were collected from the US Department of Agriculture (USDA). Since this data was older, these inputs were adjusted for inflation and advancement in energy efficiency based on the reported Energy Use Intensity data for different sectors of the US economy. Transportation from hemp cultivation site to industrial hemp processing plant was calculated and added to the environmental impacts. Electricity used by the industrial hemp processing plant to produce hemp hurds and fibers was gathered from the plant and added to the energy calculations. Finally, the GWP of hemp was calculated in kilograms of carbon dioxide equivalent per kilogram of hemp ($kgCO_{2e}/kg$). Following the calculation, we undertook a comparative analysis against existing data from the literature to validate our findings. This comparison served not only to benchmark our results but also to ensure the reliability and accuracy of the GWP values determined for hemp. Utilizing the validated GWP value for hemp, we proceeded to calculate the overall GWP of various hempcrete mix designs. This critical step allowed us to quantify the environmental impact of hempcrete, considering the specific contributions of hemp alongside other constituents within the mix.

3.2 Data Collection for Hempcrete Components

We conducted a comprehensive literature review to gather existing GWP values for the other components of hempcrete: lime along with admixtures such as plasticizer. This step was crucial for understanding the individual and collective environmental impacts of the hempcrete mix components.

A range of GWP values for hydrated lime was extracted from literature sources. This range was essential to accommodate the variability in production processes and regional differences affecting the environmental impact of hydrated lime. The literature formed a basis for understanding the broad environmental implications of this material within the hempcrete mix. We also sourced data for plasticizers and superplasticizers that offered a standardized, verified summary of the environmental impacts, including their carbon footprint. By relying on these data for these components, we ensured the reliability of our environmental impact data.

3.3 *Hempcrete Mix Design Analysis*

Our analysis focused on hempcrete mix designs incorporating 5%, 10%, 20%, 30%, 40%, and 50% hemp by weight per cubic foot of hempcrete. The mix designs were based on the studies conducted by Danché et al. [23] and Tronet et al. [24]. The plasticizer in the mix is considered as 1% lime quantity by weight [25]. These ratios were chosen to explore the impact of varying hemp content on the net GWP of a cradle-to-gate LCA of hempcrete (Fig. 1).

Using the gathered data, we calculated the net GWP for each hempcrete mix design. This calculation included the summation of GWPs for all components, adjusted for their respective proportions in the mix as shown in the equation below.

$$\sum_{c=1}^{4} W_c \times \mathrm{GWP}_c \tag{1}$$

In the Eq. (1), "*W*" denotes the ratio by weight per cubic feet of hempcrete for the four components "c" in the hempcrete mix namely, hemp, hydrated lime, and plasticizer. "GWP_c" is the corresponding GWP value of each of the components.

4 Results

In this section, we present a comprehensive analysis of the Global Warming Potential (GWP) values for hempcrete, focusing on its three main components: hemp, hydrated lime, and plasticizer. The GWP results are derived from a multifaceted approach, incorporating data from process-based calculations and existing literature. This analysis provides a solid foundation for understanding the environmental impact of hempcrete mix designs, with a particular emphasis on their potential contribution to or mitigation of global warming. Following the comparative

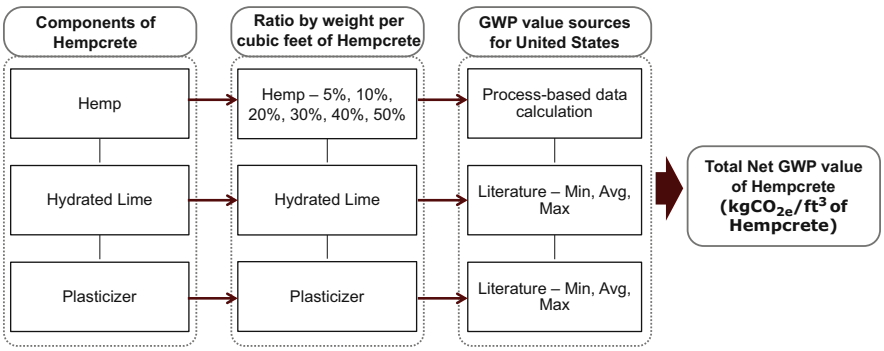

Fig. 1 Total net global warming potential calculation of hempcrete

analysis, we delve into the specific GWP impacts based on varying hempcrete mix designs, culminating with the total net GWP associated with these compositions.

4.1 Global Warming Potential (GWP) of Hempcrete Components

The data collected on the GWP of hempcrete components as shown in Table 1 reveal a significant variation in emissions, uptake, and net GWP values across hydrated lime, hemp, and plasticizer. Hydrated Lime exhibits a range of emissions from 0.823 [26] to 1.085 $kgCO_{2e}/kg$, with an average uptake that interestingly surpasses its min. emissions value based on min value of 0.571 [27] and 1.19 $kgCO_{2e}/kg$ [28], indicating a potential for net carbon sequestration under certain conditions. The average GWP for hydrated lime is notably low at 0.252 $kgCO_{2e}/kg$, suggesting a lower environmental impact relative to its counterparts. Hemp, on the other hand, demonstrates a striking characteristic with its emissions and uptake values resulting in a negative average GWP of -1.72 $kgCO_{2e}/kg$, highlighting its strong potential for carbon negativity in hempcrete mixtures. Plasticizers GWP values ranged from 0.0052 to 1.88 $kgCO_{2e}/kg$ [29], respectively, with no carbon uptake it positions them as more carbon-intensive components of hempcrete. The absence of carbon uptake for these materials suggests a straightforward contribution to GWP, unlike hydrated lime and hemp, which exhibit a complex interplay between emissions and carbon sequestration capabilities.

4.2 Environmental Benefits of Hempcrete Mix Design Alternatives

As the percentage of hemp increases in the mix, there is a notable trend toward a lower GWP, suggesting a significant environmental advantage as shown in Fig. 2. Specifically, for the 20% hemp mix, the GWP values show that while hydrated lime contributes positively to the GWP, hemp has a large negative impact, which leads to a potential for a net negative GWP in some instances, indicating carbon sequestration. As the hemp content decreases to 10% and 5%, the GWP values for hemp become less negative, yet still maintain a substantial offset against the positive contributions from plasticizer, and hydrated lime.

For instance, with a 20% hemp mix, the GWP for hemp component from a significant uptake of -7.35 $kgCO_{2e}/ft^3$ yields a net negative GWP impact, offsetting the emissions from the other components. This trend continues as the hemp content decreases, with each percentage decrease in hemp content resulting in a less negative GWP for hemp, and consequently, a smaller offset against the GWP contributions

Table 1 Global warming potential values for hemp, hydrated lime, and plasticizer

	Emissions ($kgCO_{2e}/kg$)			Uptake ($kgCO_{2e}/kg$)			Global warming potential ($kgCO_{2e}/kg$)		
Material	Min	Max	Avg	Min	Max	Avg	Min	Max	Avg
Hydrated lime	0.8230	1.0850	0.9540	0.5710	1.1900	0.8805	0.2520	−0.1050	0.0735
Hemp	0.12			1.84			−1.72		
Plasticizer	0.0052	1.8800	0.8485	–			0.0052	1.8800	0.8485

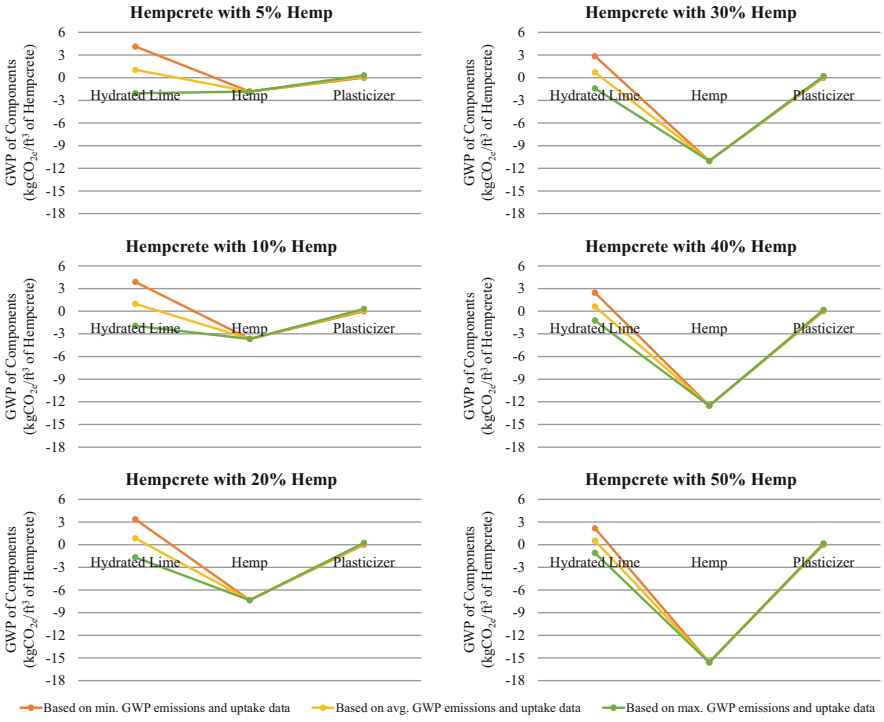

Fig. 2 Global warming potential (GWP) of hempcrete mix design

from the other components. Plasticizers show consistent positive GWP values across all mix designs, indicating a steady contribution to the GWP.

The data reveal that incorporating more hemp into the hempcrete mix design could be a critical factor in reducing the overall GWP of the material, highlighting the environmental benefits of hemp in construction materials. The GWP values also reflect that the other components, while contributing to GWP, do not significantly vary with the change in hemp content, suggesting that the role of hemp is pivotal in the mix designs for achieving lower GWP values. When applying these GWP results to practical scenarios, it is important to consider the specific application of the hempcrete, whether it be for innovative 3D printing construction techniques or for traditional building methods, as the mix design optimized for one may not be as effective or environmentally beneficial for the other.

Table 1 shows the net Global Warming Potential (kg CO_{2e}/ft^3 of hempcrete) for different hemp contents in the mix, based on minimum, average, and maximum GWP emissions and uptake data for lime as mentioned in Table 1 (Fig. 3).

It is evident that as the hemp content increases from 5% to 20%, there is a significant shift from positive to negative GWP values. Specifically, when the minimum lime GWP data are considered, the net GWP shows a descending trend from 2.3 $kgCO_{2e}$/ft^3 at 5% hemp to −3.98 $kgCO_{2e}$/ft^3 at 20% hemp, crossing the

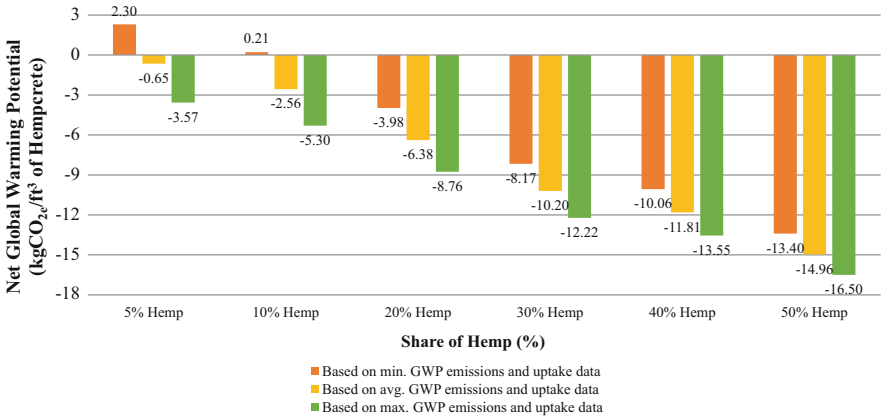

Fig. 3 Total net global warming potential of hempcrete mix designs

threshold to negative values, which implies carbon sequestration, at the highest hemp content. This trend accelerates to 50% hemp content at -13.4 $kgCO_{2e}/ft^3$. The trend becomes more pronounced when average lime GWP data are used, starting at -0.65 $kgCO_{2e}/ft^3$ and moving to 14.96 $kgCO_{2e}/ft^3$. Most strikingly, the maximum lime GWP data present negative net GWP across all hemp contents, with -3.57 $kgCO_{2e}/ft^3$ at 5% hemp, deepening to -16.5 $kgCO_{2e}/ft^3$ at 50% hemp, suggesting that the higher the hemp content, the greater the potential for the hempcrete mix to function as a carbon sink. These results emphasize the critical role of hemp's proportion in the mix design in reducing the overall GWP of hempcrete and enhancing its environmental performance.

5 Discussion

The outcomes presented in the previous section indicate the significant role of hemp in mitigating the GWP of hempcrete. Notably, the inverse relationship between hemp content and GWP indicates that hemp's inclusion is not merely beneficial but pivotal for the environmental performance of hempcrete. The data compellingly suggest that higher hemp proportions substantially enhance carbon sequestration capabilities, with potential for net negative GWP at higher concentrations, which is a promising prospect for sustainable construction practices. Furthermore, the consistency of GWP contributions from admixtures across all mixes indicates that the optimization of hempcrete for specific applications, whether in 3D printing or traditional construction, must prioritize the adjustment of hemp content to leverage its carbon-negative potential. These insights are crucial for advancing the development of environmentally beneficial building materials and for informing industry standards and sustainability benchmarks. Consequently, it is crucial to acknowledge the variability in data quality, which arises due to multiple factors. Utilizing SimaPro

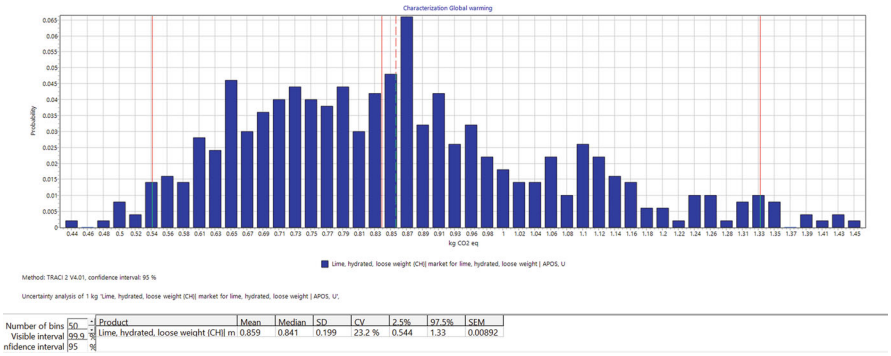

Fig. 4 Uncertainty analysis of hydrated lime GWP using Monte Carlo simulation

for uncertainty analysis, we evaluated the sensitivity of hydrated lime's GWP, with median and mean values at 0.841 and 0.859 $kgCO_{2e}$ respectively, indicating a balanced distribution close to the mean with a standard deviation of 0.199 as shown in Fig. 4. This reflects the complexity in pinpointing an exact GWP value, yet the histogram confirms a 97.5% confidence interval ranging from 0.544 to 1.33 $kgCO_{2e}$. This understanding is vital for stakeholders to refine processes and sustainability strategies.

The environmental impact of hempcrete is profoundly influenced by the characteristics of its primary components. The analysis conducted using SimaPro highlights the uncertainty associated with the GWP of hydrated lime, factors that are critical to understanding the overall environmental footprint of hempcrete.

For hydrated lime, a key ingredient in hempcrete, the variability in GWP data primarily arises from the energy consumption and emissions during its production process. The calcination of limestone, a process that emits a significant amount of CO_2, along with the energy source used (e.g., fossil fuels or renewable energy), greatly affects the GWP figs [30]. The uncertainty analysis from SimaPro highlights these variations, emphasizing the importance of sourcing and production methods in the environmental assessment of hempcrete.

Similarly, the GWP data for hemp present its own set of challenges. The cultivation of hemp, transportation to processing sites, and the processing itself contribute to the variability in the embodied energy and carbon data. Factors such as agricultural practices, the use of fertilizers, and the efficiency of transportation and processing technologies play a crucial role. The biogenic carbon uptake of hemp, a pivotal aspect of its environmental profile, introduces further uncertainty. The value of 1.84 ton CO_2 sequestered per ton of hemp, derived from literature, encompasses a range of conditions and methodologies, emphasizes the difficulty in applying a universal figure for carbon sequestration. Note that the compressive strength of hempcrete may not be comparable to conventional Portland cement concrete and its application in building assemblies may only be compared with non-load bearing components. Results indicate that increasing hemp quantity in a hempcrete mix may not only improve thermal properties but also reduce its GWP. This, however, may

adversely impact its compressive strength as well as printability through an extrusion-based 3D printing process, which must be analyzed to fully understand hempcrete's industry potential.

6 Conclusions

This paper conducts a Life Cycle Assessment to assess the Global Warming Potential of hempcrete from production to pre-use stages, analyzing mixes with 5–50% hemp by weight. We merged process-based LCA data for US industrial hemp with literature for components like hydrated lime and plasticizer, offering insights into hempcrete's carbon footprint. A thorough Life Cycle Assessment of hempcrete's potential to cause global warming has shed light on the material's environmental effects, especially regarding its ability to sequester carbon. The study confirms that hempcrete's potential for carbon negativity is directly correlated with the percentage of hemp within the mix, highlighting the importance of mix design in achieving sustainability objectives. With at least 20% hemp content by weight, hempcrete transitions to a carbon-negative material provided the carbon absorption capacity of the lime binder is factored into the calculation. Our analysis has demonstrated that while hempcrete presents a promising pathway toward reducing the construction industry's carbon footprint, the variability in the quality of data for key components like hydrated lime and hemp must be taken into consideration. The uncertainty highlighted by the variability in GWP values underscores the need for careful selection of sources and production methods to ensure the environmental benefits of hempcrete are fully realized. Future research must focus on developing probability distributions of uncertainties associated with not just the GWP impacts of lime but also the carbon sequestration values of both hemp and lime and running a sensitivity analysis to conduct a more robust LCA of hempcrete. Future research must also consider comparing hempcrete's environmental performance based on its compressive strength as compared to other traditional wall options such as wood and steel framed walls. Future discussions should also explore the implications of this research on policy formulation, industry practices, and the goal of greenhouse gas emissions reduction in the construction sector.

1 Introduction

Due to the structural advantages and the relatively low cost, concrete is one of the most used building materials in the world. However, the many benefits are beginning to be overshadowed by the high environmental impact of the production process. It is already well established that the production of cement, one of the main components of concrete, contributes for up to 8% to the global anthropogenic CO_2 emissions [1]. In order to meet the new demand for sustainability and decrease carbon emissions, concrete production needs to be adapted. Recycling of concrete could play a key role in producing more sustainable concrete; however, there is still a lack of knowledge, guidelines and regulations on how fine recycled aggregates can

be used to produce high-quality concrete. The quality of the fine recycled aggregates depends heavily on the type of waste concrete and on the applied production and storage method. For fine recycled aggregates, the amount of residual cement paste is higher in comparison to coarse recycled aggregates, which causes an even higher porosity in comparison to natural aggregates [2, 3]. This high porosity causes a large water absorption and therefore inferior performance in the fresh and hardened state [2]. Due to these downsides and a lack of knowledge, the fine fraction of recycled aggregates is now mostly landfilled or used for geotechnical and non-structural applications [2, 4]. An alternative for the use of the finer fraction is to grind it in a ball mill to obtain recycled fines (<63 μm), which can be used as a supplementary cementitious material (SCM) or inert filler. Previous research has shown that the reactivity of recycled fines is quite low; however, replacement rates of maximum 30% have been found to be feasible [5–7]. In this research, recycled concrete fines from the concrete recycling of Devagro (Waregem, Belgium) were investigated as a partial replacement for cement. First of all, the physical and chemical properties of the recycled fines are studied followed by an investigation of the reactivity and strength development using isothermal calorimetry and flexural and compressive strength tests. Finally, two concrete mixes are made: one reference mix and one mix with partial cement replacement by the fines and partial replacement of natural aggregates by recycled aggregates. The durability of these mixes is tested by compressive strength tests, shrinkage, porosity measurements and freeze–thaw tests.

2 Materials

In this research, the fine fraction of recycled concrete is studied as a partial cement replacement. These recycled fines are obtained from the waste of prefabricated concrete pavers, namely pavers with form imperfections and waste concrete from the production process. The binder used in this concrete mixture consists of 70% CEM I 52.5 R and 30% blast furnace slag. When recycled, the concrete is up to 1 year old. The production process of the recycled aggregates contains the following steps: (1) breaking down the concrete pavers into smaller pieces followed by a pre-screening where soil and organic matter are removed from the debris, (2) crushing of the material and washing of the granulates and (3) dividing the recycled aggregates in different fractions. To obtain the recycled concrete fines, the fraction with size 0/6 mm is then sieved until a fraction 0/2 mm and subsequently, this fraction is ground in a ball mill in order to obtain a desired maximal grain size of 63 μm.

To test the influence of the fines on durability, two concrete mixes were made: one reference mix and one mix where 10% of cement is replaced by recycled fines (0.10FC). The mix composition is shown in Table 1. In the mix 0.10FC, 27.8% of the sand and 100% of the coarse aggregates were replaced by recycled sand and recycled coarse aggregates, which have a water absorption rate of 7% and 5.4%, respectively. To increase the workability of the mixtures, two different PCE-based

Table 1 Mix compositions of concrete

Materials	Reference	0.10FC
Sea sand 0/2 [kg/m^3]	345	0
Sand 0/4 [kg/m^3]	515	0
River sand 0/7 [kg/m^3]	0	660

Limestone 4/20 [kg/m^3]	1030	0
Concrete aggregate 4/20 [kg/m^3]	0	802
CEM I 52.5 N [kg/m^3]	310	280
Recycled fines [kg/m^3]	0	30
Water [kg/m^3]	179	224
TechniFlow 92 (superplasticizer) [kg/m^3]	1.5	0
PowerFlow EVO503 (superplasticizer) [kg/m^3]	0	7
Total W/C	**0.546**	**0.540**

(polycarboxylates-ether) superplasticizers were used, TechniFlow 92 and PowerFlow EVO503. To keep the casting conditions as realistic as possible, the mixes were made in the concrete plant of Devagro and cast in a non-controlled environment. For each mix, 15 cubes (150 × 150 × 150 mm^3), 6 prisms (100 × 100 × 400 mm^3) and 3 cylinders (ø 100 mm, height 200 mm) were cast. The specimens were compacted using a vibrating table and covered with a plastic foil after casting to prevent moisture evaporation. All the specimens were demoulded after 24 h.

3 Methods

3.1 Characterization of the Recycled Concrete Fines

Particle Size Distribution and Particle Shape The particle size distribution of both the recycled fines and the CEM I 52.5 N was measured using a laser diffractometer with a dry dispersion unit.

The particle shape was quantified using the Occhio Flowcell FC200M-HR in combination with the Callisto 3D software.

Particle Density and Water Absorption The particle density and the water absorption were determined on the fraction 0/2 (before milling) according to the pycnometer method described in NBN EN 1097-6.

Specific Surface Area The specific surface area of the recycled fines was determined according to the standard NBN EN 196-6, using the air permeability method (Blaine method). First of all, the apparatus was calibrated using the reference material SN3c Portland Cement (CEM I 52.5 N). With this calibration, the apparatus

constant K was determined. Finally, the specific surface area of the fines was determined.

XRD and XRF A phase analysis of the fines was performed by X-ray diffraction (XRD) analysis in combination with Rietveld refinement using the Profex XRD software [3]. As an internal standard, 10 wt% ZnO was used.

X-ray fluorescence (XRF) was used to obtain the elemental composition of the fines. In order to do this, three pellets were made by mixing 18 g of fines with approximately 3–4 g of the binding agent $C_{42}H_{83}ON$ from SpectroBlend 44 μm powder.

Isothermal Calorimetry The reactivity of the fines was investigated using an isothermal calorimetry test at a constant temperature of 20 °C. Seven different cement replacement levels were tested, namely 0%, 5%, 10%, 15%, 20%, 25% and 30%. For all samples, 14 g of paste with a w/b of 0.5 was made. The paste was mixed outside the calorimeter and then put in a glass vial to be tested. The heat evolution in all samples was registered for three consecutive days.

Flexural and Compressive Strength of Mortar To investigate the influence of the recycled fines on the strength, 3 mortar mixes with different amounts of cement replacements, 0%, 10% and 25%, were made and tested. Each mixture had a water-to-binder ratio (w/b) of 0.5, and the ratio of sand to cement was 3:1. For these mixes, CEN sand with a fraction of 0/2 and CEM I 52.5 N were used. According to the standard NBN EN 196-1, 3 mortar prisms ($40 \times 40 \times 160$ mm^3) were tested at the ages of 7, 28 and 90 days.

3.2 Strength and Durability Tests on Concrete

Compressive Strength of Concrete The compressive strength of the two concrete mixes was tested on cubes ($150 \times 150 \times 150$ mm^3) according to the standard NBN EN 12390-3. For each mixture, 3 concrete cubes were tested after 2, 7, 28, 56 and 90 days of curing.

Shrinkage Autogenous and drying shrinkage were measured on concrete prisms ($100 \times 100 \times 400$ mm^3) according to the standard NBN EN 12390-16. For each concrete mix, 6 prisms were cast, demoulded 24 h after casting and wrapped in plastic foil to prevent moisture exchange with the environment during transportation to the laboratory. In the laboratory (20 °C, 60% RH), the prisms to measure autogenous shrinkage were wrapped in aluminium tape to prevent drying. Subsequently, two DEMEC-points were placed on the 3 sides of the prisms that were in contact with the formwork during casting, with a spacing of 200 mm between them. Finally, the initial distance between the two points was accurately measured using a demountable mechanical strain gauge (DEMEC). The distance was measured again after 1, 7, 14, 28, 42, 56 and 70 days after the initial measurement.

Freeze–Thaw Resistance According to the standard CEN/TS 12390-9, the freeze–thaw resistance of both concrete mixes was determined. In order to do this, cylinders with a height of 200 mm and a diameter of 100 mm were cast, demoulded after 24 h and transported to the laboratory. Subsequently, the cylinders were immersed in water until the age of 7 days was reached and then they were stored in a climate-controlled room at 20 °C and 60% RH until the age of 25 days. At the age of 21 days, 3 discs with a height of 50 mm were sawn from each cylinder. At 25 days, the discs were glued in a PVC tube with a height of 70 mm and an internal diameter of 104 mm using epoxy resin. After 28 days, the specimens were saturated for 3 days with a layer of demineralized water on top of the samples. After 3 days of saturation, the demineralized water was replaced with a 3 mm layer of 3% NaCl solution and the specimens were placed in a freeze–thaw chamber for 56 cycles of 24 h with a temperature ranging from −20 to 20 °C. After 7, 14, 28, 42 and 56 cycles, the samples were taken out of the chamber and the material which had scaled from the specimen surface was collected, dried at 110 °C and weighed when a constant mass was reached.

Porosity The porosity of both concrete mixes was determined based on the method described in NBN B 24-213. Cylinders with a height of 200 mm and a diameter of 100 mm were cast, demoulded after 24 h and transported to the laboratory where they were cured in a climate-controlled room at 20 °C and 95% RH. At the age of 115 days, 3 discs with a height of 50 mm were sawn from each cylinder. Subsequently, the discs were placed in a vacuum tank where a vacuum was created and maintained for 2 h. After 2 h, the vacuum tank was slowly filled with water while maintaining the vacuum, submerging the specimens. After another hour, the pressure in the tank was restored again until an atmospheric pressure was reached. The specimens were kept underwater until the mass gain was less than 0.1 m% over a 24 h period. When a constant mass was reached, the saturated specimens were weighed in air (m_{sat}) and underwater (m_w). Subsequently, the specimens were placed in an oven at 40 °C and weighed every 24 h until a constant mass ($m_{dry,40}$) was reached (<0.1 m% over 24 h). Then, the specimens were placed in an oven at 105 °C until a constant mass ($m_{dry,105}$) was reached. The capillary and open porosity can be determined using the following equations:

$$CP = \frac{m_{sat} - m_{dry,40}}{m_{sat} - m_w} \times 100 \quad (1)$$

$$OP = \frac{m_{sat} - m_{dry,105}}{m_{sat} - m_w} \times 100 \quad (2)$$

4 Results and Discussion

4.1 Characterization of the Recycled Concrete Fines

Particle Size Distribution and Particle Shape The particle size distribution of the recycled fines and the cement determined with the dry dispersion unit is shown in Fig. 1. The recycled fines have a less uniform size in comparison to the CEM I particles. The high value for d90 can be attributed to a non-optimized milling process. Earlier it was mentioned that the target size for the fines is <63 µm. According to these results, only 73% of the particles can actually be classified as fines, while for CEM I, 97% of the particles have a size smaller than 63 µm. This problem could be resolved by additional sieving and milling since the bigger particles are probably cushioned by the smaller ones [2].

In the recycled fines, oval, rectangular and irregular shaped particles are present. The values of the circularity and roundness in 2D are 0.564 and 0.707, respectively. These values correspond to more elongated particles without sharp edges and corners [8].

Particle Density and Water Absorption Table 2 shows the particle density of the fine fraction (0/2 mm). The measured values are similar to the values for recycled

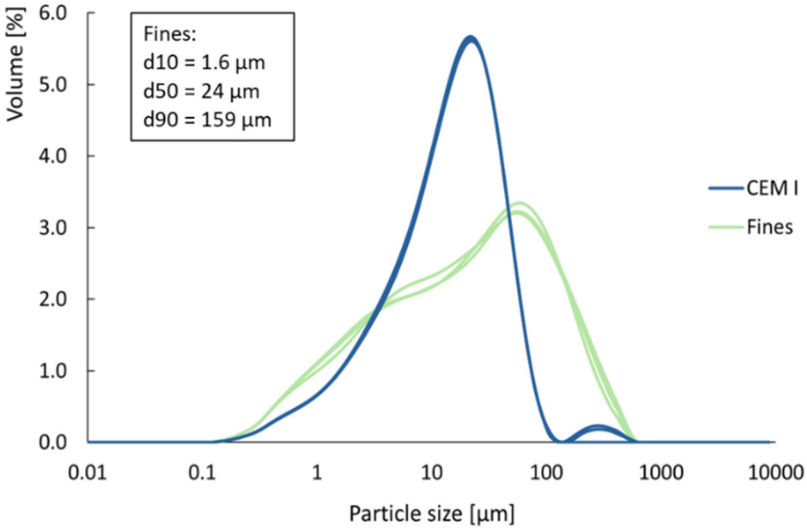

Fig. 1 Particle size distribution of recycled fines and CEM I

Table 2 Particle density of the recycled concrete fine fraction 0/2

Apparent particle density	2710 kg/m^3
Oven-dried particle density	2240 kg/m^3
Saturated and surface-dried particle density	2410 kg/m^3

Table 3 Results of XRD and XRF analysis on the recycled concrete fines

XRD		XRF	
Phase	Quantity [%]	Compound	Quantity [%]
Quartz (SiO_2)	35.86	Na_2O	1.35 ± 0.14
Calcite ($CaCO_3$)	13.61	MgO	2.17 ± 0.05
Belite (C_2S)	2.28	Al_2O_3	5.91 ± 0.11
Gypsum ($CaSO_4$ * $2H_2O$)	3.71	SiO_2	36.30 ± 1.37
Anhydrite ($CaSO_4$)	2.78	P_2O_5	0.02 ± 0.01
Portlandite ($Ca(OH)_2$)	0.20	S	2.01 ± 0.09
Albite	4.27	K_2O	0.50 ± 0.06
Muscovite 2M1	6.19	CaO	46.22 ± 1.10
Amorphous	31.10	TiO_2	2.21 ± 0.13
		Mn_2O_3	0.06 ± 0.00
		Fe_2O_3	3.25 ± 0.07

concrete fines in the literature [9, 10]. In comparison to the CEM I 52.5 N, which has a density of 3150 kg/m^3, the density is lower.

Regarding the water absorption, a value of 7.7% was obtained for the recycled fine fraction after immersion for 24 h. According to [11], the most restrictive standard (KS F2573) demands a maximum water absorption of 3%, while the least restrictive standard (DIN 4226-100) demands a maximum water absorption of 13%. Hence, the fine fraction complies with the least restrictive standard, but not with the most restrictive one.

Specific Surface Area The calculated specific surface area of the recycled concrete fines is 8690.31 cm^2/g. The fines have a higher specific surface area in comparison to the CEM I 52.5 N, which has a specific surface area of 3145 cm^2/g. Due to the rather high specific surface area of the fines, an increased reactivity can be expected. This increased reactivity can be explained by the large area and large amount of active atoms that are easily accessible for the reaction [12].

XRD and XRF The results of the XRD and XRF analysis are shown in Table 3. The results of the XRD show that quartz and calcite are the main phases present in the fines. The large amount of quartz originates from the natural aggregates present in the concrete pavers, which were most likely siliceous in nature, such as siliceous river or marine sand [3]. The large quantity of amorphous phases originates from amorphous cement hydration products (e.g. C-S-H), unreacted amorphous binder particles and amorphous $CaCO_3$ due to carbonation of the fines [3]. The presence of belite, gypsum and anhydrite can be explained by the young recycling age of the concrete pavers and therefore the presence of unreacted particles [13].

The results of the XRF analysis correspond with the results obtained with the XRD analysis. The high amount of SiO2 can possibly be explained by the siliceous sand present in the concrete pavers. The high quantity of CaO is inherent to cementitious materials.

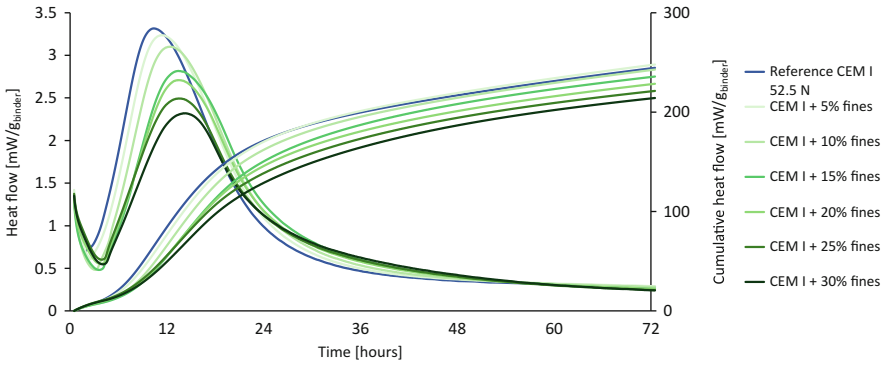

Fig. 2 Heat flow and cumulative heat flow normalized to the total binder mass

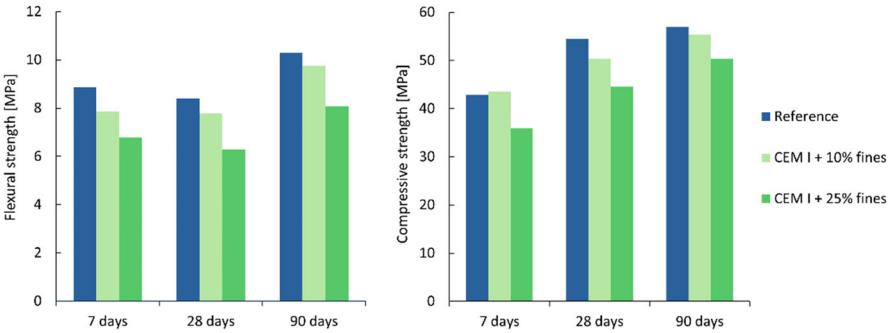

Fig. 3 Flexural and compressive strength of mortar containing 0%, 10% and 25% cement replacement by fines after 7, 28 and 90 days

Isothermal Calorimetry Figure 2 shows the heat flow and cumulative heat flow normalized to the total binder mass for mixes with 0 up to 30% cement replacement by recycled fines. As can be seen in Fig. 2, an increase in cement replacement delayed and decreased the hydration peak. However, the cumulative heat flow shows that 5% and 10% cement replacement resulted in a similar total heat production as CEM I 52.5 N after 72 h, which suggests that the hydration reaction is not negatively affected at this age by these replacement rates.

Flexural and Compressive Strength of Mortar Figure 3 shows the flexural and compressive strength of mortars containing 0%, 10% and 25% recycled fines as cement replacement. It is clear that an increased cement replacement leads to a decreased flexural and compressive strength. The compressive strength after 7 days for mortars with 10% fines is slightly higher in comparison to the reference, which indicates that there is a good early-age strength development. After 90 days, the decrease in flexural and compressive strength is limited to 5.2% and 2.8%, respectively, for mortars containing 10% recycled fines.

4.2 Strength and Durability Tests on Concrete

Compressive Strength Figure 4 shows the compressive strength of REF and 0.10FC. At all tested ages, 0.10FC has a slightly lower compressive strength in comparison to the reference. However, the maximum strength reduction was only 4.2% which occurred at the age of 56 days. Furthermore, a T-test indicates that there is no significant statistical difference between REF and 0.10FC at all tested ages (level of significance = 5%, $p > 6.7\%$).

Porosity The capillary and open porosity of both REF and 0.10FC are shown in Table 4. The incorporation of recycled fines, sand and coarse aggregates in the concrete increased the capillary and open porosity by 45.5% and 47.5%, respectively. This increase in porosity can probably be attributed to the lower reactivity of the binder and the use of recycled aggregates in the 0.10FC in comparison to natural aggregates in the reference.

Shrinkage The autogenous (dashed-dotted line), drying (dashed line) and total (solid line) shrinkage of REF and 0.10FC are shown in Fig. 5. It can be seen that at the age of 70 days, a higher total shrinkage was observed for the 0.10FC mix in comparison to the reference. However, when looking at the autogenous shrinkage, the concrete containing 10% recycled fines expands instead of shrinks. This is probably due to the higher porosity and high water retention capacity of recycled aggregates causing internal curing and preventing autogenous shrinkage [14]. On the

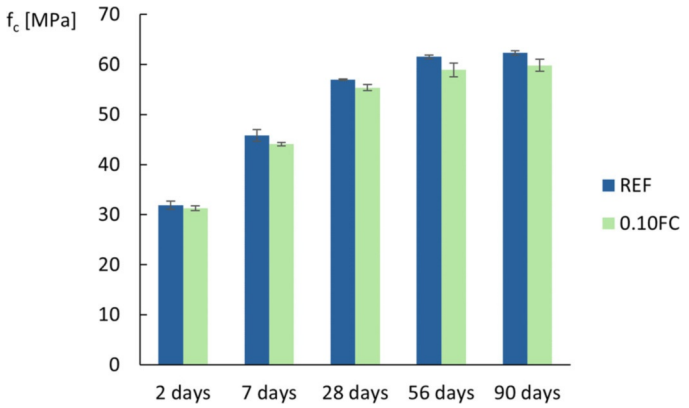

Fig. 4 Compressive strength of REF and 0.10FC after 2, 7, 28, 56 and 90 days. Error bars represent the standard error

Table 4 Porosity of concrete. The standard error is added in the table

	REF	0.10FC
Capillary porosity [%]	6.6 ± 0.3	9.6 ± 0.2
Open porosity [%]	12.0 ± 0.4	17.7 ± 0.2

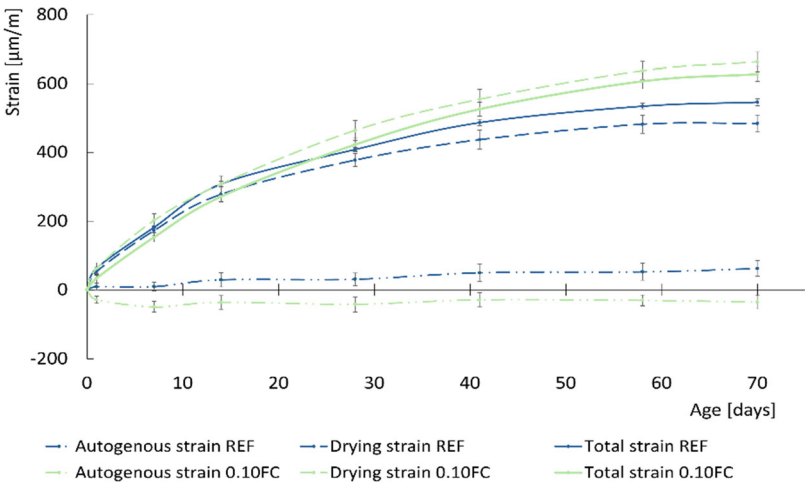

Fig. 5 Autogenous, drying and total shrinkage strain of REF and 0.10 FC

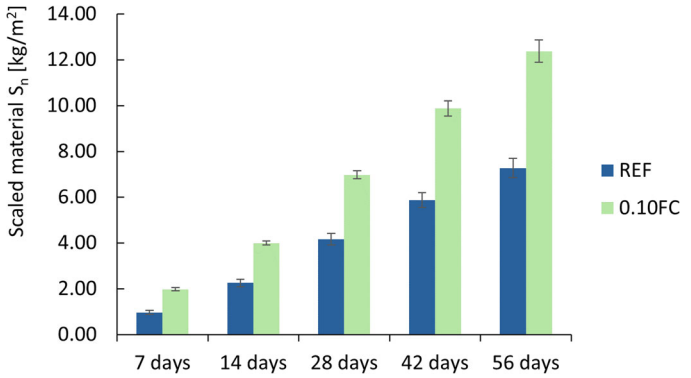

Fig. 6 Scaled material during freeze–thaw with de-icing salts of REF and 0.10FC

other hand, 0.10FC has an increased drying shrinkage, which is probably caused by the evaporation of the higher water content in the recycled aggregates.

Freeze–Thaw Resistance The mass of scaled material during the freeze–thaw test with de-icing salts after 7, 14, 28, 42 and 56 days is shown in Fig. 6. According to EN 12390-9, the limit value for scaling after 56 cycles is 1 kg/m^2, which suggests that both of the materials have a poor freeze–thaw resistance [15]. This was expected since the mix designs belong to an exposure class XF1. On average, the addition of recycled fines, sand and coarse aggregates into the concrete increases the scaling by 77.8% in comparison to the reference mix. This high decrease in freeze–thaw resistance was also found in previous literature [16]. The decrease can possibly be explained by the reduced content of $Ca(OH)_2$ in the hydration products, which can

cause fast superficial carbonation and lead to more susceptibility to freeze–thaw scaling [17].

Environmental Impact A preliminary LCA-analysis showed that the global warming potential (GWP) decreased from 313 kg CO_2 eq for the reference concrete to 288 kg CO_2 eq for the concrete with 10% recycled fines and recycled sand and coarse aggregates, which corresponds with a decrease of 8%. The savings are mostly found in the raw material supply, due to a lower cement consumption, and in transport and manufacturing. A disadvantage of the green concrete is the lower recycling potential in comparison to the reference mix.

5 Conclusions

In this research, the use of recycled fines was investigated as a partial cement replacement. This included a characterization of the fines and their reactivity and an investigation of the durability of concrete with 10% cement replacement. It could be concluded that the fines are less uniform in size in comparison to cement which is probably attributable to a non-optimized milling process. The heat production during hydration after 72 h was similar to a CEM I for replacement rates up to 10% and the reduction of strength of mortars containing up to 10% fines is limited. A 'green' concrete containing 10% fines and partially recycled aggregates has a beneficial effect on the autogenous shrinkage in comparison to a reference concrete without fines and with natural aggregates. This can be attributed to the water retention ability of the recycled aggregates which serve as water reservoirs during hydration. The reduction in compressive strength was only 4.2% after 56 days. The freeze–thaw resistance of both the reference mix and the green concrete was insufficient, and the green concrete increased the scaling by 77.8% after 56 days of freeze–thaw cycles. A preliminary LCA analysis showed that the global warming potential is reduced by 8% if the green concrete is used.

1 Introduction

Most of Portugal's architectural heritage is characterized by walls built with natural stone or solid brick. In addition to these substrates, the most common mortars to be used in rehabilitating of these buildings are produced based on cement or lime (hydraulic or aerial) [1, 2].

According to the manufacturer of Natural Hydraulic Lime NHL 3.5, this material is a natural hydraulic binder suitable for the production of coating mortars. This mortar can be applied to the rehabilitation and conservation of old and historic architectural structures, or new construction work. This product integrates, in a single substance, the aerial setting and hydraulic setting processes, without the need for additional additions. With these characteristics, it can be applied internally and externally, and on the substrates of new masonry in prefabricated blocks or ceramic brick and stone masonry [3].

However, research on mortars generally takes place in a laboratory environment, where various properties are evaluated according to the relevant standards. These standards recommend the manufacture of standardized test specimens, molded into metallic shapes and subjected to specific curing conditions. In practical reality, the application of mortar occurs on substrates made of different materials and under different conditions, which often differ from the controlled conditions found in a laboratory.

Some studies have already been conducted to detect the influences that substrates can have on mortars. The results showed changes when these mortars were compared with mortars molded in standardized molds [4–6].

This research aims to analyze the physical durability of oyster shells in hydraulic lime-based mortars. In addition to the work trying to predict the in-service behavior of hydraulic lime mortars applied to solid brick substrates, one of the mortar mixtures incorporates oyster shell to recover old construction techniques. Mortars based on lime from oyster shells were used in ancient buildings in coastal regions. In the Algarve (Southern region of Portugal), for example, can find buildings with an insulation layer made up of a mixture of medium-grained sand with trampled and compacted cockle shells [7].

If it is feasible to predict the behavior of the mortar on the substrate based on the characteristics determined in the laboratory, the decision to initiate a rehabilitation action will be based on and informed more solidly and consciously.

2 Materials and Methods

The materials for this research were chosen from the perspective of rescuing old construction techniques from coastal regions and rehabilitating these old buildings that still exist. Natural hydraulic lime was chosen as a binder to produce the mortars and apply them to solid ceramic brick substrates (21.6 × 10.2 × 5 cm). The sand was composed of four types of calibrated sand. The oyster shell was donated by a cooperative in the southern region of Portugal, and was used to replace the sand aggregate. With this, two different types of mortars were produced: a control group and a group with a replacement of 30% of the sand aggregate by oyster shell aggregate (30%-OS).

When the oyster shell arrived at the university laboratory, its preparation included washing with water, drying in an oven until constant mass, and grinding in a cutting

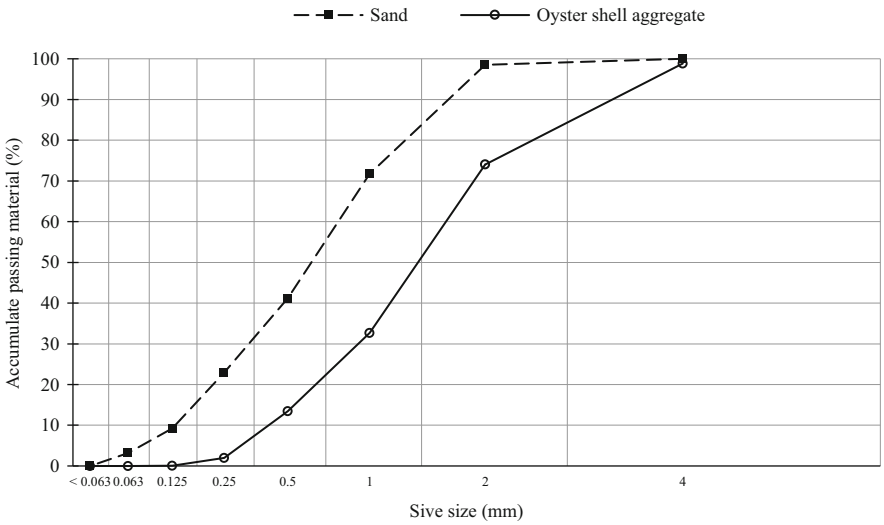

Fig. 1 Particle size distribution (sand and oyster shell as aggregate)

Table 1 Composition of the mortars produced

Mortars	Binder (%)	Sand (%)	Oyster shell aggregate (%)	Water/binder ratio
Control	100	100	0	1.07
30%-OS	100	70	30	1.18

mill (to transform the shell as a substitute for sand). Particle size distribution of sand and oyster shell aggregate were found according to the NP EN 933-1 standard [8] and are shown in Fig. 1.

The mortars were produced with of a mixer and a plastic pail. The mortar ratio corresponded to 1:3, and the sand was replaced by 30% by shell, in volume. The composition of the mortars can be seen in Table 1.

The quantity of water added to the mixtures was adjusted prior to the production of all specimens under study. The quantity of water was determined by a consistency test, carried out in the fresh state of the mortars according to the EN 1015–3 standard [9].

After mixing, the specimens were first molded in standard molds (prisms: 40 × 40 × 160 mm and circles 15 mm thick and 100 mm in diameter). Then, a layer of the same mortar was applied to one of the surfaces of the solid brick substrates. To guarantee the uniformity and thickness of 20 mm of the coating at the time of application, a wooden mold was used. Using a 40 x 40 mm metal mold and a 100 mm diameter polyvinyl chloride (PVC) mold, markings were made on the layer of fresh mortar applied. Immediately before application, the surface of the bricks was moistened by spraying with water, using a spray bottle, to simulate real, normal application conditions. A 5 × 5 mm fiberglass mesh was incorporated to facilitate subsequent detachment of the applied mortar layer. The process of applying

Fig. 2 Specimens preparation under in-service condition: (**a**) molding the mortar on the solid brick substrates; (**b**) marking the specimens on the fresh mortar layer; (**c**) accelerated aging curing; (**d**) detaching of mortar from the substrates

mortar to the solid brick can be seen in Fig. 2a. The marking of the specimens in the still-fresh mortar layer is shown in Fig. 2b.

The curing process of the specimens molded in standardized molds and the mortars applied to the substrates followed the specifications of the EN 1015–11 standard [10]. All tested material was kept in a controlled laboratory environment at 20 °C and 95% relative humidity for 7 days, followed by subsequent days at 20 °C and 65% relative humidity until the test date. In addition to curing in the laboratory for 28 days, the solid brick and mortar models were subjected to accelerated aging cure [11] (Fig. 1c). Basically, the models were subjected to two stages of four cycles, with the first step of the second series being adapted for technical reasons:

- First stage—four cycles: 60 ± 2 °C for 8 h ± 15 min; 20 ± 2 °C and 65 ± 5% relative humidity for 30 ± 2 min; −15 ± 1 °C for 15 ± 15 min; 20 ± 2 °C and 65 ± 5% relative humidity for 30 ± 2 min.
- Second stage—four cycles: The sets were moistened with 300 ml of water each and were conditioned in a climatic chamber at 95% relative humidity and 20 ± 1 °C for 8 h ± 15 min; 20 ± 2 °C/65 ± 5% relative humidity for 30 ± 2 min; −15 ± 1 °C for 15 min ± 15 min; 20 ± 2 °C and 65 ± 5% relative humidity for 30 ± 2 min.

After that, the coating layer was detached from the substrates, and specimens with dimensions of 40 × 40 × 15 mm and circles of 15 × 100 cm were easily obtained (Fig. 1d). The prismatic specimens from the standardized molds were cut into 15 mm thick slices, to have the same dimensions as the cured specimens detached from the substrates. This allowed the comparison of performance between different molding conditions and mortar composition.

The identification of the mortars is as follows:

- Control: control mortar molded in standard molds;
- 30%-OS: mortar with 30% replacement of sand aggregate with oyster shell aggregate molded in standard molds;
- Control/SB: control mortar applied to solid ceramic brick and with accelerated aging curing (representing in-service conditions);

Fig. 3 Tests on mortars in the hardened state: (**a**) bulk density; (**b**) open porosity; (**c**) water absorption by capillarity; (**d**) water vapor permeability

- 30%-OS/SB: mortar with 30% replacement of sand aggregate with oyster shell aggregate applied to solid ceramic brick and with accelerated aging curing (representing in-service conditions).

The results of the characterization tests in the fresh and hardened state of the mortars are presented below in both laboratory and real-world conditions after curing by accelerated aging, application, and detachment from the substrate. Although the specimens did not have the dimensions recommended by current standards, the tests were based on their guidelines. The hardened state tests analyzed were: bulk density and open porosity [12] (Fig. 3a and Fig. 3b), water absorption coefficient by capillarity [13] (Fig. 3c), and water vapor permeability [14, 15] (Fig. 4d).

The bulk density and open porosity began the test with specimens dried in an oven at 70 °C (dry weight). After that, the specimens were transferred to a container connected to a vacuum pump (24 h). Then, water was introduced until the specimens were submerged, and the vacuum pump remained on for another 24 h. A hydrostatic balance was used to record the mass of the specimen immersed in water, as well as the mass of the saturated specimen.

The specimens were waterproofed, with plastic film, on their side faces, to guarantee a unidirectional flow, before starting the water absorption test by capillarity. During the test, the specimens remained in a layer of water with a height of 5–10 mm. The specimens were weighed 5, 10, 30, 60, 90, 180, 300, 480, 1440, 2880, 4320 minutes after the start of the test.

In the case of the water vapor permeability test, the specimens (20 mm thick and 100 mm in diameter, approximately) were tested using the wet trough method, so that vapor diffusion was unidirectional and exclusively through the specimen. After preparing the specimens, they were placed in a climate chamber with constant temperature and relative humidity (20 °C and 50%, respectively). An initial and periodic weighing was carried out until a constant mass variation per unit of time was obtained.

The results of all tests in the hardened state were entered into the Statistic® 7.0 software. An analysis was performed using one-way ANOVA followed by the Tukey test, which assessed the existence of significant differences at the 5% significance level ($p < 0.05$).

3 Results and Discussions

3.1 Fresh State

The slump flow result obtained for the two types of mortar produced was 170 mm. This index corresponds to the suggestion in EN1015–2 [16] that the slump flow measurement be 175 ± 10 mm for mortar with a bulk density greater than 1200 kg/m^3. In the same way, the quantity of water used in the mortar was sufficient to allow it to be applied to solid brick.

3.2 Hardened State

Table 2 presents the density (D) and open porosity (OP) results.

The density result of the mortar produced with oyster shell (30%-OS and 30%-OS/SB) was lower than the density presented by the control mortar (Control and Control/SB), both for the mortars molded in the standard molds and mortars in-service conditions. In the case of open porosity, mortars with oyster shells demonstrated greater results compared to the control mortar. The density of the aggregates explains the results found in the mortars, as the oyster shell aggregate is heavier than the calibrated sand aggregate. This implies lower densities and greater porosities. When studying cement mortars with marine waste, Ez-zaki et al. [17] attribute a decrease in apparent density and consequently an increase in apparent porosity due to the greater water demand these mortars needed to reach an adequate consistency.

After applying the mortars to the solid brick and curing through accelerated aging, the densities of the Control/SB (1820 kg/m^3) and 30%-OS/SB (1679 kg/m^3) mortars increased in relation to the Control (1775 kg/m^3). m^3) and 30%-OS (1619 kg/m^3) mortars, respectively. In the case of open porosity, the mortars reduced their results after in-service conditions. Travincas et al. [6] analyzed industrial cement mortar applied to different substrates (concrete plate; concrete block; light-weight concrete block; and hollow ceramic brick). The authors also concluded that

Table 2 Density and open porosity tests of mortar

	D (kg/m^3)				OP (%)			
Mortars	A	SD	CV (%)	NS	A	SD	CV (%)	NS

mortars produced in standard molds showed lower density and greater open porosity results, compared to applied and detached mortars, regardless of the type of substrate.

The analyzes prove that the density results are significantly different in terms of mortar composition but that the curing and molding conditions also cause changes in the results. The same happens in the case of open porosity. However, the control mortar submitted in-service situations did not show significant differences in its results. The oyster shell mortar showed a significant difference in behavior when subjected to different conditions than the laboratory standard.

The water absorption coefficients by capillarity are shown in Table 3.

The water absorption coefficients decreased for the Control/SB and 30%-OS/SB mortars, compared to the Control and 30%-OS mortars, considering the same groups of mortars. The highest water absorption coefficients were for mortars that had oyster shell in the composition.

Although the absorption coefficients of the 30%-OS and 30%-OS/SB mortars are greater than the coefficients of the Control and Control/SB mortars, the statistical analysis demonstrated that these differences are not significant in relation to the Control mortar. The Control/SB mortar presented the lowest water absorption coefficient, however the conditions in service did not change this coefficient, to the point that the result was significantly different in relation to Control.

Through the water vapor permeability test it was possible to obtain Table 4.

The application of the control mortar and the mortar with 30% oyster shell on the solid brick, as well as curing by accelerated aging, contributed to the reduction of water vapor permeability results for both mortars. Through the statistical analysis carried out, no results were found with significant differences among any of the mortars studied. The Control/SB and 30%-OS/SB mortars showed smaller differences in behavior (in the order of 8%), while the Control and 30%-OS mortars showed differences in results of approximately 19%.

Table 3 Water absorption coefficient by capillarity of mortar

Mortars	A ($kg/(m^2.s^{0.5})$)	SD ($kg/(m^2.s^{0.5})$)	CV (%)	NS

30%-OS	0.415^{a}	0.017	4	3
Control/SB	0.363^{b}	0.011	3	6
30%-OS/SB	0.387^{a}	0.014	4	7

Table 4 Water vapor permeability test of mortar

Mortars	A (kg/(m.s.Pa))	SD (kg/(m.s.Pa))	CV (%)	NS
Control	$1.80E\text{-}11^{a}$	6.20E-12	34.51	3
30%-OS	$1.46E\text{-}11^{a}$	7.21E-13	4.94	3
Control/SB	$1.21E\text{-}11^{a}$	1.18E-12	9.74	3
30%-OS/SB	$1.32E\text{-}11^{a}$	5.00E-13	3.79	3

The results of these hydraulic lime mortars differ from the results found by Travincas et al. [6]. The authors concluded that mortars produced in standard molds showed lower water vapor permeability results, compared to applied and detached mortars, regardless of the type of substrate. This trend may have occurred due to the pore distribution checked by MIP.

Although the 30%-OS and 30%-OS/SB mortars presented the highest water vapor permeability values (when analyzing the groups), the standard deviation and coefficient of variation of these mortars were lower.

4 Conclusion

This research aimed to analyze the physical durability of oyster shells in mortars based on hydraulic lime. In this case, a control mortar and a mortar with 30% replacement of sand aggregate were replaced by oyster shell aggregate.

With the same consistency for the mortars, specimens were molded under standard laboratory conditions, and other specimens simulated conditions considered in-service (application of a layer of mortar on a solid ceramic brick support and curing by accelerated aging).

In most results, mortars produced with oyster shell showed lower densities, higher porosities, water absorption coefficient and vapor permeability when compared to control mortar. However, these results showed no significant differences using the Tukey test.

Furthermore, the results presented confirm changes in the performance of the coating layer applied to the substrate surface. In some cases, both the control mortar and the shell mortar showed significant differences in their properties after application to the solid brick support and curing by accelerated aging, compared to laboratory conditions.

Therefore, mortars with oyster shell have demonstrated that their results do not differ from standard mortar, as well as improving their performance under service conditions. A substrate characterization analysis would improve understanding of the effects caused to mortar coatings.

When studying hydraulic lime mortars containing oyster shell applied to a solid ceramic brick support, at least two advantages can be cited: ancient cultural aspects of construction present mainly in coastal locations are valued, as well as important evidence for cases of rehabilitation of old buildings. With this work it can be said that changes occurred in the properties of the mortars being influenced by the support, as well as the oyster shell has potential for use in construction. Future studies with oyster shell could explore whether this bioproduct has potential as a thermal material.

1 Introduction

Carbon dioxide emission reduction has become a prominent global concern in recent years. The construction sector stands out with a substantial 40% contribution to the overall carbon footprint, making it a major player in CO_2-emission [1, 2]. The cement industry is considered as the largest CO_2-contributor in this sector responsible for about 8% of global emissions [3, 4]. To address this issue, exploring alternative binders, e.g., alkali-activated binders (AAB), has emerged as a promising strategy to mitigate carbon emissions. By only substitution of traditional binders with alternative binders, about 80% of CO_2-emission reduction could be possible [5–7]. However, achieving carbon-neutral conditions in the cement industry requires a multifaceted approach, combining various methods aimed at reducing CO_2-production along with the adoption of alternative binders. Life cycle assessment (LCA) studies on alternative binders highlight AAB as particularly promising,

demonstrating the lowest CO_2-emissions among the other alternatives. Using carbon-capturing techniques in AAB can lead to a reduction of more than 90%.

Two components of the materials used in concrete have a CO_2-absorption potential. Binders containing alkaline or alkaline earth elements inherently possess the ability to react with CO_2, particularly in humid conditions [8]. Additionally, recycled aggregates containing old cement paste are capable of absorbing CO_2 due to their high calcium content. The reaction of calcium hydroxide with CO_2 is considered as the dominant reaction in ordinary Portland cement (OPC) matrix [9]. The CO_2 diffuses in the pore water of the unsaturated matrix, followed by its reaction with carbonatable solutes, i.e., $Ca(OH)_2$ (calcium hydroxide) solute [8, 9]. Similarly, aggregates extracted from alkali-activated concrete (AAC) can absorb CO_2 through their reaction with alkaline or alkaline earth elements. The rate of carbonation in alkali-activated slag mortar has been reported considerably higher than that of OPC, leading to the decalcification of calcium silicate hydrate (CSH) [10, 8]. Depending on the type of activator used, the carbonation rate of AAB can vary [10]. AAB activated with hydroxide activator shows more rapid carbonation rate compared to the one activated with waterglass [11].

The use of recycled aggregates in concrete production has increased sharply in recent years [12, 13]. This trend can be attributed to the dual objectives of addressing the scarcity of natural resources and mitigating the release of construction and demolition waste (CDW) into the environment [14, 15]. CDW constitutes the largest global waste stream by around 3 billion tons annually [16]. This inclination toward sustainability also extends to concrete manufactured with alkali-activated binders (AAB). Consequently, it becomes imperative to assess the feasibility of recycling such concrete. Furthermore, the potential to absorb carbon dioxide during its service life, as well as after recycling is a key factor for the calculation of CO_2-uptake. Leemann et al. [17] indicated that recycled concrete aggregate (RCA) from OPC absorb 9–21 wt.% CO_2 . The CO_2-uptake of concrete structures was estimated about 17% of the total emission produced during the cement manufacturing in Sweden in 2011 throughout their service life [18].

The reduction of porosity and water absorption of concrete, as well as RCA is associated with the aggregate carbonation [19]. Subsequently, the mechanical behavior of RCA will be improved, followed by the improvement of corresponding behavior of concrete made with them [20]. Due to the current and future tendency for using low-carbon footprint concrete, the recycling of it and the CO_2-uptake potential of recycled materials should be clarified. In addition, the recognition of these recycled materials behavior in treated and non-treated state will be a useful parameter in reusing them in concrete.

Regarding the lower CO_2-emission of AAC in comparison with than of OPC, it is foreseen that this type of concrete will be partly replaced with ordinary concrete in the future. GGBS is considered as one of the main precursors used in this system [7]. However, GGBS production is limited to around 408 million tons in 2022 worldwide [21]. In contrary to the announcement about the reduction of GGBS production, it is reported that its production will reach around 497 million tons by 2035 [21]. In addition, thanks to the replacement of GGBS with supplementary

precursors, the GGBS demand could be reduced. Therefore, it is necessary to evaluate the feasibility of recycling this type of concrete after the end of service life of the structures made with them. Regarding the importance of CO_2-capturing in civil structures, the sequestration potential of the aggregates extracted from them could also be considered for their utilization in the future.

2 Materials and Testing Procedures

2.1 Materials

In this research, aggregates, for primary mixtures included natural and recycled aggregates type 1 according to EN 12620 and DIN 4226-101. The properties of aggregates in primary mixtures had no influence on the CO_2-uptake of recycled aggregates extracted from the concrete made with them. Therefore, they were neglected to be described in this study. Mixes based on alkali-activated ground granulated blast furnace slag (GGBS) using these aggregates were produced. Subsequently, aggregates extracted from these two concrete mixtures containing natural and recycled aggregates were sieved and characterized. Then, the aggregates properties were tested and exposed to carbonation.

In alkali-activated concrete mixtures, GGBS was the only precursor employed in this study. The chemical composition of GGBS is shown in Table 1. The GGBS had a Blaine value of 4050 cm^2/g and a density of 2.87 g/cm^3. It was activated with 8% activators, including sodium hydroxide (NaOH, 16 mol), sodium silicate ($Na_2O.nSiO_2$, $n = 2.1$), and potassium silicate ($K_2O.nSiO_2$, $n = 1.7$).

The description of aggregates extracted from AAC mixes in this study before and after carbonation is depicted in Table 2.

2.2 Mix proportions and Production

For the generation of recycled aggregates from alkali-activated concrete, two reinforced concrete slabs were produced based on the mix proportions M1 and M2, presented in Table 3. Both M1 and M2 shared identical binder compositions, differing solely in the types of aggregates used. M1 was made with natural aggregates. In M2 the coarse aggregates (2/8 mm and 8/16 mm) were recycled concrete aggregate type 1. These slabs were cured in a plastic foil for 28 days. The compressive strength of the specimens corresponding to the slabs was tested to ensure that the targeted strength of slabs was achieved at 28 days. Subsequently, the slabs were crushed to produce recycled materials.

Additionally, mix M3 was produced, which consists of 100% coarse aggregates extracted from the concrete slab made with aggregates A(M1) (recycled from mix M1), see Table 3. CM3 is another mixture with a similar mix composition to M3 in

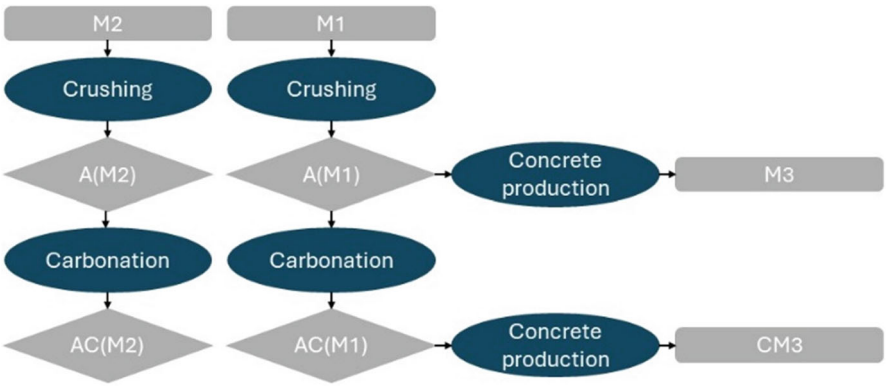

Fig. 1 The visual procedure of material preparation and concrete production

which the extracted aggregates from M1 (A(M1)) were carbonated and then used in concrete production. All the concrete mixes in this study had an equal water to binder ratio (w/b) of 0.38. The difference between the water content of mixes in Table 3 is due to the difference of water absorption in aggregates. Furthermore, the water content of alkaline solutions was also considered in the total water content of mixtures. A visual sketch of material preparation and concrete production is demonstrated in Fig. 1.

The aggregates were dried before concrete production. To prevent a significant workability drop after the production, caused by water suction in dried aggregates, they were initially mixed with the required water for saturation in a concrete mixer for 30 seconds and remained in it for 10 minutes to achieve about 90% of the total saturation. Subsequently, the aggregates were mixed with other ingredients of the mixture for 5 minutes.

2.3 Testing Procedures

The water absorption and densities of the primary aggregates, as well as produced aggregates were determined according to EN 1097-6. For this test, three specimens from each sort of aggregates were tested and the average values were subsequently reported. For CO_2-absorption testing, five specimens from each sort of aggregates, each weighing 70–120 g, were selected. The non-carbonated aggregates were dried in 105 ± 5°C until reaching constant mass state, followed by a cooling procedure to room temperature under vacuum conditions. The non-carbonated aggregates in dried condition were weighed. Subsequently, they were placed in a CO_2 chamber having 1% CO_2 concentration at 20 ± 2°C temperature and a relative humidity (RH) of 57 ± 5%. The aggregates were weighed again after 7 and 14 days to justify their CO_2 absorption. At the end of each interval and before weighing the specimens were dried through the mentioned procedure above.

Fresh concrete properties were tested using slump and flow table tests according to EN 12350-2 and EN 12350-5, respectively. The air content of concrete mixtures was determined based on EN 12350-7.

This study investigated the hardened concrete properties, specifically focusing on compressive strength, tensile splitting strength, and elastic modulus, as outlined in EN 12390-3, EN 12390-6, and EN 12390-13, respectively. The compressive strength tests of concrete mixes were carried out on 150 × 150 × 150 mm cubes. Tensile splitting strength tests were performed on a prism having 100 × 100 × 600 mm dimension. A cylindrical specimen with 150×300 mm dimension was produced for the elastic modulus test. All the three above-mentioned tests were carried out at the ages of 2, 7, 28, and 91 days.

3 Results and Discussions

3.1 Aggregates

Figures 2 and 3 demonstrate the carbon dioxide absorption capacity of the aggregates A(M1) and A(M2) (extracted from recycled AAC mixtures (M1) and (M2)), respectively. It is observed that the maximum carbonation level of recycled aggregates based on AAC is reached after 7 days, requiring no further exposure. Notably, fine recycled aggregates showed a higher carbonation capacity than coarse aggregates. The 8/16 mm recycled AAC aggregate shows the lowest CO_2-absorption potential by around 2 wt.%. The reason could be the higher porosity of the fine recycled aggregates compared with the coarse recycled aggregates, which expedites the CO_2 penetration. Moreover, the higher available specific surface in the fine aggregates and the higher amount of old mortar content in them lead to a superior absorption capacity in fine recycled aggregates than the corresponding coarse recycled aggregates. Indeed, the natural aggregate parts of recycled aggregates can

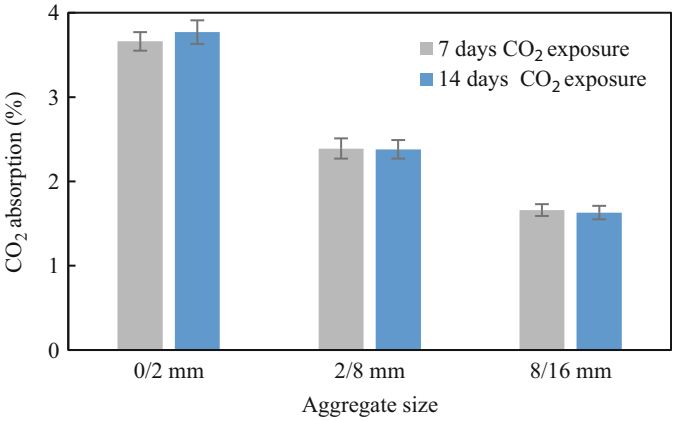

Fig. 2 CO_2-absorption of aggregates A(M1) (recycled from mix M1, including natural aggregates)

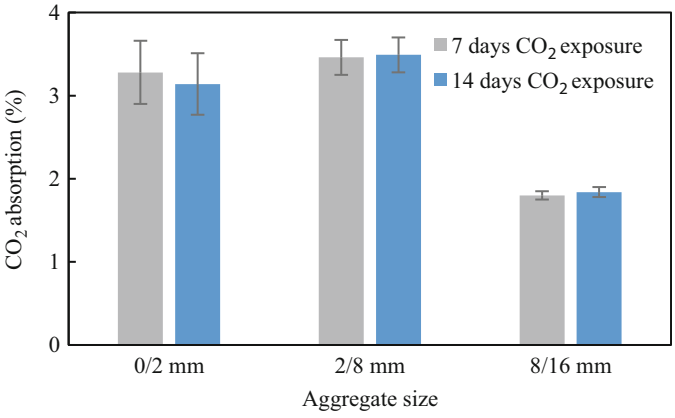

Fig. 3 CO_2-absorption of aggregates A (M2) (recycled from mix M2, including recycled aggregates)

be considered as non-absorbent parts (Fig. 2). Old concrete usually tends to be crushed through their weakest part in the crusher. Old mortar content in recycled aggregate is the dominant weak part compared to the natural stone content [22]. This observation aligns with the differing fracture mechanism of normal-strength and high-strength concrete. In normal-strength concrete, the rupture occurs through the binder, while the high-strength concrete usually ruptures through the aggregate [23]. Given the weaker nature of the old mortar, as well as the interfacial transition zone (ITZ) between the aggregate and mortar in normal-strength concrete, the old mortar content becomes a critical factor [23]. For this reason, the amount of old mortar paste content in the fine recycled aggregates is usually higher than its content in the larger grain fractions. Thus, the finer fractions, which have higher porosity, should have higher CO_2-absorption potential than the others. It is observed that the

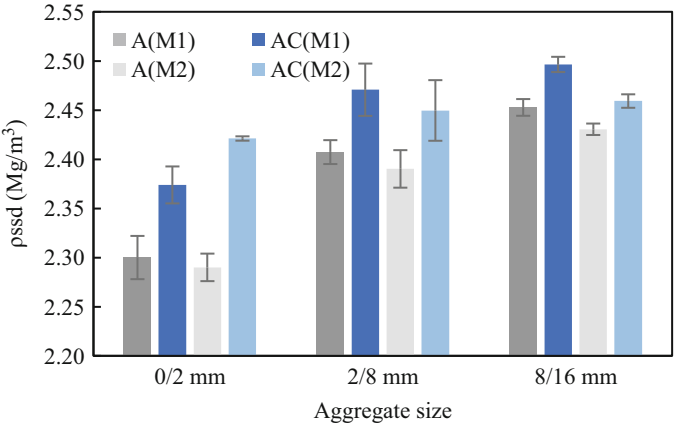

Fig. 4 Density of recycled AAC aggregate in saturated surface dried state

2/8 mm A(M2) absorbed 1% higher amount of CO_2 in comparison with 2/8 mm A (M1). However, the 8/16 mm aggregates from A(M1) and A(M2) showed almost similar CO_2-capturing potential.

The density variations of recycled AAC aggregates before and after carbonation in saturated surface-dried state (SSD) are shown in Fig. 4. It is seen that the fine aggregates with 0/2 mm size from both M1 and M2 mixtures have the lowest densities in comparison to the corresponding 2/8 mm and 8/16 mm aggregates. In contrast, 8/16 mm aggregates showed the highest densities compared to the corresponding aggregates with smaller sizes. This observation confirms the previously mentioned higher porosity in fine aggregates in comparison with coarse aggregates.

Furthermore, the carbonation of recycled AAC aggregate increases the density in the SSD state, regardless of the mix composition of old concrete and the size of the aggregate. The difference between the density of aggregates in the carbonated and non-carbonated state is larger for 0/2 mm than 2/8 mm fraction. Subsequently, that for the 2/8 mm is more significant than that for the 8/16 mm grains. The higher potential of CO_2-absorption in finer fractions, explained before, can be substantiated as the primary reason.

The water absorption of recycled AAC aggregates as one of the crucial parameters for the evaluation of porosity, which subsequently affects their durability properties, is illustrated in Fig. 5. The results highlight the positive influence of carbonation on the water absorption reduction of aggregates. The effect of carbonation on the water absorption variation depends on the size of aggregates. The fine recycled AAC aggregates (0/2 mm) show higher water absorption drop compared with 2/8 mm fraction, as well as 8/16 mm aggregates from the same source. Similarly, the coarse recycled AAC aggregates with 2/8 mm size show a bit larger water absorption than the 8/16 mm aggregates from the corresponding mixture.

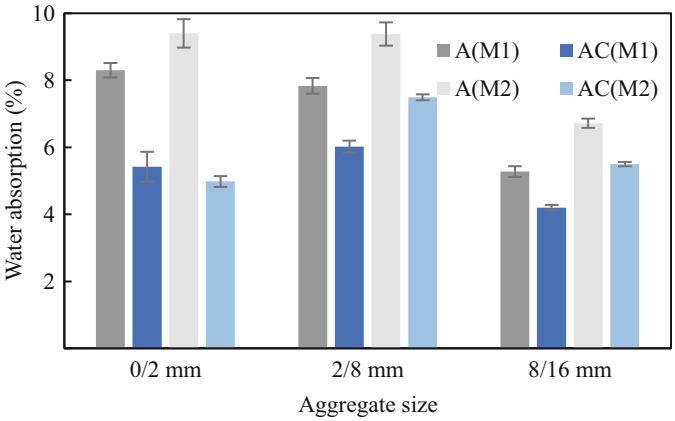

Fig. 5 Water absorption of recycled AAC aggregate

Thus, carbonation is meaningful not only in terms of CO_2-footprint decrease but also considering the positive influence on the durability behavior of recycled aggregates. It was also reported that the water absorption and porosity of RCA from OPC decreases through carbonation treatment [19].

3.2 Concrete

Figure 6 depicts the compressive strength of AAC mixture M3 and CM3, produced with recycled aggregates extracted from AAC mixture M1 in both non-carbonated and carbonated states named A(M1) and AC(M1), respectively. The use of carbonated recycled AAC aggregates in AAC concrete shows a higher compressive strength at all ages compared to the concrete made with the corresponding non-carbonated aggregates. The compressive strength development of AAC with non-carbonated aggregates seems to be retarded after 28 days. While its trend in AAC with carbonated aggregates is followed by a moderate increase after 28 days. Higher alkalinity of the aggregate ambient, originated from the presence of alkaline solution in newly made concrete could lead to the reactivation of non-activated precursors in recycled AAC aggregate.

Figure 7 illustrates the tensile splitting strength of AAC made with A(M1) and AC(M1). The trend of strength development is similar to that of compressive strength depicted in Fig. 6. The notable difference between the tensile strength of the mixtures made with the carbonated and non-carbonated aggregates at 91 days could be primarily because of the late reactivity of the recycled AAC aggregates. However, the carbonation of recycled AAC aggregates results in tensile strength enhancement of AAC at all ages.

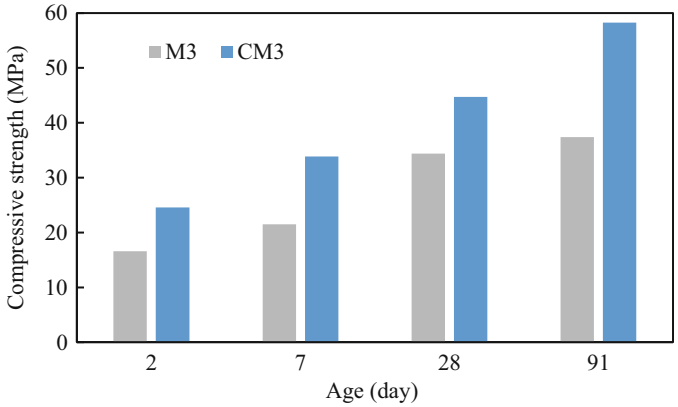

Fig. 6 Compressive strength of AAC with carbonated (CM3) and non-carbonated (M3) recycled AAC aggregate from mix M1

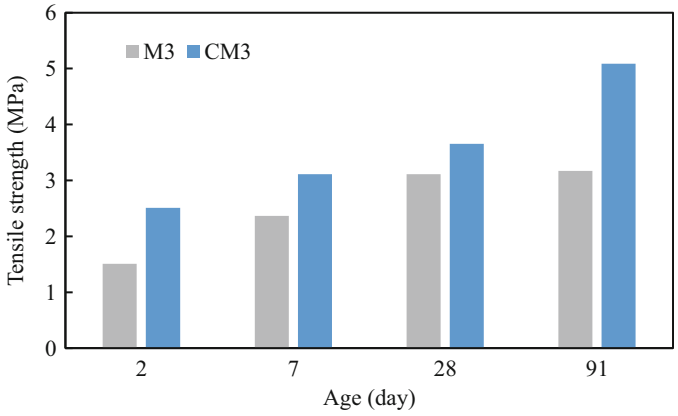

Fig. 7 Tensile splitting strength of AAC mixtures with carbonated (CM3) and non-carbonated (M3) recycled AAC aggregate from mix M1

The elastic modulus of AAC mixtures with A(M1) and AC(M1) aggregates is demonstrated in Fig. 8. The AAC mixture made with non-carbonated aggregates showed higher elastic modulus values than that made with carbonated aggregate, until 28 days age. It is also observed that the difference between the elastic modulus of both mixtures progressively diminishes until 28 days, reaching an equal point after 28 days. In contrary to early ages, the mixture made with carbonated recycled AAC aggregates showed a superior elastic modulus compared to the corresponding value of the mixture made with non-carbonated aggregates at 91 days. Despite the difference between the elastic modulus of both concrete mixes, this is not more than 10% of the total values at 28 or 91 days.

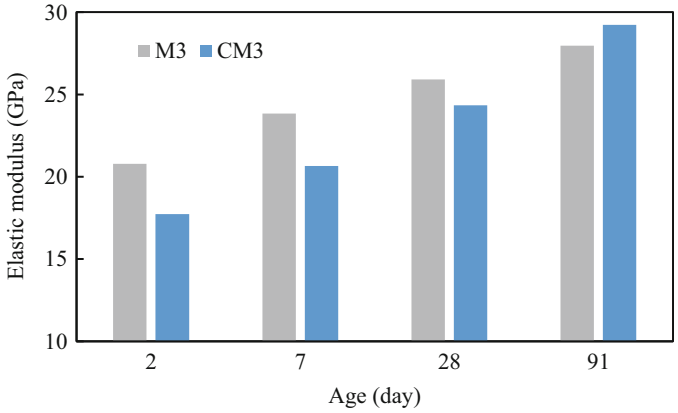

Fig. 8 Elastic modulus of AAC mixtures with carbonated (CM3) and non-carbonated (M3) recycled AAC aggregate from mix M1

4 Conclusion

1. One-week exposure of recycled aggregates to 1% CO_2 leads to a complete carbonation in all aggregate sizes (0/2, 2/8, and 8/16) tested.
2. Fine recycled aggregates from ACC can absorb up to 4 wt.% CO_2. This value can be considered for the coarse aggregates size having 8/16 mm size 2 wt.%.
3. Carbonation of recycled AAC aggregates increases their SSD densities. In addition, these aggregates can show approximately up to 4% reduction of the water absorption due to the carbonation. Smaller size aggregates are more influenced by carbonation in terms of density and water absorption than larger grains.
4. Compressive and tensile strength of AAC with recycled AAC aggregate improve by using carbonated aggregates. The strength increase increment at 91 days due to the carbonation of aggregates is considerably higher than that at earlier ages.
5. The elastic modulus of AAC with recycled AAC aggregates is negatively influenced by using carbonated recycled AAC aggregates until 28 days. This value shows a slight enhancement by the carbonation of these aggregates.

1 Introduction

Crude iron ore reserves are distributed among various countries, with Brazil, Australia, and China collectively contributing to 63% of the world's iron ore production [1]. Brazil, in particular, plays a significant role in global iron ore production, accounting for approximately 19% of the total output [2]. With an annual production of around 430 million tons [3], Brazil holds a prominent position in the global iron ore market, representing about 5% of its GDP [4].

However, the mining sector encounters a significant challenge related to the substantial waste generated during mineral extraction and processing [5]. According to Kalisz et al. (2022), this sector generates an estimated 65 billion tons of waste

annually, posing significant storage and environmental management challenges [6]. For instance, North Americans produce over ten times more solid mine waste per capita than household garbage, while China's solid mine waste inventory approaches 70 billion tons [7, 8].

The main wastes of this operation are waste rock and iron ore tailings (IOT). The first represents a layer of soil and rock to be removed to access the ore and, which has no economic value [9], and the second is the material discarded in the ore processing stage [10]. The waste/metallic ore ratio resulting from surface mining is typically between 2 and 5, depending on location-specific conditions [11]. In Brazil, between 2010 and 2019, approximately 3.9 billion tons of waste rock and 1.3 billion tons of IOT were generated [12].

In general, both wastes are deposited in piles and dams [13, 14]. These geotechnical structures require adequate management and constant monitoring to guarantee stability and safety, which represents a high cost to the entrepreneur [12]. There are several records of pile and dam failures that resulted in the loss of human life, loss of equipment, and environmental damage [15–18].

Consequently, utilizing waste materials in cementitious materials represents a more sustainable alternative, than their disposal in piles or dams [12]. While there is ample literature on the use of IOT in civil construction (as summarized in Table 1), studies on the utilization of waste rock remain limited.

Therefore, incorporating waste rock in mortar production not only represents a sustainable solution for mining waste disposal but also offers a readily available means of reducing the amount of cement in mortar mixtures, thus mitigating greenhouse gas emissions associated with cement production, notably carbon dioxide.

Table 1 Use of waste from iron ore extraction in civil construction

2 Experimental Program

2.1 Materials

The mortar mixtures comprised Portland cement type V-ARI, conforming to Brazilian standard NBR 16697 [52], waste rock, sand with a maximum diameter of 300 μm and a density of 2.64 g/cm^3, and water. The cement has between 90 and 100% clinker plus calcium sulfate and up to 10% carbonaceous material, density of 3.08 g/cm^3 and a fineness, on a 45 μm sieve, of 0.6%.

The waste rock utilized in this study was supplied by the vale mining company and was proven by the extracted of iron ore in cava conceição, situated in Itabira, quadrilaterro ferrífero region, Minas Gerais, Brazil. Following mineral removal, via detonation, the waste was transported to the disposal site, where it was collected. Prior to using the waste rock, it underwent sieving on a 75 μm sieve.

The waste rock has density of 2.79 g/cm^3, fineness on 45 μm sieve of 27,8%, and moisture content of 0.4%. X-ray fluorescence (XRF) analysis determined the waste rock's oxide composition (refer to Table 2), revealing SiO_2 + Al_2O_3 + Fe_2O_3 content exceeding 70% (93.60%), low calcium oxide (CaO) content (0.59%), and absence of SO_3. Additionally, trace amounts of toxic compounds, including chromium, lead, and copper, were detected, each constituting less than 0.001%. However, the waste rock exhibited a strength activity index with Portland cement at 28 days, as determined by NBR 5752 [53], of 72%, falling below the 75% threshold outlined in ASTM C618 [54].

Figure 1 illustrates the ternary diagram representing the CaO - SiO_2 - (Al_2O_3 + Fe_2O_3) system of waste rock, IOT, and various mineral additions. It is noteworthy that the composition of the waste rock utilized in this study closely mirrors that of fly ash [55–58], metakaolin [59–61], Brazilian IOT [32, 34], and Brazilian waste rock sourced from another source [51].

The waste's morphology was examined via scanning electron microscope (SEM) images, revealing grains with lamellar shapes (refer to Fig. 2). Energy-dispersive X-ray spectroscopy (EDS) analysis showed that the sample is composed of silicon (72.1%), aluminum (13.3%), iron (10.3%), and potassium (4.3%), consistent with its chemical composition.

Mineralogical analysis via X-ray diffraction (XRD) identified crystalline phases in the waste rock sample, mainly composed of quartz (62.8%), kaolinite (27.1%), and biotite (9.0%). Goethite and hematite are present in concentrations below 1%.

Table 2 Major chemical compounds of waste rock

Compound	SiO_2	Al_2O_3	Fe_2O_3	K_2O	TiO_2	P_2O_5	CaO	Other
Waste rock (%)	60.10	21.40	12.10	3.74	1.07	0.59	0.32	< 0.01

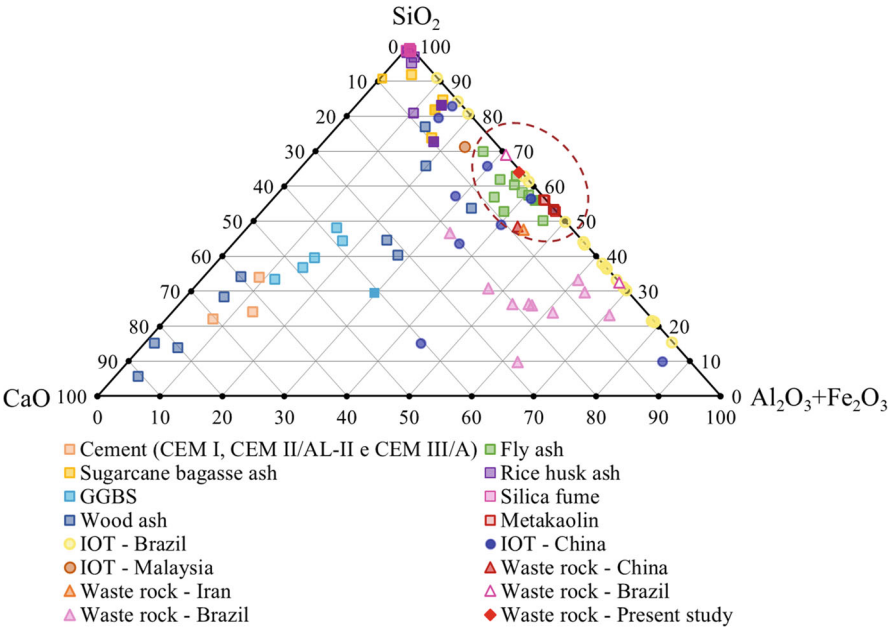

Fig. 1 Ternary diagram of waste rock and other types of mineral additions

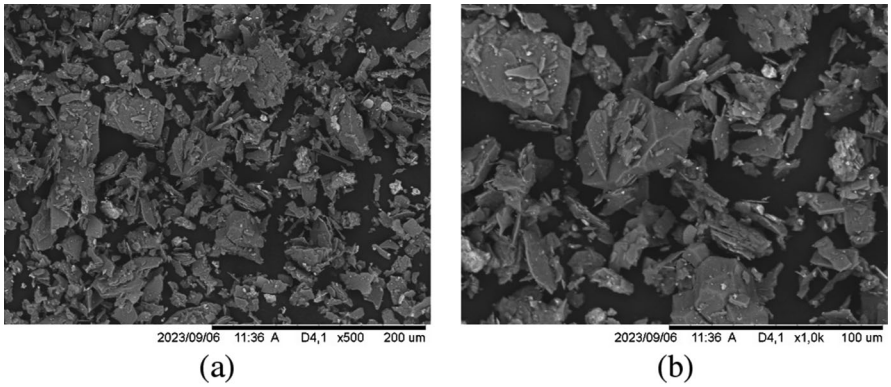

Fig. 2 SEM images with approximation of (**a**) 500× and (**b**) 1000×

2.2 Mixtures Design Details

Mortar mixtures were designed with cement partially replaced by 10%, 20% and 30% waste rock (in mass). The water/(cement + waste rock) ratio was maintained at 0.40, and the sand/(cement + waste rock) ratio was maintained at 0.36. Details of the mixture designs are presented in Table 3.

Table 3 Material quantities used in the mortar mixtures

Mix	Waste rock/ (cement + waste rock) (%)	Quantities (kg/m^3)			
		Cement	waste rock	Sand	water
B0	0	1152.90	0	415.03	461.14
B10	10	1026.40	114.04	410.54	456.16
B20	20	902.56	225.64	406.15	451.28
B30	30	781.39	334.88	401.86	446.51

The consistency of mortars was evaluated with spread values determined in accordance with NBR 13276 [62]. Densities of fresh mortars were obtained by weighing the compacted fresh mortar in a vessel of 400 ml capacity. Following molding, mortar specimens were cured in a water tank until the testing day.

2.3 Experimental Tests

The test procedure involved determining the compressive strength, young's modulus, splitting tensile strength, density, water absorption, and total porosity of mortars, by using three cylindrical specimens measuring 50 × 100 mm (diameter × height). Compressive strength was assessed at 7 and 28 days, in line with the NBR 7215 [63] standard. Splitting tensile tests were conducted at 28 days, following the guidelines of NBR 7222 [64], while density, water absorption, and porosity tests, at 28 days, adhered to the NBR 9778 [65] standard. Young's modulus was obtained by fitting a linear trend to the compressive strength versus strain curves up to 30% compressive strength.

3 Results

3.1 Physical Properties

The spread values determined by consistency tests resulted in measurements of 245 mm (B0), 237 mm (B10), 239 mm (B20), and 221 mm (B30). It was noted that the in-corporation of waste rock slightly enhanced the workability of the mixtures. This improvement may potentially enable a reduction in the water/cement ratio while maintaining consistent workability. Densities of fresh mortars presented values of 2.08 g/cm^3 (B0), 2.03 g/cm^3 (B10), 2.02 g/cm^3 (B20), and 2.01 g/cm^3 (B30).

After 28 days of curing, water absorption, porosity, and density tests were conducted on both the reference mortar (B0) and waste rock-mortars (B10, B20 and B30). Figure 3a illustrates a notable augment in water absorption of all waste rock-mortars in comparison to the B0 mortar. This rise in water absorption, observed

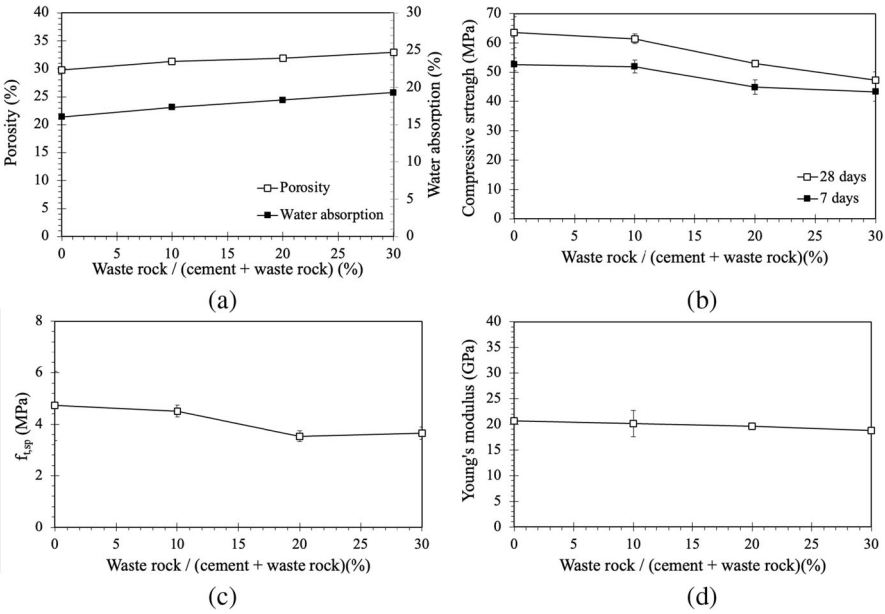

Fig. 3 Influence of waste rock amount on the (**a**) water absorption and porosity, (**b**) compressive strength, (**c**) splitting tensile strength, and (**d**) young's modulus

on waste rock-mortars can be estimated as up to 20%, when used 30% waste rock (B30), and can be attributed to the higher porosity of waste rock-mortars, as depicted in Fig. 3a. About density results, the mortars exhibited densities at 28 days of 1.86 g/cm^3 (B0), 1.81 g/cm^3 (B10), 1.74 g/cm^3 (B20), and 1.70 g/cm^3 (B30). Similar to fresh densities results, the reduced densities were due to lower densities of waste rock compared to cement density.

3.2 Mechanical Properties

In Fig. 3b, the compressive strength of mortars at 7 and 28 days is depicted. At both ages, it is evident that the increased substitution of cement with waste rock led to a reduction in the compressive strength of the mixtures, when compared to the mixture without waste rock (B0). Specifically, with 10% waste rock, the reduction was not significant at 7 days, but was 4%, at 28 days. With 20% waste rock, the compressive strength decreased by 15%, at 7 days, and 17%, at 28 days, while with 30% waste rock, the reductions were 18%, at 7 days, and 26%, at 28 days. This trend primarily stems from the lower cement content in the waste rock-mortars, rather than a slower cement hydration reaction. This is evident when observed the evolution of compressive strength on the time.

The 7-day compressive strength of the reference mortar (B0) equated to approximately 83% of its 28-day compressive strength. Conversely, specimens containing 10%, 20%, and 30% waste rock exhibited a relatively higher rate of compressive strength development (B10: 84%, B20: 85%, and B30: 92%), attributed to the nucleation effect at early ages, when cement was replaced by waste rock, enhancing the hydration reaction of the aluminates [34].

Although the compressive strength of waste rock-mortars has been reduced, an analysis of the eco-efficiency performances of waste rock-mortars at 28 days, by using the binder intensity (bi) index, proposed by Damineli et al. [66], indicates that waste rock-mortar was more efficient than the reference mortar because the bi of reference mortar (18.2 kg/m^3.MPa) was higher than the bi of waste rock-mortars (B10: 17 kg/m^3.MPa, B20: 17.4 kg/m^3.MPa and B30: 17 kg/m^3.MPa). According to Damineli et al. [66], the bi index quantifies the overall amount of binder required to achieve 1 MPa of compressive strength.

Similar to compressive strength results, Fig. 3c indicates that the tensile strength was not significantly changed when 10% cement was replaced by waste rock. However, when cement was replaced by 20% and 30% waste rock, the tensile strength was reduced up to 25%. Young's modulus presented the similar behavior, with a maximum loss of 11% (Fig. 3d), when compared with the reference mortar.

4 Conclusion

The aim of this study was to identify and assess the primary characteristics of mining waste rock produced in Brazilian region. Additionally, the feasibility of using waste rock as a partial substitute for Portland cement in mortar mixture was explored. The investigation yielded the following key findings:

The physical–chemical, mineralogical, and morphological analyses of waste rock revealed it to be an inert material, suitable as an alternative filler for mortar mixtures.

Optimal performance was observed with a 10% replacement of cement with waste rock, as it did not significantly alter mechanical properties. In other way, the use of 20% or 30% waste rock led to reductions in both compressive and tensile strength and young's modulus.

Incorporating waste rock in mortar mixtures resulted in a shortened hydration period, particularly evident in compressive tests conducted at 7 days, attributed to a nucleation effect.

While waste rock had a diminishing effect on the modulus of elasticity and density of the mortars, its impact was less pronounced compared to its influence on compressive strength. Conversely, water absorption and porosity increased in waste rock mortars compared to those without waste rock.

Although the inclusion of waste rock in the mixture led to reduced mechanical strength, it was found that all mixtures containing waste rock were more environmentally efficient compared to those without it. This indicates the feasibility and sustainability of mortars with levels of 10%, 20% and 30% cement replacement by this filler.

Based on the findings, additional strategies could be identified for treating the waste rock prior to its incorporation into cementitious mixtures. To this end, the authors are presently exploring the effects of thermal pretreatment, aiming to enhance the waste's reactivity.

Acknowledgments The funding for this study was provided by Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) and Fundação de Amparo à Pesquisa do Estado do Rio de Janeiro (FAPERJ). The authors extend their gratitude to Vale company, for supplying the waste rock used in the research.

1 Introduction

The global water demand is ever-increasing to such an extent that water scarcity will be one of the biggest problems facing the world in the coming years. Both in South Africa and abroad, water is rapidly becoming a scarce resource. The World Economic Forum ranked both the water crisis and social instability as the third highest threats to conducting business in South Africa in 2021 [1]. The Western Cape in South Africa experienced severe water scarcity from mid-2017 to mid-2018, and more recently in the hydrological year from 2021 to 2022, below-average rainfall resulted in 19% lower dam levels than the previous year [2].

An often overlooked factor that may contribute to the alleviation of water scarcity and increase the sustainability of concrete is water management. The United Nations Environmental Program has indicated that over the entire life cycle, the construction industry accounts for as much as 30% of global freshwater use [3]. Water is used throughout the concrete production process, from the generation of power to washing the aggregates, mixing and transportation of fresh concrete and concrete curing. With proper planning and management, the strain on freshwater resources could be reduced globally by using alternative water sources for many of these activities in the concrete construction industry.

Research suggests that non-potable water such as treated domestic wastewater (TDW) could be used to produce concrete of suitable quality for the construction industry, thereby reducing the industry's demand for potable water resources [4]. TDW is domestic wastewater that has been treated to a level that it can safely be discharged into water bodies. TDW is typically 99.9% pure water with the remaining 0.1% being made up of suspended and dissolved solids, and microorganisms [5]. TDW has the potential to substitute the water requirements of the concrete industry, provided it fulfills the requirements for concrete production.

Common substances found in non-potable water which can at certain concentrations be deleterious for concrete include chlorides (may affect the setting time of fresh concrete and promote reinforcement corrosion in hardened concrete), sugar (can result in set retardation), sulfates and acids (chemical attack), and organic matter (may influence cement hydration or cause air entrainment) [6].

While various secondary water resources can be considered for concrete production, each alternative source needs to be investigated with regard to the requirements set in national standards. In South Africa, SANS 51008 [7] (equivalent to ASTM C1602 [8] and BS EN 1008 [9]) stipulates acceptable levels of harmful substances in concrete mixing water, including chlorides, sulfates, alkalis, sugar, phosphates, nitrates, lead, and zinc. According to [7], water recovered from processes in the concrete industry, water from underground resources, natural surface waters, and industrial wastewater can all be considered for use in concrete manufacture, if successfully tested against the limiting values for the harmful substances mentioned above. In cases where the limits set in [7] are not met, the standard stipulates that the water can still be used to produce concrete if certain values of setting time and compressive strength are met.

As of 2018, the total treated effluent capacity of Cape Town's wastewater treatment plants was 164.5 ml per day [10]. The research study presented in this paper was therefore conducted as a pilot project to assess the feasibility of utilizing treated domestic water to produce structurally sound and durable concrete in South Africa. The study was intended to inform local long-term water management strategies and in turn secure water supply for the concrete industry in times of water scarcity.

2 Aims and Scope of the Study

The primary aim of the experimental investigation was to determine if TDW could be used for concrete manufacture according to SANS 51008 [7]. This included chemical analysis of the TDW samples, evaluation of the setting time, slump retention and compressive strength assessment.

3 Methodology

Four samples of treated domestic wastewater were collected from WWTPs around Cape Town at the effluent stage. They were labeled A, B, C, and D for confidentiality reasons. WWTPs A, B, and C employ the activated sludge process (ASP) for wastewater treatment while WWTP D employs membrane bioreactor (MBR) technology for wastewater treatment.

Water was sampled from the respective plants in two batches of 25 l each, the second being collected 4 weeks after the initial samples were collected. The main reason for the double sampling was to check for water quality consistency. It was noted that WWTP B treated both domestic and industrial wastewater with the fractions of each wastewater type varying throughout the day. Maximum industrial wastewater was expected during the afternoon at 13:00 with 40% industrial and 60% domestic wastewater being treated at this time. The sampled water was outsourced to a water treatment lab to assess the chemical impurities present in the waters and was stored in the laboratory prior to concrete mixing. The results of the chemical investigation were compared to the requirements of [7] to check the suitability of the TDW for concrete manufacture and are presented in Sect. 4.1.

The effect of TDW on concrete fresh and hardened properties was investigated for two different w/c ratios, namely, 0.40 and 0.60. The mix designs are summarized in Table 1.

Testing of fresh properties included setting time using a Vicat Apparatus according to [11] and slump testing according to [12]. Setting time tests were conducted 3 days after water collection for all sample waters as well as potable water.

For compressive strength testing, 100-mm cubes using TDW were cast within 2 days of water collection and cured. Concrete cubes cast using potable water were used as controls for all the results obtained from various tests. The cube specimens

Table 1 Mix designs

w/c	CEM II A-M 42.5N (kg/m^3)	Phillipi dune sand (kg/m^3)	Crusher dust (kg/m^3)	19 mm Graywacke (kg/m^3)	Water (l/m^3)	Superplasticizer (l/m^3)
0.4	425	740	0	1050	170	0.667
0.6	283	441	441	1050	170	0

were taken out of their molds 24 h after casting, placed under plastic sheets for an additional 72 h and then stored in an environmental room at 50% relative humidity and a temperature of 23 °C until testing. The curing regime was intended to mimic practical curing procedures and adverse site conditions. Compressive strength was tested at 7 and 28 days following [13].

4 Results and Discussion

4.1 TDW Chemistry

Table 2 summarizes the results of the wastewater chemical analyses and compares these to results from the literature and the requirements given in [7].

As seen in Table 2, the TDW samples passed SANS 51008 [7] requirements. Consequently, the TDW used in this research was expected to produce concrete with acceptable fresh and hardened properties. Table 3 shows the TDW chemical analysis results for the secondary samples and the percentage changes in the measured values between the initial and secondary TDW samples from the four different plants. Although large percentage changes can be noted between the initial and second TDW samples, all the water samples from the second sampling passed the water quality requirements for concrete production outlined in [7].

From Table 3, it was observed that TDW C had an extremely high Chemical Oxygen Demand (COD) value. COD generally indicates the organic content in the water that may lead to retardation in concrete setting time and thus impacts early age strength. Consequently, a high COD value can severely affect concrete properties.

Table 2 Chemical analysis results of the initial samples of TDW and tolerable limits

	Wastewater initial samples				Average from literary sources	Tolerable limits [7]
	A	B	C	D		
pH	7.2	6.9	7.1	6.5	7.7	>4

[a]Percentage change between initial and second sampling

SANS 51008 [7] does not provide any limiting values for COD, nor does any other standard and therefore, it is unknown when COD begins to negatively affect concrete quality.

Additionally, it was noted that Escherichia coli (E. coli) concentrations were significantly high for TDW A and C, being in excess of 2420 CFU/100 ml. This was far from the safe range normally given as <10 CFU/100 ml for drinking water [14]. TDW B had an E. coli concentration of 159–178 CFU/100 ml. While this was lower than TDW A and C, it also fell short of the safe range. It was observed that TDW D was exceptionally close to the safe range with a concentration of 13–16 CFU/100 ml. This was to be expected as WWTP D makes use of MBR technology. This technology employs filters which range from 5 to 240 µm, and thus successfully filters out microorganisms and settleable and suspended solids [15]. WWTPs A, B, and C use the conventional ASP to treat wastewater. This generally produces a lower-quality TDW [15]. From Tables 2 and 3, it was thus evident that further disinfection of TDW A, B, and C would have to be recommended if they are to be used safely in the construction industry.

Cape Town is currently in a phase where wastewater treatment facilities are reaching their end of life as many equipment and facilities need to be replaced. Additionally, many plants are being overwhelmed with the quantity of wastewater being treated and are running over capacity. These factors have significant implications on water quality and consistency thereof. Thus, it can be expected that water quality will vary over time. Therefore, in order to gain a better understanding of how water quality fluctuates as a result of WWTP-related problems, more samples have to be collected over a longer period. If it can be proven from this expanded testing period that the worst sample passes the requirements of SANS 51008 [7], then in essence, TDW in Cape Town should be suitable for use as concrete mixing water. A positive aspect observed, however, was that some of the WWTPs are in the process of expanding which is a good indication for future TDW quality.

4.2 Setting Times

To comply with SANS 51008 [7], initial and final setting times of cement paste samples made with TDW must exceed 60 min and may not exceed 12 h, respectively, and may not differ by more than 25% when compared to paste samples made with potable water. SANS 51008 [7] requires the initial and final setting times of non-potable water used in concrete production to be within 25% of that of potable water. The results of the initial setting time tests using the different TDWs are presented in Fig. 1.

Having recorded an initial setting time of 120 min for the control samples, it was required that the samples made using TDW have an initial setting time between 90 and 150 min. The samples that failed to meet these criteria were those made using TDW B and the sample made using the secondary TDW C. While the delayed initial setting time for the second TDW C may be attributed to its high COD value, TDW B

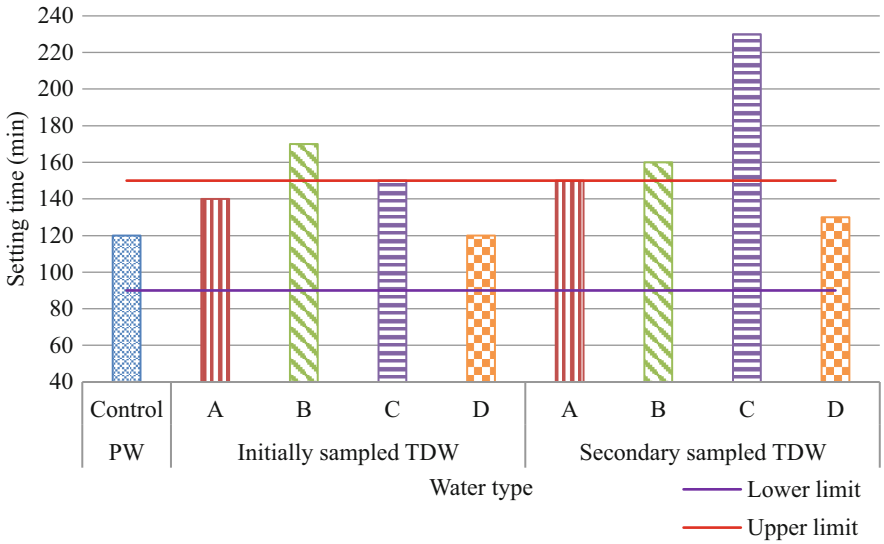

Fig. 1 Initial setting times for all sampled TDW

has significantly lower COD values. The delayed initial setting time for TDW B could, however, be a result of its chemical composition. As discussed previously, WWTP B treats industrial wastewater in addition to domestic wastewater. Industrial wastewater may contain metals such as lead and zinc which are known to retard concrete setting time. It would thus be beneficial to test for these impurities in TDW from this specific WWTP and the other WWTPs that treat industrial wastewater.

The results of the final setting time tests using the different TDWs are presented in Fig. 2. The control sample had a final setting time of 230 min and therefore the samples made using TDW were required to have a final setting time between 173 and 288 min. The initially sampled TDW C sample had a final setting time of 180 min, while the second samples yielded a much higher final setting time of 450 min. This significant increase in the final setting time may be attributed to the significant increase in phosphorus, phosphates, and COD that are known to retard setting time. The color of TDW D was nearly the same as that of potable water. This, in addition to the low COD and low impurities content, resulted in similar setting times for TDW D and the control.

The longer initial setting times of the TDW B samples are at most 50 min longer than the control. Considering that the final setting times of the TDW B samples were all within the required range, TDW B may still be considered suitable for industry application without the use of accelerating admixtures, if the delay in initial setting time is accounted for. On the other hand, the significantly higher initial setting time for the second TDW C sample as compared to the control may require the use of an accelerator to attain more practical initial and final setting times.

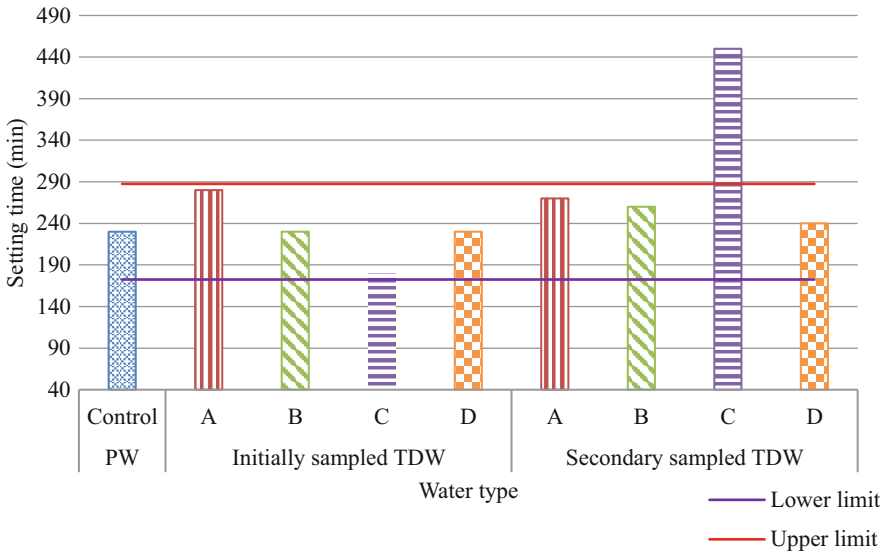

Fig. 2 Final setting times for all sampled TDW

4.3 Workability

The design slump values were 85 ± 25 mm and 65 ± 25 mm for the 0.4 w/c ratio and 0.6 w/c ratio concrete mixes, respectively. Figures 3 and 4 present the slump values for both the initial and second samples of TDW for the 0.4 w/c mix and the 0.6 w/c mix, respectively.

In comparing between the initial and second samples of TDW to assess if any adverse effects arose as a result of water quality inconsistencies, it was observed that the results were similar. It was observed that TDW A and B always had a higher slump than the control and a higher slump than TDW C and D. It was initially thought that this result could be due to the total solids content of the TDW. An increase in total solids increases the sticky content in concrete and thus makes it less workable. However, from the chemical analyses, it is noted that the total solids content is highest in TDW A. Thus, if this were the cause of the observed results, less workability would be expected for TDW A. Additionally, TDW B had similar total solids content to that of TDW C and D. Therefore, the higher workability observed for TDW A and TDW B could not be attributed to the total solids content of the TDW.

While the cause of the observed trend in the slump test values requires further investigation, the test results do show that TDW does not adversely impact concrete workability as all the results were within the tolerance limits of the design slump. This is further supported by the results obtained by [4, 16–18].

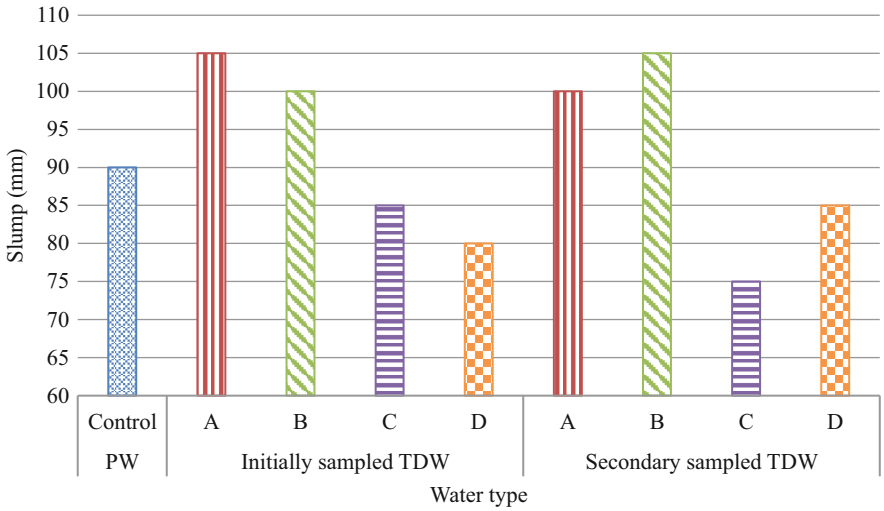

Fig. 3 Slump values for initially and secondary sampled TDW for w/c = 0.4

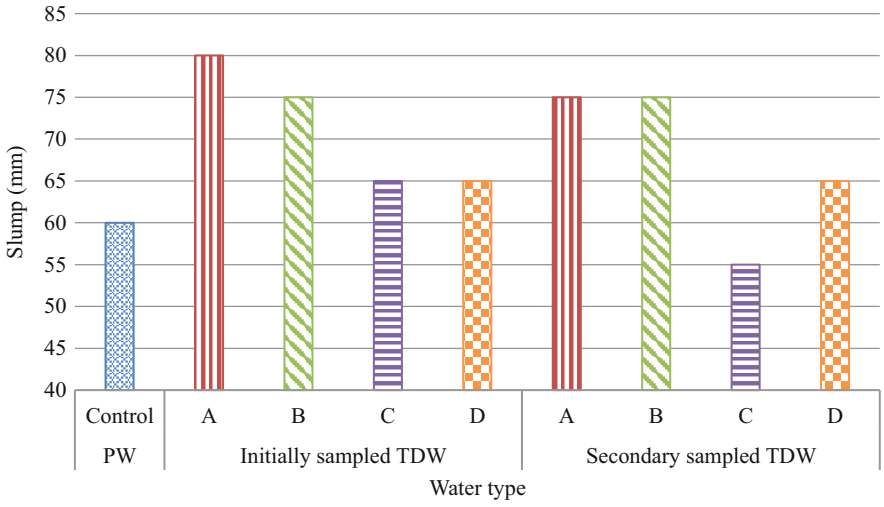

Fig. 4 Slump values for initially and secondary sampled TDW, w/c = 0.6

4.4 Compressive Strength

Concrete compressive strength is used extensively as an index of various concrete properties as well as concrete quality [19]. It is one of the main guidelines used to assess whether non-potable water is suitable for use as mix water in concrete

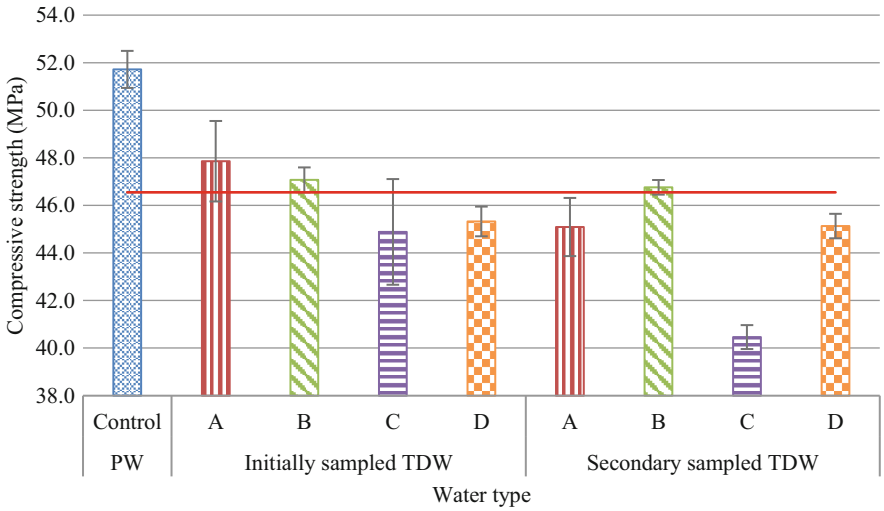

Fig. 5 Seven-day compressive strength results with standard deviations for TDW concrete, w/c = 0.4

manufacture according to SANS 51008 [7]. In this study, 7- and 28-day compressive strengths were assessed as a result of using TDW as mix water.

To pass the 7-day compressive strength check stipulated in SANS 51008 [7] which requires a compressive strength within 90% of the control, a compressive strength of 46.6 MPa was required for the 0.4 w/c ratio concrete mix. The results of the 7-day compressive strength test for the 0.4 w/c mix are presented in Fig. 5.

Only the initial sample of TDW A and the TDW B samples achieved compressive strengths above 46.6 MPa. No clear trend was observed in the 7-day compressive strength results to explain the shortfall for the TDW samples that did not achieve the required compressive strength. However, it was postulated that the much lower compressive strength of the second TDW C concrete samples may be due to the high concentrations of phosphorus, phosphates, and COD which in addition to retarding the setting time also delay the compressive strength development of the concrete. Another observation made was that TDW D yielded compressive strength values of 45.3 MPa and 45.1 MPa for the initial and second samplings, respectively, indicating consistent compressive strength results and corresponding to the consistent setting times recorded.

The results of the 7-day compressive strength test for the 0.6 w/c mix are presented in Fig. 6. A compressive strength of 24.9 MPa was required for samples to meet the 7-day strength criteria stipulated in SANS 51008 [7] for the 0.6 w/c ratio concrete mix. All TDW concrete samples passed this requirement, except for the secondary TDW C with 23.0 MPa. Again, this result may be cautiously attributed to the chemical species present in the TDW causing set retardation and delaying compressive strength gain.

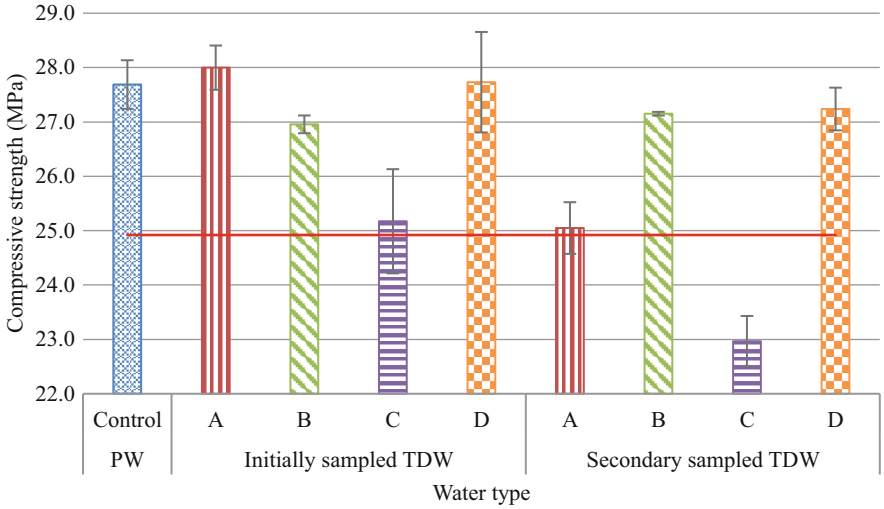

Fig. 6 Seven-day compressive strength results with standard deviations for TDW concrete w/c = 0.6

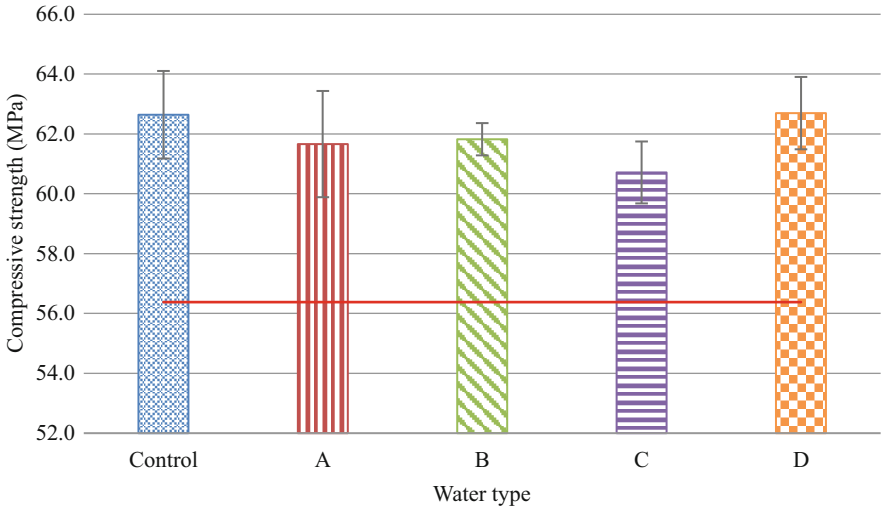

Fig. 7 Twenty-eight-day compressive strength results with standard deviations for TDW concrete, w/c = 0.4

The 28-day compressive strength test was performed on only the samples made using the initial samples of TDW due to the time constraints and is presented in Figs. 7 and 8 for the 0.4 and 0.6 w/c ratio, respectively.

The 0.4 w/c ratio concrete mix required samples to have a compressive strength of 56.4 MPa to pass the 28-day compressive strength requirement outlined in SANS 51008 [7]. At 28 days, all TDW concrete samples passed the requirement with the

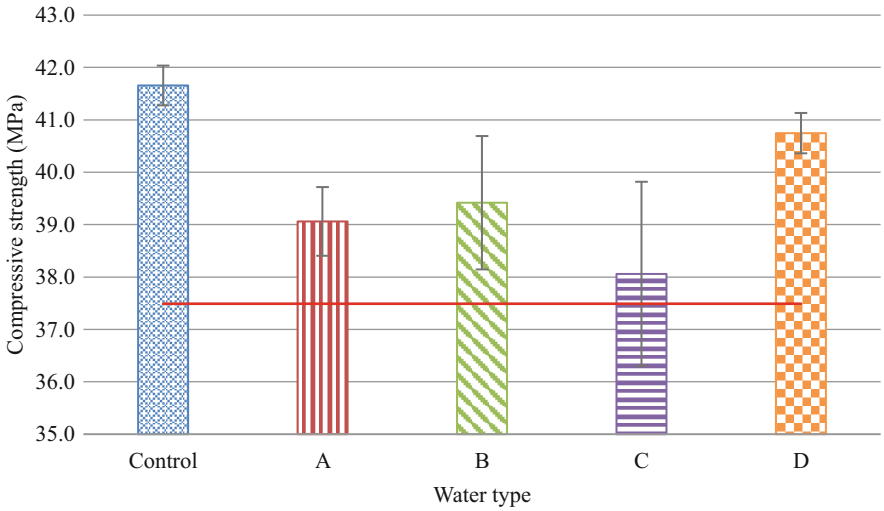

Fig. 8 Twenty-eight-day compressive strength results with standard deviations for TDW concrete, w/c = 0.6

lowest compressive strength recorded being 60.7 MPa for TDW C. For the 0.6 w/c ratio concrete mix, the TDW concrete samples were required to possess a compressive strength of 37.5 MPa to adhere to SANS 51008 [7] requirements. All samples passed this check with the lowest compressive strength being 38.1 MPa for TDW C. Potable water produced the highest compressive strength at 41.7 MPa.

While not all the TDW concrete samples passed the 7-day compressive strength test for both w/c ratios, all the samples passed the 28-day compressive strength requirements stipulated in SANS 51008 [7]. In comparing the 7-day to the 28-day compressive strength test results, it was evident that using TDW as mixing water delays the compressive strength development of the concrete. The variability in the compressive strength test results may be attributed to the chemical composition of each of the TDW samples used and how the chemical species interact in the concrete mix. To fully understand this interaction, more tests than those required in the SANS 51008 [7] and presented in this paper would be necessary.

5 Concluding Remarks and Way Forward

Various tests were conducted to investigate the effects which TDW has on concrete properties when used as mix water. From the initial and final setting time tests, no clear correlation between the setting times and the chemical composition of the TDW could be surmised. While not all the recorded setting times were within 25% of the control samples, the recorded setting times may still be practically acceptable for industry application, especially if accelerating admixtures are used to reduce the

setting time. Similarly, a correlation between the measured slump and the chemical composition of the TDW could not be determined. However, all the measured slumps were within the stipulated ranges.

Only the initial sample of TDW A and the TDW B samples achieved the required 7-day compressive strengths for the 0.4 w/c mix, and all TDW concrete samples achieved the required 7-day compressive strengths for the 0.6 w/c mix except for the secondary TDW C. While no clear trend was observed in the results to explain the shortfall for the TDW samples that did not achieve the required 7-day compressive strength, all the samples had gained sufficient compressive strength by the 28th day to pass the requirements stipulated in SANS 51008 [7]. It was thus concluded that using TDW as mixing water delays the compressive strength development of the concrete.

The findings of this study show that TDW produces concrete with sufficient workability, setting time, compressive strength when comparing it to literature and the control. However, quality control of the TDW is of the utmost importance to ensure the consistent production of good quality concrete.

1 Introduction

Cementitious materials are the most used construction materials due to their relatively low cost and ease of production, which essentially requires fluid concrete to be poured into moulds and be allowed to set [1, 2]. Although excellent in compressive strength, the inherent brittleness and poor tensile strength of these materials result in low energy absorption and sudden fracture when the material tensile strength is exceeded. Consequently, cementitious materials are unsuitable for high-energy absorption applications such as vibration and impact resistance. Several approaches have been employed to improve the ductility for such brittle materials, such as through embedding of ductile reinforcement materials, e.g. steel rods, steel strands

and fibres [3], polymers [4, 5], natural fibres [6, 7] and only recently auxetic materials derived from altering the geometries of conventional materials [2, 8]. While conventional materials expand laterally when compressed axially and contract laterally under axial tension, auxetic materials contract laterally when compressed axially and expand laterally under axial tension. This counter intuitive behaviour of auxetic materials that results in Negative Poisson's Ratio (NPR) can be exploited for enhancing indentation resistance [9, 10], shear resistance [9, 11], strain-hardening, energy absorption, crashworthiness, damping [9, 12, 13]; as well as physical characteristics such as acoustic behaviour [11] and inherent synclasticity under bending moments [13].

Auxetic behaviour has been cheaply achieved in several studies by altering the geometry of conventional materials. The most studied auxetic geometry with potential application in structural engineering is the re-entrant honeycomb structure [14]. Several studies have investigated re-entrant honeycomb structures with concrete infill. The study of Zhong et al. [15] investigated the compressive strength behaviour of fabricated re-entrant honeycomb aluminium structures with 0.4 mm of sheet thickness. The height and width of the re-entrant honeycomb structure were 110 mm and filled with 16 MPa concrete. The elastic modulus and tensile strength of the aluminium sheets were 69 GPa and 274 MPa, respectively. The study reported the enhancement of the composite against compression, buckling, flexure and shear failures. The study investigated the confinement effect of the auxetic honeycomb lattice to the transverse deformation of the concrete matrix. The influence of dimensional parameters such as cell wall thickness, cell angle and cell size on the auxetic response of the composite was also investigated. The method of manufacture of the aluminium re-entrant honeycomb was firstly by folding plain sheets of aluminium, then stacking and gluing the folded sheets. The same type of honeycomb was used in the study of Zhou et al. [16], although with foam concrete as the cementitious matrix. Zhou et al. [16] investigated the in-plane uniaxial quasi-static and dynamic compressive strength of the auxetic mesh-reinforced foam concrete. The sample failure evolved from predominantly compression to shear especially as the density of the foam concrete increased. The study recommended the use of auxetic meshes to enhance load-bearing of porous cementitious structures.

Apart from sheet folding and crimping into re-entrant shapes, another popular method of introducing auxetic behaviour in metal sheets is through perforations. Perforations in the form of orthogonal ellipses have been shown to create nodes of rotation within the perforation grids and hence cause NPR [14, 17]. For example, in the study of Luo et al. [17], 8 mm, 10 mm and 12 mm thick stainless steel sheets were perforated in orthogonal alternating elliptic patterns (using laser cutting technology) and folded into tubes. The tubes were then filled with concrete and tested in compression after 28 days. The elliptical-perforated tubes were compared with circular-perforated tubes with the same area of perforations. The elliptical-perforated tubes provided active restraint to the lateral strain of the concrete, thereby enhancing the axial compressive strength of the composite.

Investigations of auxetic behaviour through perforation of materials are scarce and focused on tubular structures used as external confinement to the cementitious phase. Also in such studies, the auxetic behaviour is limited to the material plane of

the confinement. This means that, apart from the confining edge provided by the sheet metal, the greater volume of the cementitious phase is unaffected by the auxetic behaviour of the sheet metal. Furthermore, for structures such as re-entrant honeycombs, there is lack of continuity in the cementitious matrix as each cell is separated by a continuous sheet of metal. In this study, the possibility of introducing auxeticity throughout the composite in re-entrant honeycomb structures through perforations is explored. The perforations are also expected to enhance the bond strength between the metal sheet and the cementitious matrix, as well as additional confinement, thereby improving the mechanical properties of the overall composite.

The effect of the perforations on the compressive capacities of the samples is investigated by comparing the force–displacement curves of the circular-perforated, elliptic-perforated and peanut-perforated samples with the non-perforated samples. Subsequent paragraphs, however, are indented.

2 Materials and Methods

2.1 Re-entrant Honeycomb Structure

Cold-reduced (CR4) steel sheets of 0.9 mm thickness were supplied by The Metal Store, UK, and cut into strips of 1200 × 70 mm and used for the non-perforated samples. For the perforated samples, a plasma cutter was used to carry out the perforations before the sheet was cut into the 1200 × 70 mm strips. All the perforated samples have the same volume of materials which is exactly half the volume of the non-perforated samples. Details of the dimensions of the sheets and perforations are shown in Fig. 1.

For both perforated and non-perforated sheets, the samples were folded into re-entrant shapes at 75° angle of inclination as shown in Fig. 2i. The folded metal sheets were stacked upon one another and welded using TIG welding. Non-perforated solid plates of the same thickness were welded on to the top and

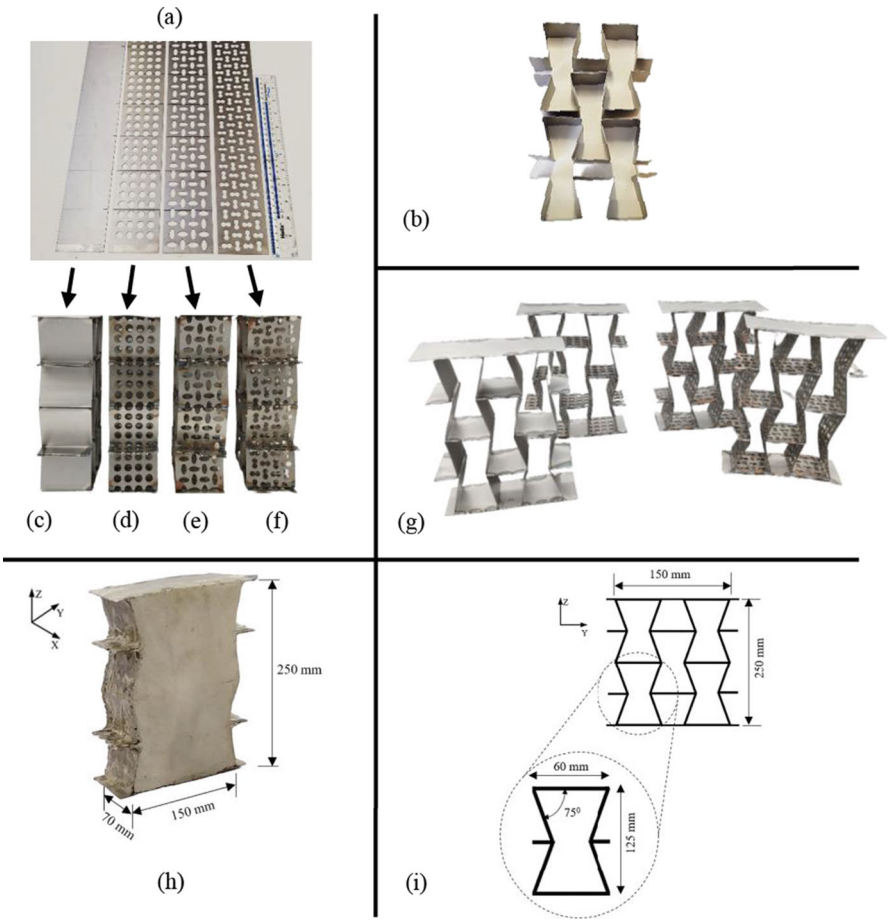

Fig. 2 (**a**) Non-perforated and perforated mild steel strips; (**b**) folded strips into re-entrant shapes; side views of welded (**c**) non-perforated, (**d**) circular-perforated, (**e**) elliptic-perforated, (**f**) peanut-perforated re-entrant honeycomb structures; (**g**) some welded re-entrant meshes; (**h**) mesh-mortar composites; (**i**) dimension details of re-entrant structure

the bottom of each auxetic structure in order to contain the mortar within the structure during casting (see Fig. 2g).

2.2 Mortar

The materials used for the mortar were Hanson general-purpose cement (32.5R) and natural sand that complies with the ASTM C33/C33M as sharp concreting sand. The sand with 4 mm maximum aggregate size together with the cement were all obtained

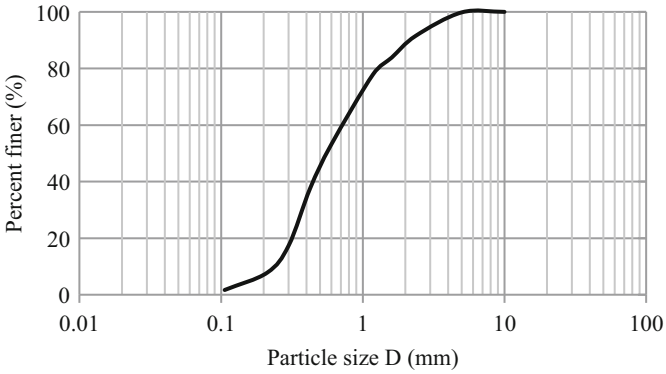

Fig. 3 Particle size distribution of sharp sand used for the cement mortar

from Jewson Exeter, UK. The mortar consisted of the binder and aggregate in 1:5 mix ratio while the water/cement ratio was 0.48 [18]. Sikamix mortar plasticiser was added to the water at a dosage of 2.5 ml plasticiser per kg of cement before mixing with the aggregates. The binder and aggregate were first dry-mixed in a rotating drum after which the measured water containing mortar plasticiser was added. The mixing continued for 5 min, following the requirements of ASTM C33/C33M until a consistent mix was achieved. Figure 3 presents the particle size distribution. The external side of the outer walls of the honeycomb were covered with transparent stick tape (Sellotape) to avoid the concrete seeping through. The re-entrant honeycomb structures were then placed on a flat wooden plate and held onto the plate using steel wires. The mortar was then poured into the plate and vibrated for about 2 min and left undisturbed for 24 h. At the end of the 24 h period, the sticky tapes were removed, and the honeycomb–concrete composites were transferred into a water tank and cured under ambient temperature for 28 days prior to testing.

2.3 Tensile Strength Test

The perforated and non-perforated strips were tested in tension to investigate their tensile capacities and auxetic behaviour. The tensile strength test was carried out in displacement control (at 5 mm/min) in an Instron 34TM-30 universal testing machine, according to ASTM A370 – 11. Figure 4 shows images of some of the tensile test samples before and after testing. The Poisson's ratios of the samples were calculated by obtaining six (6) lateral width measurements along each sample length before and after the tensile test, using a digital vernier caliper and dividing the change in the average final width by the change in the final longitudinal length of each sample.

2.4 Compressive Strength Test

The mortar-filled auxetic composites were tested in compression in compliance with ASTM C39 in displacement control at 5 mm/min. The test was stopped after a travel distance of 75 mm.

3 Results and Discussion

3.1 Tensile Strength Test of Perforated Mild Steel Strips

While the circular-perforated samples underwent reduction in the lateral direction, the elliptic- and peanut-perforated samples expanded in the lateral direction, hence indicating NPR (see Fig. 4). The overall behaviour of the samples was governed by the resistance mechanism of each constituting unit cell. For the circular-perforated samples, the axial tension force from the machine was resisted by the material in between the holes with direct axial straining and yielding until failure. Conversely, the orthogonal arrangement of holes in the elliptic- and peanut-perforated sheets, provided alternating material paths for load resistance, hence, causing the rotation of the unit cells (see Fig. 4d, e). The rotations of the cells caused an increase in the lateral dimension until the cells were aligned in the vertical axis of loading.

It was after this alignment, that the cells began to strain and yield in the axial direction of loading subsequently with some strain-hardening until failure. Consequently, the circular-perforated samples possessed relatively higher stiffness and

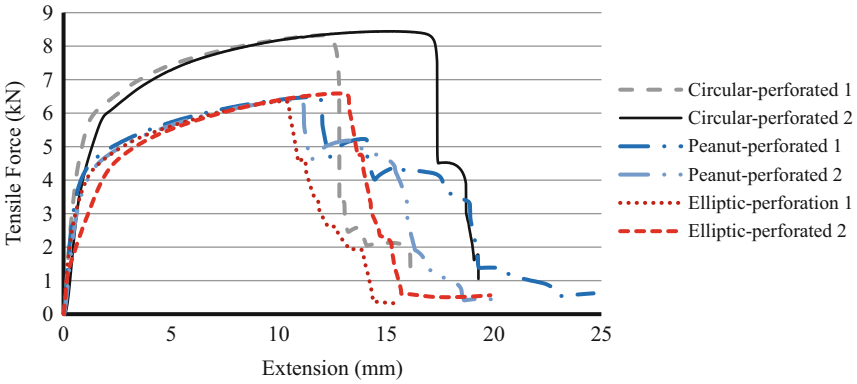

Fig. 5 Tensile strength curves of the perforated steel sheets

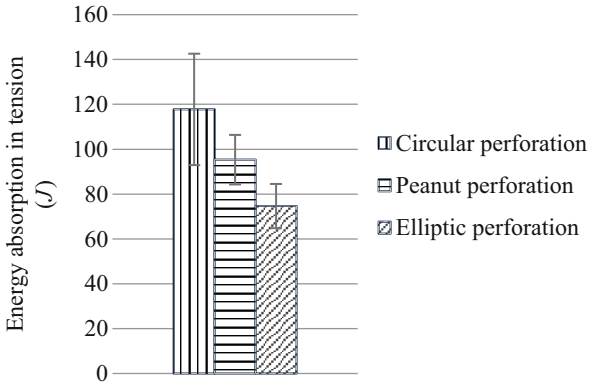

Fig. 6 Energy absorption from tensile strength curves of the perforated steel sheets

tensile strength as shown in Fig. 5. Average tensile capacities and Poisson's ratios of 8.39 kN, 6.47 kN, and 6.44 kN and −0.214, −0.246, and 0.279 were obtained for circular-, elliptic- and peanut-perforated samples, respectively. The variation between individual tensile test strip samples of the same category is due to possible inconsistencies in the perforations as well as in the testing procedure.

A simple uniaxial tensile strength test alone is not sufficient to account for energy dissipation through rotation of the unit cells of the auxetic strips; therefore, the circular-perforated strips seemed to possess more energy absorption (i.e. the area under the load–extension curve). Although the difference in average tensile capacities between the elliptic- and peanut-perforated samples is negligible, the average energy absorption of the latter is about 28% greater due to its relatively higher NPR (see Fig. 6). It is also important to note that only two samples each were tested for tensile strength behaviour for each category of perforated strip. This small sample size is a limitation and will be increased in future studies.

3.2 *Compressive Strength Test*

Generally, the stress–strain behaviour of re-entrant honeycomb structures is characterised by three major regimes: the linear elastic stage, the softening or plateau stage and the densification/destruction stage [19]. However, in this study, at the start of loading, the compressive load on the auxetic steel-mortar composite, increased linearly with displacement. The slope of the load–displacement curve then reduces at the onset of cracking within the mortar (see Fig. 7). Nevertheless, the capacity of the samples increased until excessive cracking within the mortar resulted in the rapid reduction of the load–displacement curve. This rapid reduction in capacity is followed by a plateau regime, which further evolves into the densification of the composite with subsequent crushing/destruction. The crushing stage succeeded the densification stage with concrete spalling from the cells of the auxetic meshes as depicted in Fig. 8.

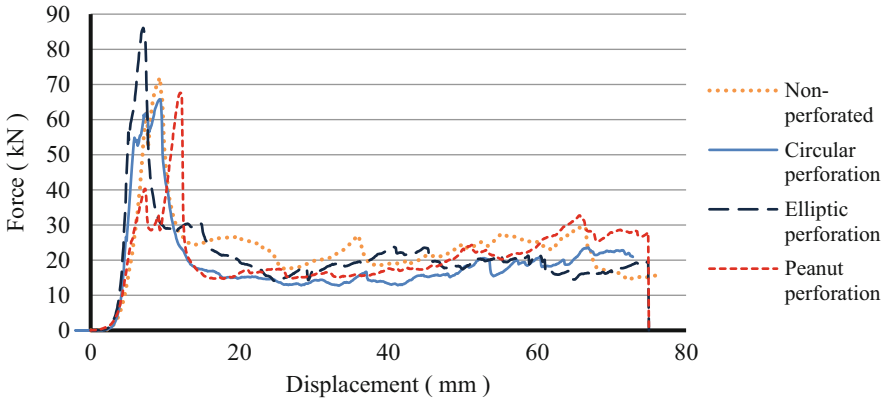

Fig. 7 Compressive behaviour curves of samples with the maximum compressive strengths for non-perforated and perforated re-entrant honeycombs

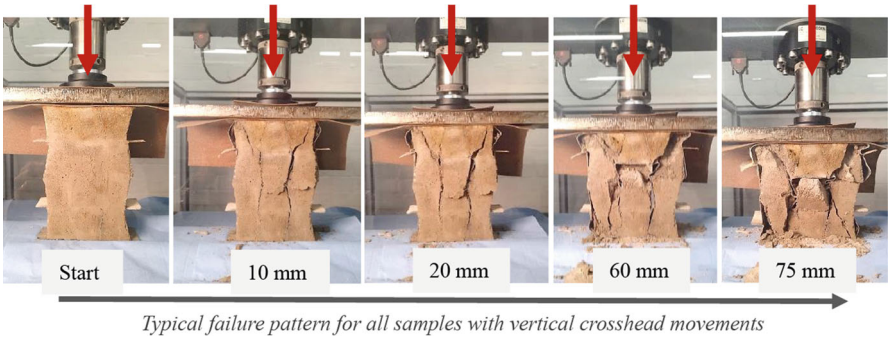

Fig. 8 Compressive strength testing of non-perforated and perforated re-entrant honeycomb–mortar composites

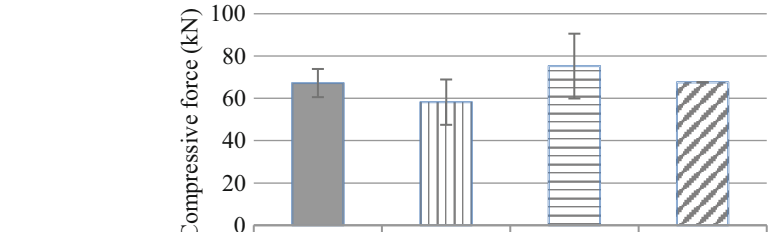

Fig. 9 Average compressive strengths of non-perforated and perforated re-entrant honeycombs

Figure 7 is the compressive behaviour curves of selected samples having maximum compressive capacities for non-perforated and perforated re-entrant honeycombs–mortar composites. Figure 9 presents the average compressive capacities (with standard deviations) of all the categories. Due to the enhanced bonding and the auxetic action provided by the perforations, the average compressive capacity of the elliptic-perforated samples increased by about 12% and 19% compared with the unperforated and circular-perforated samples, respectively. The compressive capacity of the peanut-perforated sample was greater than the circular-perforated samples by about 17%. However, there was negligible improvement in the compressive capacity of the peanut-perforated samples compared with the unperforated samples. This could be attributed to the trapping of larger grains of aggregates in between the 'neck' of the peanut perforation, thereby creating weak zones within the composite. The respective energy absorption for the samples was calculated using Eq. (1).

$$\int_0^l Fdl \tag{1}$$

where F is the applied load (in kN) and l is the corresponding displacement (in mm).

The amount of steel used for each perforated steel–mortar composite category is exactly half the mass of the steel used for the non-perforated samples. According to Eq. (2), this corresponds to a 50% mass consumption ratio (TMCR) for the perforated samples [20]. Recent studies show that cellular auxetic structures can be obtained with up to 34% of material in comparison with their homogeneous counterparts [20]. Although the process of perforation could result in extra costs, advancements in manufacturing technologies could offset these costs allowing for innovative engineering load bearing applications.

$$\text{TMCR} = \frac{\text{mass of auxetic component}}{\text{mass of homogeneous component}} \times 100\% \tag{2}$$

The different samples can also be compared using Eq. (3) which specifies a dimensionless design optimisation factor (*Df*) [20]:

$$Df = \frac{k}{\text{displacement} \times \text{TMCR}} \times 100\%, \tag{3}$$

where k is empirically chosen as 1 and having the same unit as the displacement (or strain, deformation, rotation, etc.) [21]. In this study, the highest *Df* resulted from the auxetic reinforcements. These are the samples with the highest compressive capacity and use the least amount of steel reinforcement (i.e. the elliptic- and peanut-perforated samples). The *Df* of the perforated samples are more than that of the non-perforated samples with values of 9.3, 25.5, 19.4 and 16.5 for non-perforated, circular-perforated, elliptic-perforated and peanut-perforated samples respectively. Parameters such as TMCR and *Df* can be used as selection tools for the dimensions of perforation and for the design of other components. For components in flexure, the displacement in Eq. (3) can be replaced with deflection or strain. Although the normalised average energy absorption from the compressive strength curves was highest for the non-perforated samples (Fig. 10), it should be noted that the perforated samples have exactly 50% less steel reinforcement.

The perforated steel re-entrant honeycomb-reinforced mortar composite developed in this study can be used for applications such as lightweight beams, columns, sandwich panels and shear walls. The perforations improve bonding between the reinforcement and matrix through continuity of the matrix as well as through the NPR of the steel sheets. Such composite also does not require additional formwork for making them since the cellular arrangement can keep the wet concrete in place. Further studies are however required to investigate the effects of perforation parameters such as aspect ratio and angular orientation of the holes in order to tailor them for specific load-bearing components. The next stage of this research involves investigations on the mechanical behaviour on a larger sample size in order to enhance the rigor and impact of the results.

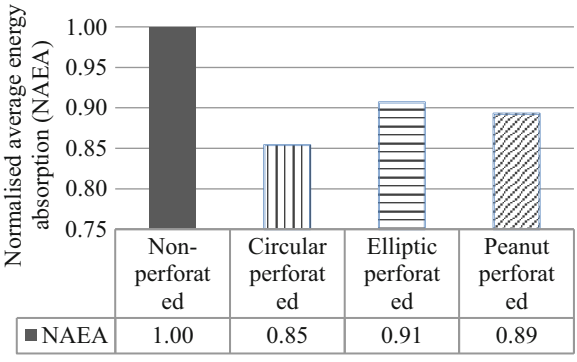

Fig. 10 Normalised average energy absorption for all perforated samples under compression

4 Conclusions

This paper focused on the behaviour of perforated re-entrant auxetic steel honeycomb–mortar composite. The need to improve the bond strength between steel and concrete through auxeticity led to the orthogonal perforation of the steel strips. The tensile strength behaviour of the steel strips was assessed as well as the compressive strengths of the respective composites with circular, elliptic and peanut orthogonal perforations in the re-entrant steel honeycomb. Consequently, the following key findings are highlighted:

- The tensile capacities of circular-perforated sheets are over 29% greater than those of the orthogonal elliptic- and peanut-perforated sheets.
- The difference in average tensile capacities between the elliptic- and peanut-perforated samples is negligible; however, the average energy absorption of the latter is about 28% greater.
- Due to the enhanced bonding and the auxetic action provided by the perforations, the average compressive capacity of the elliptic-perforated samples is about 12% and 19% greater than that of the unperforated and circular-perforated samples.
- Parameters such as the 'design optimisation factor' and 'total mass consumption ratio' can be used to select the optimum dimensions for perforations.
- The perforated steel sheets use only 50% of the material constituting the non-perforated steel sheets, implying that introducing auxeticity through perforations can reduce overall material usage. This can offer benefits in specialised steel-reinforced cementitious load bearing applications such as concrete shear walls.

1 Introduction

Water stands as the primary component in concrete mix proportions and is an indispensable resource for sustaining life. Typically, freshwater serves as the primary choice for mixing and curing concrete, yet its availability is finite. A study conducted by the WRI (World Resources Institute Europe) [1] revealed that the demand for water is escalating due to urbanization, population growth and socio-economic advancements. Industries, particularly the construction sector, consume approximately 19% of the global water supply [2]. If current concrete preparation practices persist over the next 35 years, an estimated 590–710 km^3 of water will be expended solely for this purpose [3]. The United Nations' report of 2022 [4]

highlighted that over 40% of the world's populace faces challenges regarding freshwater availability, exacerbated by the escalating infrastructure development, which intensifies the strain on natural water resources. Hence, the exploration of alternative water sources for concrete production becomes imperative.

Considering that the Earth's surface is predominantly covered by water, with seawater accounting for approximately 96.5% of the total, utilizing seawater for concrete mixing presents a viable solution to conserve freshwater resources and ensure sustainability [5]. Seawater, however, comprises a complex blend of salts, organisms, dissolved gases, suspended sediments and organic matter, which can either positively or negatively impact concrete properties. Despite its controversial reputation, the historical application of seawater in concrete dates back to the Second World War, where it was utilized for constructing coastal structures in California and Florida [6]. Moreover, recent research challenges the prevailing wisdom against using seawater salts in structural concrete. While it is widely believed that these salts can compromise the durability of conventional reinforced concrete, evidence suggests that they do not significantly impact the properties of plain cement concrete and mortar. Nevertheless, the diverse salts found in seawater engage in chemical interactions with the constituents of concrete, resulting in alterations of concrete properties. This study aims to investigate the influence of seawater on the fresh and hardened properties of cement mortar when seawater replaces freshwater for mixing and curing purposes.

2 Materials and Methods

The study utilized Norcem's CEM I 42.5 N – SR3 cement, as per EN 197–1 standard. Table 1 outlines the chemical composition of this cement. Tap water and seawater were used for mixing and curing of mortar mixes. The seawater employed in this study was produced synthetically following the guidelines outlined in ASTM D1141 standards. The seawater used had a pH of 8.4, and its chemical composition is detailed in Table 2. Natural sand with a particle size of 0/8 mm was used as fine aggregate. The specific gravity of the natural sand was measured at 2.65, with a water absorption rate of 0.5% and a particle density of 2.66 Mg/m^3. Mortar specimens were prepared following EN 196–1:2016 guidelines. The proportion of water to cement 0.50 and cement to sand 1:3 were maintained during mortar preparation. This allowed for an examination of how the different water types affected the properties of the cement mortar over time.

Table 1 Major oxides in cement

Oxide	CaO	SiO_2	Fe_2O_3	Al_2O_3	K_2O	SO_3	NaO_2	MgO
Values (%)	60.66	20.45	4.28	3.36	0.45	2.67	0.28	1.90

Table 2 Elemental content in artificial seawater

Element	Amount (grams per liter)
Sodium chloride (NaCl)	24.53
Sodium sulfate (Na_2SO_4)	4.09
Magnesium chloride ($MgCl_2$)	5.20
Potassium chloride (KCl)	0.695
Calcium chloride ($CaCl_2$)	1.16
Sodium bicarbonate ($NaHCO_3$)	0.201
Boric acid (H_3BO_3)	0.027
Potassium bromide (KBr)	0.101
Sodium fluoride (NaF)	0.003
Strontium chloride ($SrCl_2$)	0.025

3 Tests on Mortar

Multiple examinations were undertaken to evaluate the characteristics of cement mortar. A heat of hydration test was executed on a paste comprising cement mixed separately with tap water and seawater. An isothermal calorimeter was used for measuring the heat of hydration of cement for 72 h by following the guidelines of EN 196–11 (2018). For testing the mechanical properties of cement mortar, compressive and flexural strengths tests were conducted on all mortar mixes. Mortar test specimens 40 mm × 40 mm × 160 mm prisms were prepared according to EN 196–1 (2016) and tested for flexural and compressive strengths after 1, 3, 28 and 90 days of curing at room temperature. Additionally, the electrical resistance and resistivity of various mortar mixes were assessed according to ASTM C1876–19 at 28 and 90 days of age. The RCON device, utilizing AC impedance technique, developed by Giatec Scientific Inc., was employed for the measurement of electrical properties. For this experimental evaluation, cylindrical mortar samples with a diameter of 100 mm and a length of 200 mm were utilized. Electrode plates were positioned on both end surfaces of the mortar specimens, with water-saturated sponges serving as conductive mediums. A current frequency of 1 kHz was utilized for resistance measurement. By applying an alternating current voltage across the specimen's cross-section between the two electrodes, the current flowing through the pore network within the mortar specimen was quantified. Moreover, the assessment of permeable pore volume, absorption, dry bulk density and apparent density in TWM and SWM mortar specimens was conducted in accordance with the procedure outlined in ASTM C642–13. Four parallel mortar discs from each mortar mix, with 100 mm diameter and 50 mm length were utilized for this examination, each cured for a duration of 90 days.

4 Results and Discussion

4.1 Heat of Hydration

The variation of heat flow in cement with tap water and seawater was measured up to 3 days as shown in Fig. 1. It was reported that the peak of cement paste mixed with seawater exhibited greater magnitude and became evident earlier compared to cement paste mixed with tap water. The highest heat flow of cement with tap water was found as 2.45 mW/g at 10.88 h, whereas with seawater, it was found as 3.42 mW/g at 8.89 h. In accordance with existing literature, it has been discovered that the hydration process of cement is expedited by seawater due to its high chloride content [7–9]. Sikora et al. (2020) [10] also found an about 19% increase in the peak of seawater-mixed cement paste than the peak of distilled water cement pastes in heat of hydration test. The possible reasons behind the increased cement hydrations might be:

1. Chloride ions, being smaller than hydroxyl ions, diffuse into the initial hydration products of cement. These products form a protective layer on the surface of cement particles. However, when chloride ions interact with water, they weaken or break down this protective layer. As a result, the breakdown of hydration products such as tri-calcium silicate is enhanced, leading to an increased rate of cement hydration [16].
2. Additionally, a blend of negatively and positively charged ions coexists within cement grains. When these grains encounter water, they tend to flocculate. In contrast, chlorides carry a negative charge. When seawater introduces chlorides into concrete, they are absorbed onto the cement grains surfaces, rendering them to acquire a negative charge. This intriguing process leads to the separation and unique behavior of cement grains, further enhancing the process of hydration of cement [17].

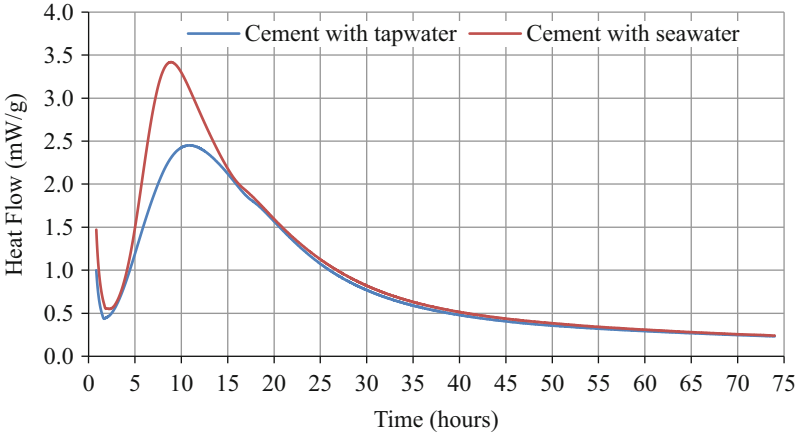

Fig. 1 Heat of hydration of cement with tap water and seawater

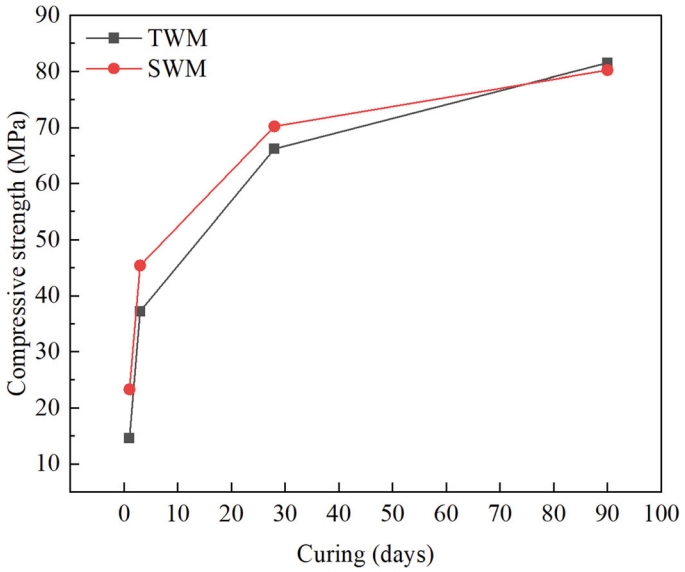

Fig. 2 Compressive strength of TWM and SWM

4.2 Compressive Strength

The compressive strength of the mortar with seawater and tap water after 1, 3, 28 and 90 days of curing is shown in Fig. 2. Seawater mortar gained more compressive strengths at the ages of 1, 3 and 28 days as compared to mortar prepared and cured in tap water whereas little reduction in the later age (90 days) compressive strength of seawater mortar than that of tap water mortar. The increment in compressive strength of seawater mortar was found as 60.1%, 22% and 6% at 1, 3 and 28 days of curing respectively and reduction at 90 days was 1.6% than that of tap water mortar. Previous studies also show that seawater contributes to enhance initial compressive strength in concrete. However, over time, it diminishes the subsequent strength [11, 12]. Justnes et al. (2022) [13] also found the increment in the compressive strength of concrete with seawater as compared with fresh water. In a study by Mori et al. (1981) [14], it was observed that the difference in strength between concrete mixed with seawater and that mixed with freshwater is relatively small after a decade of exposure testing.

4.3 Flexural Strength

Figure 3 shows the flexural strength of cement mortar by using seawater and tap water. Flexural strength of cement mortar with seawater increases by 42.9% at 1 day curing age and then decreases by 12.7%, 21.3% and 27.6% at 3, 28 and 90 days of

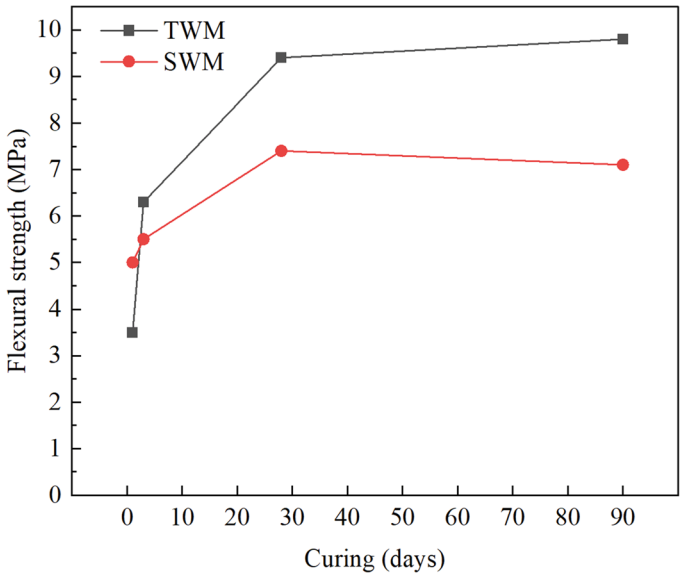

Fig. 3 Flexural strength of TWM and SWM

curing respectively. In Wegian's (2010) [15] study, it was observed that seawater concrete exhibited greater flexural strength during the initial period. However, seawater concrete experienced a reduction in flexural strength by 3.8–14.5% compared to freshwater concrete as it aged. Earlier studies have observed that, concrete mixed with seawater displays enhanced strength in the early phases because of the existence of NaCl. This substance expedites the breakdown of tricalcium silicate, prompting faster hydration reactions [16]. Consequently, additional hydration components are generated, occupying the concrete voids and improving its microscopic arrangement [17].

4.4 Electrical Resistance and Resistivity

The electrical resistance and resistivity of mortar mixes TWM and SWM is presented in Table 3. The use of seawater tends to reduce the resistance and resistivity of mortar, both at 28 and 90 days. This reduction diminishes as the mortar age increases at 28 days, the electrical resistance decreases by 23%, and at 90 days, by 7%. Similarly, resistivity decreases by 19% at 28 days and 4% at 90 days. Li et al. (2021) [8] also observed a decrease in the electrical resistivity of concrete when seawater was used as the mixing water, attributing it to the higher concentration of ions in the pore solution. This suggests that seawater, having more ions than tap water, likely possesses higher conductivity, thus resulting in lower resistivity in

Table 3 Electrical resistance and resistivity of TWM and SWM

	Electrical resistance (ohm)		Electrical resistivity (ohm-meter)	
Curing days	TWM	SWM	TWM	SWM
28	962.0	740.0	37.0	30.0
90	1070.0	995.0	42.5	41.0

Table 4 Water absorption, density and permeable voids of TWM and SWM

Properties	TWM	SWM
Water absorption after immersion (%)	8.08	7.54
Bulk density dry (mg/m^3)	2.16	2.19
Apparent density (mg/m^3)	2.62	2.63
Volume of permeable voids (%)	17.57	16.89

seawater mortar compared to tap water mortar. Jahani et al. (2023) [18] reported an increase in the electrical resistivity of seawater concrete at 7 days but observed a gradual reduction thereafter, at 28, 180, 365 days, and 3 and 4 years. This trend was attributed to the growth in the number and size of expansive crystals in seawater concrete over time, leading to potential cracking and increased porosity due to expansion. Consequently, the electrical resistance of seawater concrete decreases. Saleh et al. (2023) [19] investigated the influence of ion movement through the pore solution on concrete resistivity. The study anticipated that the use of seawater, rich in free chloride ions during mixing and curing, would lower the resistivity of concrete.

4.5 Water Absorption, Density and Permeable Voids

An essential aspect contributing to concrete's durability lies in its ability to withstand the ingress of harmful ions. The porosity of concrete is often assessed through its water absorption behavior, revealing insights into its permeable pore volume and connectivity. The data presented in Table 4 demonstrate that the incorporation of seawater leads to a decrease in water absorption and permeable voids within the mortar. However, the effect is not pronounced. Moreover, both the bulk density and apparent density display similar trends for both TWM and SWM mortar compositions.

The decrease in voids and water absorption highlights the dense microstructure characteristic of SWM. This phenomenon could potentially stem from the filling of concrete pores by salts found in seawater. Additionally, the formation of a common hydration product known as Friedel's salt (FS) occurs through the reaction between seawater chlorides and calcium-aluminate hydrates, along with calcium hydroxide in cement, as illustrated in Eq. 1. The precipitation of FS aids in compacting pore structures, thereby resulting in reduced voids and absorption levels [20].

$$3CaO \cdot Al_2O_3 \cdot 6H_2O + Ca(OH)_2 + 2Cl^- + 4H_2O \rightarrow 3CaO \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O\ (FS) + 2OH^- \quad (1)$$

5 Limitations and Recommendations for Future Research

The research findings suggest that seawater poses no significant harm to mortar, indicating its potential use in plain concrete construction. Seawater accelerates the hydration rate, leading to enhanced initial strength in mortar. Additionally, it reduces water absorption and diminishes the volume of permeable voids in cement mortar. However, it also results in lower electrical resistivity due to the high concentration of ions in the pore solution. The current study is confined to conducting mechanical tests along with durability for a duration of up to 90 days. However, conducting a long-term study would provide a more comprehensive understanding of concrete performance in seawater environments. Furthermore, exploring additional durability parameters such as microstructure studies and investigating the effects of seawater on concrete performance under various environmental conditions like freezing and thawing, wetting and drying and acid attack could offer valuable insights for future research endeavors.

While seawater holds promise for plain concrete construction, challenges arise in utilizing seawater for reinforced concrete due to the corrosive nature of chlorides which affect steel reinforcement. Alternative solutions, such as non-corrosive reinforcements like fiber-reinforced bars, stainless steel and aluminum, have been employed in the past studies to mitigate corrosion. Yet, the long-term durability of such reinforcements remains uncertain, necessitating further research in this area for more effective seawater utilization. Supplementary cementitious materials (SCMs) offer another avenue for minimizing seawater‘s impact by binding chloride ions and enhance the durability of seawater concrete.

6 Conclusions

In summary, the present study yields the following key findings:

- Cement mixed with seawater generates more heat and exhibits an earlier peak compared to tap water.
- Seawater mortar shows higher strengths at 1, 3 and 28 days than tap water mortar. There is a slight reduction in 90 days compressive strength for seawater mortar compared to tap water mortar.
- Seawater increases flexural strength by approximately 42.9% at 1 day, but it decreases at 3, 28 and 90 days.
- The use of seawater tends to reduce the electrical resistance and resistivity of mortar at both 28 and 90 days. This reduction diminishes as the mortar ages.
- The incorporation of seawater in mortar results in a reduction in water absorption and permeable voids, indicating a denser microstructure.

Thus, this study presents a comparative analysis of the effects of seawater and tap water on the fresh, mechanical and durability properties of cement mortar. It also provides perspectives on attaining improved durability and sustainability in seawater-based concrete through present research work.

1 Introduction

It is known that the resistance to earthquakes increases due to the decrease in the mass of the structure with the use of lightweight concrete articles [1]. Moreover, it has become increasingly popular in the construction industry due to its advantages such as low thermal conductivity, high fire resistance, and low-cost articles [2–4]. Due to these positive effects, lightweight concrete has become more preferred, especially on the building façade [5, 6]. With the green economy approach adopted after the Paris climate agreement, it was understood that various methods have been applied to ensure the sustainability of lightweight concrete facades. These methods include (i) reducing energy consumption in the production process of lightweight concrete [7, 8] and (ii) using recycled materials [9, 10]. It is known that there are

applications such as (iii) reducing the amount of waste [11, 12]. Additionally, it was reported that the use of photocatalytic materials provides self-cleaning properties on the facade and improves indoor air quality [13]. Among many semiconductors, it was determined that nano-TiO_2 (nT) is generally used as a photocatalyst due to its advantages. Among the phases of nT, it was determined that the anatase phase is generally preferred because it shows a faster photocatalytic effect. It was understood that various studies have been carried out on extending the strength, durability, and service life of lightweight concrete facades and increasing the energy efficiency performance [14, 15]. However, it was observed that limited and contradictory research was conducted regarding the use of waste materials in the sustainability and composition of lightweight concrete mixtures. It was reported that construction waste increases rapidly, especially after severe earthquakes [16]. For this reason, encouraging the use of recycled concrete aggregate and effectively disposing of construction-demolition waste is of great importance for the understanding of green economy. In this context, it was understood that new research is necessary on the effect of the use of recycled concrete aggregate on the strength performance of lightweight concrete mixtures. In this study, the effect of changing the recycled concrete aggregate usage rate on the compressive strength and flexural strength performance of self-cleaning lightweight concrete mixtures (SCLWC) was examined. For this purpose, the compressive strength and flexural strength performances of mixtures produced by substituting 25% and 50% recycled concrete aggregate instead of pumice aggregate in an SCLWC mixture containing 1% TiO_2 and 100% pumice aggregate were examined.

2 Material and Method

2.1 Materials

In this study, CEM I 42.5 R type cement complying with TS EN 197-1 Standard was used as the binder. The chemical composition and some physical and mechanical properties of the cements supplied by the manufacturer are shown in Table 1.

Within the scope of the study, some properties of NT used to provide self-cleaning properties to lightweight concrete mixtures are shown in Table 2.

Pumice (P) and recycled concrete aggregate (RCA) with a maximum grain diameter of 2 mm were used in the preparation of photocatalytic self-cleaning lightweight concrete mixtures. The specific gravity and water absorption capacity values of the aggregates determined in accordance with EN 1097-6 are shown in Table 3. A single type of water reducing admixture was used to achieve the target emission value of 240 ± 20 mm. Some properties of the water reducing admixture used, provided by the manufacturer, are shown in Table 3. In order for the change in aggregate grain size not to affect the results, all aggregates were sieved and used in a similar gradation curve.

Table 1 Chemical composition, physical properties, and mechanical properties of cement

Material	(%)	Physical properties		
SiO_2	18.8	Specific gravity		3.15

HRWRA	1.023–1.063	32	5.8	<0.1	<10

In order to provide the desired slump value in the lightweight concrete mixtures produced, a single type of high-range water reducing admixture (HRWRA) was used. Some technical specifications of the admixture used, provided by the manufacturer, are given in Table 4.

2.1.1 Preparation of Mixtures

Within the scope of the study, experiments were carried out by substituting recycled concrete aggregate in certain proportions (50% and 25% by volume) instead of pumice aggregate into the mixture containing 1% of the cement weight of NT and 100% pumice as aggregate, prepared by taking into account the studies in the literature. A total of 3 self-cleaning lightweight concrete mixtures were prepared (Table 5). Mixture calculation was made on 1 m^3 concrete. Mixtures with a water/cement ratio of 0.46 are designed according to ACI 211-2 Standard. The plasticizer admixture requirements of mixtures with a constant spread value of 220 ± 20 mm have been determined.

The naming of the mixtures was made according to the aggregate type and substitution rate. For example, the nomenclature of the mixture in which 50% recycled concrete aggregate was replaced was 50P-50RCA. The material rates and quantities used in the production of 1 m^3 lightweight concrete are shown in Table 5.

2.2 Method

2.2.1 Determining the Admixture Requirements of Mixtures

Spreading values of mortar mixtures were determined in accordance with ASTM C1437 standard. Admixture requirements for mixtures with a spreading value of 220 ± 20 mm have been determined. The 7-day compressive strength of the mixtures was determined on 50 mm cube samples according to ASTM C109 Standard. The 7-day flexural strength of the mixtures was determined by performing a three-point bending test on 40 × 40 × 160 mm prism samples in accordance with TS EN 196-1 Standard. Each value was calculated by taking the average of 3 measurements. Some images of the experiments carried out within the scope of the study are shown in Fig. 1.

Table 5 Amounts of materials used in the production of 1 m^3 SCLWC (kg/m^3)

Mixture	Cement (kg/m^3)	Aggregate (kg/m^3)		nT (%)	w/b
		Pumice	RCA		
100 P	544.5	605.3	–	1[a]	0.46

50 P-50 RCA	4.9

3 Experimental Results and Discussion

3.1 Admixture Requirement of Mixtures

The admixture requirements of the mixtures produced within the scope of the study are shown in Table 6. When the admixture requirement of lightweight concrete mixtures was examined, it was observed that the admixture requirement decreased by approximately 8.78% and 10.09% depending on the increase in the use of recycled concrete aggregate. This was attributed to the higher water absorption capacity of pumice compared to recycled concrete aggregate. However, it is thought that the fact that pumice has a more porous and rough structure may also cause this

situation. In a study conducted by Karthika et al. [17], the effect of substituting pumice aggregate with 50%, 80%, and 100% coarse aggregate on the spreading performance of concrete mixtures was examined. As a result, it was determined by the researchers that with the increase in the pumice substitution rate, the flow performance of the mixtures decreased by approximately 70%, 75%, and 77%, respectively, compared to the control mixture without pumice. Similarly, in a study conducted by Hossain et al. [18], it was found that the workability of mixtures decreased with the increase in pumice content. It was reported by researchers that this situation is due to the low density and porosity of pumice.

3.2 Compressive Strength of Mixtures

Unit volume weight and compressive strength values of lightweight concrete mixtures are shown in Fig. 2. It was determined that all mixtures produced are classified as lightweight concrete since their unit volume weight values are lower than 2000 kg/m^3. As expected, the unit volume weight values of lightweight concrete mixtures increased due to the decrease in the amount of pumice used in the mixtures. This is due to the fact that the specific gravity of pumice is 54% lower than that of recycled concrete aggregate. Similar results were reported by Mardani et al. [15]. It is understood from Fig. 2 that the compressive strength values increased due to the decrease in the amount of pumice usage in the lightweight concrete mixtures produced. Compared to the control mixture using 100% pumice, it was determined that the increase in compressive strength in question was 24% and 53%, respectively, in mixtures with 75% and 50% pumice usage rate. This is thought to be due to the fact that recycled concrete aggregate has a less porous structure than pumice. A similar effect was also expressed by Taşdemir et al. [19] and Remasar et al. [5]. In addition, since the Los Angeles abrasion resistance of recycled concrete aggregate is

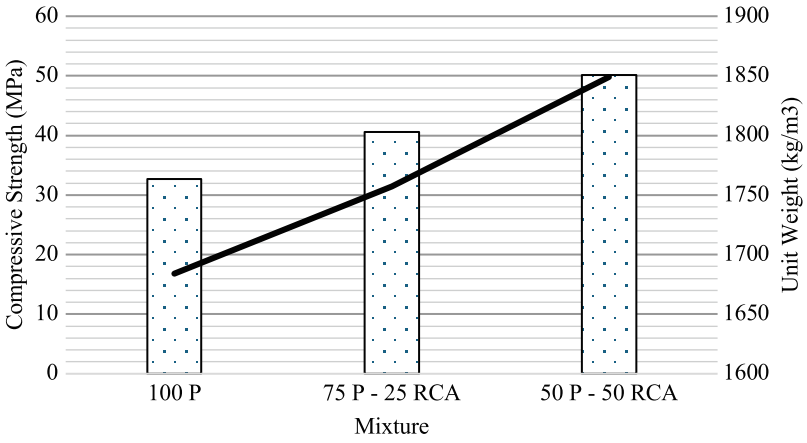

Fig. 2 Compressive strength (column chart) and unit volume weight (line chart) values of mixtures

10% higher than that of pumice aggregate (Table 3), it is thought that the decrease in the use of pumice aggregate in the mixtures affects the compressive strength performance positively. In another study, Lo et al. [20] emphasized that the compressibility performance of aggregates positively affects the compressive strength.

3.3 Flexural Strength of Mixtures

The 7-day flexural strength results of the mixtures produced within the scope of the study are shown in Fig. 3. It was determined that, similar to compressive strength, flexural strength values increase due to the decrease in the pumice usage rate. It was determined that the increase in question was 4% and 7%, respectively, in mixtures containing 75% and 50% pumice, compared to mixtures containing 100% pumice aggregate. It was determined that the loss of flexural strength due to the increase in pumice usage rate is quite low compared to the loss of compressive strength. It was reported by Bideci et al. [21] that in lightweight aggregate concretes, fracture occurs in the aggregate, not at the interlayer transition zone (ITZ), due to the porous and weak structure of the aggregate. Similarly, in another study by Mardani et al. [16], it was stated that the fracture resistance in ITZ decreased due to the lower strength and hardness properties of lightweight aggregates. It is also thought that due to the rough texture of pumice aggregate, it strengthens the ITZ of concrete and reduces the loss of flexural strength. For this reason, with the use of pumice aggregate and nano-TiO_2, in lightweight concrete mixtures that already have a strong ITZ, the flexural strength increased slightly by decreasing the amount of pumice aggregate, which has a very high water absorption capacity and low strength.

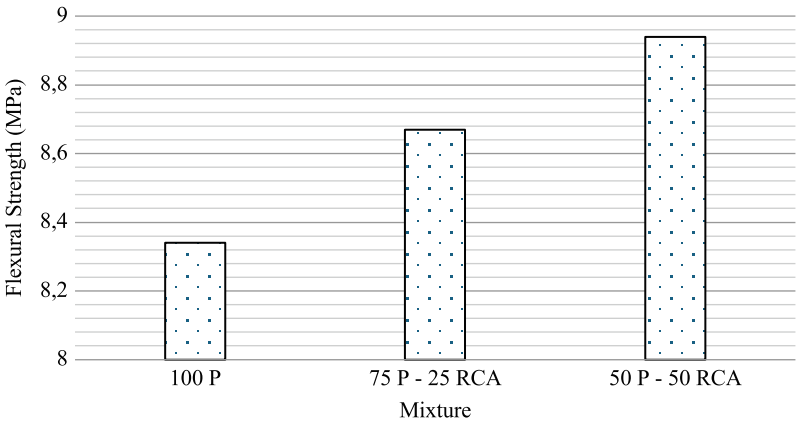

Fig. 3 Flexural strength values of mixtures

4 Conclusion

As a result of the materials used and the experiments carried out within the scope of the study, the following information was obtained:

1. It was determined that the need for admixture decreases due to the increase in the use of recycled concrete aggregate.
2. It was determined that the unit volume weight values of lightweight concrete mixtures increase due to the decrease in the amount of pumice.
3. It was understood that the compressive and flexural strength values increased due to the decrease in the amount of pumice usage. It was measured that the increase in question was lower for flexural strength values.

1 Introduction

Over the past decades, South Africa has experienced a steady increase in population, reaching approximately 61.5 million people in 2023, alongside a corresponding rise in urbanization, projected to reach 71% by 2030 and 80% by 2050 [1]. This demographic expansion has fueled increased construction activities, leading to a substantial generation of construction and demolition waste (C&DW). Significant amounts of C&DW are generated from the construction of new buildings and the demolition and maintenance of existing structures. While a portion of this waste is used in low-grade applications such as road base construction and landfill cover materials, most of it ends up in landfills. This waste poses environmental challenges due to its large volume and issues associated with landfill disposal. Notably, the traditional linear approach of using virgin materials prolongs these challenges,

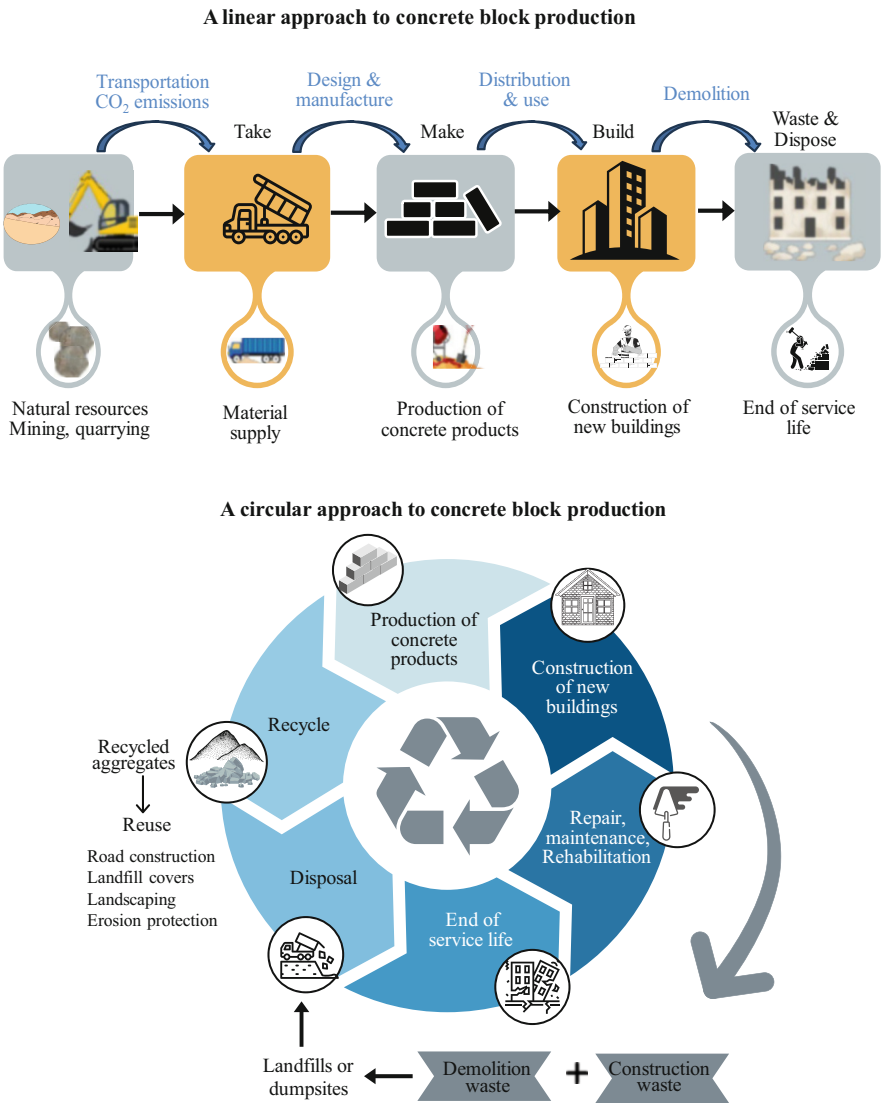

Fig. 1 A traditional linear approach to a circular economy in concrete block production

contributing to environmental issues such as increased energy usage and CO_2 emissions resulting from the mining and transportation of raw materials and the use of cement in concrete production. This approach is economically and environmentally unsustainable. To address these concerns and promote a circular economy, shifting to C&DW reuse and recycling is imperative. A circular economy emphasizes reusing, repairing, maintaining, and recycling materials to maximize societal value over time (see Fig. 1).

In the context of C&DW, this involves exploring alternative materials like recycled aggregates (RAs). The process includes sorting and crushing C&DW and sieving them into fractions suitable for new concrete production. This approach holds significant potential for applications in concrete brick and block production, particularly in the context of housing development in South Africa. Embracing recycling practices is crucial for fostering resource efficiency and reducing the carbon footprint associated with construction activities.

2 C&DW in South Africa

C&DW constitutes a significant portion of waste in South Africa, accounting for up to 30% (7.8 million tons) of the annual 26 million tons of municipal solid waste [2]. This category includes concrete, bricks, mortar, wood, plastics, metals, and soil waste from local cut-and-fill operations [3]. Figure 2 shows an ideal example of C&DW constituents at a specific demolition site in South Africa. Despite its substantial volume, there has been limited focus on circularity and diversion from landfills for C&DW. Concrete from C&DW is commonly reused as aggregates in subbases for road construction and landfill cover. However, hesitations persist regarding using RAs in new concrete due to uncertainties about their properties. On a smaller scale, recovered materials like bricks, blocks, wood, and window or door frames can be used in communities with limited financial means.

Recycling is not a recent development practice in SA. It has only become apparent as the government began to pressure people to use materials consciously,

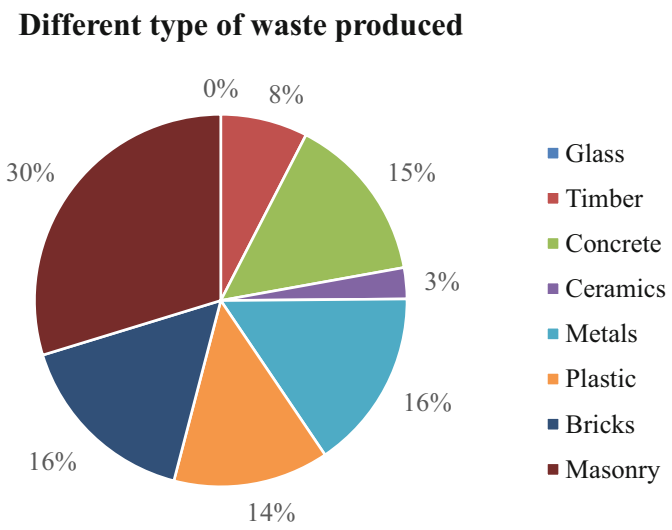

Fig. 2 C&DW makeup. (Data retrieved from Mogodi [4])

as there is an increase in demand for raw materials. However, the country lags behind with a recycling rate of about 20% in 2017 [5], significantly lower than those observed in countries like China, European countries, and the United States (with recycling rates exceeding 70%). Recycling efforts are concentrated in provinces with larger populations, such as the Western Cape and Gauteng. Certain companies have identified and demonstrated opportunities for using RAs from C&DW in the construction industry. These initiatives need replication and support to foster widespread adoption.

South Africa faces challenges related to landfill space shortage due to the closure of older landfills, rising operational costs, and limitations in constructing new ones. The Western Cape Province, specifically Cape Town, anticipates exhausting its landfill capacity by 2032, with escalating disposal costs [6]. This situation drives waste service providers to explore cheaper alternatives, including illegal dumping, which poses environmental, financial, and aesthetic consequences.

Despite robust environmental and waste regulations in South Africa, challenges persist in implementing and enforcing these laws. C&DW is often disposed of as general waste instead of properly categorized for source separation and recycling. Noncompliance issues plague several landfills. Efforts have been made to strengthen waste management regulations by imposing penalties and requiring accreditation for waste service providers and generators in some provinces. Construction projects and demolition companies require an approved integrated waste management plan before project commencement. Additionally, the National Waste Management Strategy (NWMS) has set goals for waste prevention and recycling, but more comprehensive waste management plans and research are needed to manage C&DW in South Africa effectively. The country must address coordination issues between the relevant authorities, allocate resources, and prioritize waste management to achieve the targets set in the Waste Act and promote a circular economy.

3 Recycled Aggregates in Concrete

The construction industry generates a significant amount of C&DW, which can be recycled as RAs to replace the natural aggregates (NAs) in concrete. This recycling initiative has gained prominence globally due to the excessive consumption of approximately 20 billion tons of natural resources annually in fresh concrete production [7]. The overexploitation of natural resources, leading to scarcity, has prompted research and increased use of RAs in some developed countries. However, in South Africa, where NAs were initially low-cost and readily available, the adoption of RAs was limited. Over the years, environmental awareness and the scarcity of NAs have driven the recycling of C&DW to solve the NA shortage. The recycling process involves sorting and crushing C&DW to produce fine and coarse fractions of RAs, which find applications in low- and high-strength concrete production, road construction, and landscaping. Using RAs conserves natural resources and reduces costs, landfill airspace, and cement usage, offering environmental benefits.

The focus of studies on RAs in concrete has been primarily on structural concrete, mainly using concrete waste—recycled concrete aggregates (RCAs). The presence of masonry or clay brick components in C&DW has raised concerns due to their porous microstructures, leading to limitations on masonry to 10% in structural concrete standards [8, 9]. Some studies suggest removing masonry elements from C&DW for structural concrete, whereas others argue for their potential use [10]. The debate centers on the impact of mortar content or masonry on the durability performance of RCAs, requiring further investigation for conclusive evidence. Wickins [11] added that if separation at the source is enforced, then there are potential uses for clay masonry and concrete materials in low- and high-grade structural and nonstructural applications.

An RCA is a two-phase composite material consisting of original NA and adhered mortar from crushed concrete. The adhered mortar, containing both hydrated and unhydrated cement, may be weak and porous, negatively impacting the performance of RCAs in concrete. This can lead to decreased aggregate density, increased water absorption, increased water demand, and subsequent effects on the mechanical and durability properties [12, 13]. Some studies suggest that adhered mortar provides self-cementing properties to RCAs as latent cement particles react with water, producing hydrate compounds. The self-cementing mechanism, primarily influenced by fine fractions of RCAs (<5 mm), is still being understood. High levels of active calcium silicate hydrate (CSH), the primary hydration product of Portland cement, tend to be found in finer fractions. Their intrinsic properties are influenced by the age, grade, and mix proportions of the original concrete [14].

Little research on RCAs has been conducted in South Africa, covering diverse aspects, as detailed in Table 1. The first research conducted by Clayton in 1987 at the University of Cape Town (UCT) examined the feasibility of using RCAs in structural concrete, highlighting the high absorption due to porosity in RAs

Table 1 Research on RCAs in South Africa

Author, year	Aspects covered	Type of RA used	Concrete application
Clayton F., 1987 [15]	Introduce the concept of recycling demolished concrete waste	Coarse RCAs	Structural concrete
Kutegeza B., 2004 [16]	Performance of concrete made with RAs	Coarse and Fine RCAs	Structural concrete
Kearsley and Mostert, 2012 [17]	Parent concrete of different strength classes	Coarse and Fine RCAs	Structural concrete
Paul S.C., 2011 [18]	Volume change and durability of RAC[a]	Coarse RCAs	Structural concrete
Wickins K., 2013 [11]	Influence of on-site recycling and concrete mixing procedures	Coarse RCAs and CMAs[a]	Structural concrete
Immelman D., 2013 [10]	Influence of replacement and concrete properties	Coarse RCAs	Structural concrete
Kahabi N.S., 2022 [19]	Durability of RCAs	Fine RCAs	Structural concrete

[a]*RAC* recycled aggregate concrete, *CMA* concrete masonry aggregates

[15]. Kutegeza's 2004 study at UCT found that fine and coarse recycled aggregates exhibited higher absorption rates by 7 and 10 times, respectively, compared to natural aggregates, which reduced compressive strength when aggregates were combined [16]. Kearsley and Mostert from the University of Pretoria also assessed RCA performance in concrete [17], whereas other studies explored optimal replacement levels for better mechanical and durability properties [10, 11, 18, 19]. As depicted in Table 1, most studies have predominantly focused on structural concrete (with a strength of 25 MPa and upward). The use of RCAs in structural concrete has shown negative impacts depending on factors like adhered mortar quality, replacement level, waste sources, crushing process, water-to-cement ratio (w/c), and moisture state during mixing. The negative impacts are more significant in fine RCAs than in coarse RCAs. It was suggested that good-quality RCAs at 30% for coarse and 25% for fine replacement of NAs might be suitable for structural concrete. Despite these studies attempting to establish expected outcomes, further research is essential to fill gaps and contribute to guideline and specification development.

4 Recycled Aggregates in Concrete Products

The drawbacks associated with using RCAs in structural concrete can be mitigated using concrete mixtures for mechanized molded concrete products like bricks and blocks. The manufacturing process involving molding mixed materials under a combined vibrating and compacting action using mechanized machines reduces the importance of maintaining a workable mix. This process demands only a small amount of water for introduction into the molding machine, easing challenges related to controlling w/c and workability. The production of bricks and blocks requires less cement than that of structural concrete, reducing the carbon footprint.

4.1 The Concrete Product Industry in South Africa

The South African construction industry extensively relies on concrete products, such as bricks and blocks, due to their durability, strength, and cost-effectiveness compared to alternatives like fired clay bricks. The clay brick industry has been noted to have about three times more embodied energy than concrete bricks and blocks. Concrete bricks and blocks are made from Portland cement, fine aggregates, coarse aggregates, water, and admixtures. These concrete products are typically made from virgin materials using a low-strength concrete mix, with a strength range of 7–15 MPa, and they do not require reinforcement. Concrete mixes typically contain 10–15% cement, with a water-to-cement ratio of around 0.3–0.6 and a cement-to-aggregate ratio of around 5–20% by mass. The manufacturing process of these concrete products consists of five basic processes: batching, mixing, molding, curing, and cubing (packaging), as illustrated in Fig. 3 [11]. The process

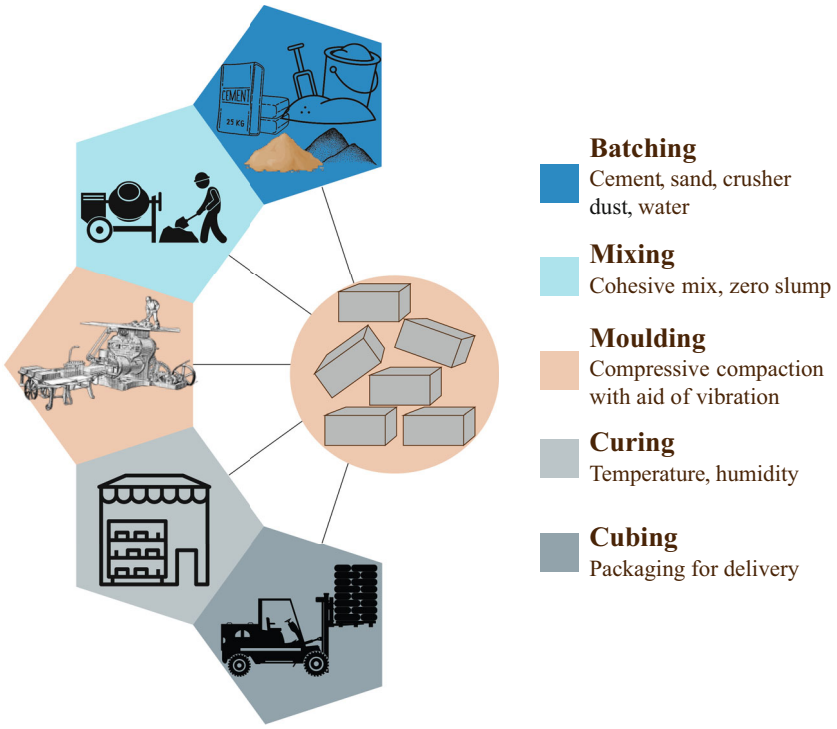

Fig. 3 The production process of bricks and blocks

involves mass production in factories using the dry mix pressed method with the aid of vibration forces, allowing for flexibility in shapes, thicknesses, densities, and strengths to meet diverse civil engineering project requirements.

The use of RAs in bricks and blocks is currently practiced in the South African construction industry, specifically in Cape Town. This is done to maximize recycled material usage for environmental benefits while ensuring cost-effectiveness. This shift is driven by the economic advantage of using RA, which costs 10% less than virgin materials. Although about 12 brick and block manufacturing companies are available in Cape Town, only a few incorporate RAs into their products, primarily due to misconceptions surrounding their properties. Quality control measures are lacking across the industry, resulting in varying product quality from one company to another. As a result, each company adopts practices based on their individual preferences, contributing to the inconsistency in product quality within the market. For instance, while some companies advocate for the inclusion of clay brick materials as waste, proclaiming potential enhancements to the final product, others caution against exceeding specific thresholds of 5% or 10% due to concerns about increased water requirements and compromised material density.

In the South African context, the current practice involves using various constituents of C&DW, such as concrete waste, mortar, or clay bricks, without separating

them at the source. The application relies on the local availability of materials. Hence, it is crucial to determine the composition and physical properties of these materials before incorporating them into concrete production, as it provides a deeper insight into the materials and their anticipated performance.

4.2 Properties of Recycled Aggregates in Concrete Products

Despite the widespread use of concrete products, there has been a lack of research in South Africa regarding using RAs in low-strength concrete products such as bricks and blocks. However, studies from other countries, particularly China and some European countries, have shown that the mechanical properties of concrete products are significantly influenced by the properties of RAs [20–25]. Factors such as density, water absorption, water content, cement content, and compaction methods play crucial roles in production and performance. Density is the main factor that indicates the packing capacity of the material, which influences the water requirement. Aggregates with more cement paste on their surface tend to have low densities due to the less dense mortar than NAs. Hence, fine fractions usually have lower densities compared to coarse aggregates. Furthermore, material compaction at the maximum moisture content corresponding to the maximum dry density is critical to achieve the best strength and durability. When compacting materials such as RAs with a certain amount of water, the density tends to increase until the maximum moisture content is reached, where the material obtains the maximum density, after that, it starts to decrease.

Studies have found that RCAs often enhance the strength of concrete products due to their inherent quality and residual cementitious content. Particle size distribution, aggregate size, shape and surface texture, density, and water absorption play pivotal roles in influencing workability and compressive strength [14, 23]. However, the presence of contaminants in these aggregates may weaken the bond within the cement matrix, leading to a reduction in the overall concrete strength. Common trends in using masonry in concrete block production include decreased density and compressive strength, along with increased water absorption [22, 23]. Some studies suggest that incorporating crushed masonry as a fine aggregate replacement yields superior results compared to its use as a coarse aggregate replacement due to the fine particles' filler effect [24]. Compared to RCAs, it has also been observed that blocks with masonry materials can experience an increase in strength at a later stage, attributed to further hydration of unhydrated cement phases in the RCA.

While the replacement level of RCAs in structural concrete tends to be limited, concrete bricks and blocks might allow higher replacement of NAs. Studies have shown that replacing fine and coarse aggregates with RAs at 25% and 50% levels, respectively, has little impact on the compressive strength of bricks and blocks [20, 25]. However, a more than 50% replacement level tends to decrease strength. This reduction can be mitigated by increasing cement content, using a combination of fine aggregates, and using proper design considerations and curing techniques.

Despite the perceived negative properties associated with RAs, different beneficiation methods can be used to improve their quality. Most of the methods have been primarily used in structural concrete on RCAs, and only steam and CO_2 curing and the use of admixtures such as plasticizers have been applied in the production of concrete products [26, 27]. Steam and CO_2 curing enhance strength and durability, whereas plasticizers improve the binding properties of the dry mix concrete. Additionally, a two-stage mixing method initially used in structural concrete shows promise for improving properties such as water absorption and strength of the concrete made with RAs [28]. Furthermore, pre-wetting of aggregates is practiced in the industry as it tends to enhance the absorptive capacity of RCAs and reduce dust from crushing.

4.3 Performance Requirements of Concrete Products

Concrete masonry units, encompassing bricks and blocks, are subjected to rigorous codes and standards, such as the South African National Standard (SANS), European Standards (EN), and the American Society for Testing Materials (ASTM). Specific manufacturing, construction, and design directives are laid out in diverse SANS standards like SANS 1215, SANS 10145, and SANS 10164-1, encompassing criteria such as dimensions, compressive strength, and soundness. EN 12620, BS 8500, ASTM C90, and ASTM C129 also cover various performance attributes. However, these codes primarily focus on natural aggregates, with no specifications for using RAs and contamination in concrete products. Therefore, for optimal use of RAs and desired properties in concrete products, careful consideration of replacement levels, mix design, and quality control measures is essential, especially in adherence to the existing standards.

4.4 Potential Impacts of Using Recycled Aggregates

The significance of using recycled C&DW for low-strength concrete production is multifaceted. Primarily, it contributes to environmental benefits by reducing the landfill waste and greenhouse gas emissions associated with transportation and disposal. Moreover, this practice aids in conserving natural resources by reducing the demand for virgin materials such as gravel and sand. Economically, it offers a viable and cost-effective alternative for construction companies. The research by Ohemeng and Ekolu [29] underscores this point, revealing that RAs' production cost is notably lower than that of NAs. For instance, producing one ton of coarse RCA costs approximately 40% less than coarse NAs while offering a significantly higher environmental benefit, approximately 97% greater than NAs [29].

Despite these evident benefits, using RAs has various limitations that need consideration. RAs sourced from demolition sites may exhibit variability in

composition, gradation, and contaminants, necessitating rigorous quality control measures to ensure consistent product quality. Persistent concerns revolve around the long-term durability and structural performance of concrete containing RAs, including issues such as weaker interfacial transition zones and reduced bond strength between RAs and cement paste. Furthermore, the absence of standardized testing methodologies and specific regulations governing the use of RAs complicates its widespread adoption, highlighting the need for clear guidelines and compliance measures within the industry.

5 Challenges and Opportunities

Despite the promising potential of RA, integrating these materials into construction applications faces challenges such as perception, inconsistent quality, regulatory hurdles, and the absence of standards. While developed countries have made progress in C&DW recycling, emerging economies like South Africa lag behind due to slow acceptance and recognition of the use of recycled materials, which can be attributed to a lack of awareness and knowledge regarding the benefits and appropriate utilization of these materials.

For decades, research has predominantly focused on RAs in structural concrete, leading to their adoption in some national standards. These codes mandate the recycling of concrete waste, excluding masonry waste. Bricks and blocks can, however, be made from C&DW from various sources like concrete, masonry, clay, and soil. Furthermore, the substitution of NAs with RAs in structural concrete is constrained by limitations in replacement levels. High replacement levels in structural concrete pose challenges to mechanical and durability properties, leading researchers to suggest that RAs might be suitable for low-strength concrete bricks and blocks, especially in the context of housing development in South Africa [11]. Despite the long-standing existence of discussions on recycling, a significant knowledge gap exists regarding low-strength concrete in South Africa, contributing to a need for an understanding of the behavior of recycled materials and their impact on concrete product performance.

The absence of certifications and standards for RA use in concrete, including low-strength products like bricks and blocks, is a hindrance. The current South African standards, SANS 1083:2006, do not provide specifications for recycled materials, necessitating the establishment of guidelines and quality control procedures for consistent and high-quality recycled C&DW concrete products. Additionally, construction companies are not obligated by any laws to use C&DW in their projects. So, to promote the use of C&DW, there is a need for policy changes mandating a minimum percentage of RAs in concrete. This could create market demand and benefit low-cost housing, roads, stormwater management, erosion protection, and dolosse production.

The self-cementing properties of RCAs offer an opportunity to reduce cement consumption in block production, contributing to efforts to reduce the carbon

footprint in the construction industry. Investigating the mechanism behind the self-cementing properties of RCAs can provide insights into optimizing concrete product performance.

Existing research advocates for techniques like using water-reducing admixtures such as plasticizers, steam, and CO_2 curing, a two-stage mixing approach, and mix design adjustments to enhance RA properties. Furthermore, pre-wetting of RAs in the industry is also encouraged. However, the practicality of the industry in terms of the sustainability of steam and CO_2 curing is questionable due to cost implications, energy requirements, and environmental impact. The influence of using plasticizers, pre-wetting of aggregates, and the two-stage mixing method on the properties of recycled materials and low-strength concrete needs to be understood.

Challenges in classifying C&DW, which comprises various waste streams, including hazardous waste and contaminants, highlight the importance of source separation. Implementing technologies from other countries, such as European nations, can improve waste separation in the South African context.

Furthermore, the lack of stringent tracking systems for C&DW generation statistics in South Africa, as seen in many countries, poses a challenge to circular economy development. Accurate data on C&DW types and quantities by location are crucial for effective waste management and circular economy initiatives in South Africa.

Lastly, continued research and technological improvements are crucial to for addressing the limitations and enhancing the quality and performance of recycled aggregate-based concrete products. Collaboration among stakeholders is essential to navigate the uncertainties and promote the sustainable integration of RAs in concrete products.

6 Outlook

Concrete production, essential for new construction and maintenance, uses millions of tons of materials annually. Addressing material procurement by specifying RAs in concrete applications could establish a sustainable market, significantly utilizing a large amount of C&DW each year. Converting a percentage of annually landfilled C&DW back into aggregates would lead to substantial benefits, including waste diversion, reduced carbon footprint, cost savings, and improved resource efficiency.

Developing material specifications for using RAs in concrete could attract private sector investment in crushing and sieving operations. However, a potential obstacle arises from the perception that RAs may need to meet standards. Understanding the behavior and influence of recycled materials on product performance is crucial to address this. This understanding can contribute to formulating guidelines and specifications for the construction industry, fostering reliability in using RAs. Comprehensive research in this area is thus essential for promoting the sustainable use of RAs in low-strength concrete products such as bricks and blocks, ensuring environmental benefits and industry acceptance.

1 Introduction

Calcium silicate hydrate (C-S-H) is one of the main cement hydrates in Portland cement. The molecular dynamics method is crucial for studying the properties of cement hydrates at the nanoscale [1, 2]. To simulate the C-S-H gel at the nanoscale is not an easy task due to its long-range disorder. In recent years, the simulation of the structure of C-S-H gel at the nanoscale has been optimized multiple times [3–5], and using the corrected structure of tobermorite 11 Å to simulate C-S-H gel is becoming more and more accurate. However, few researchers have studied the performance difference between the corrected model and the uncorrected C-S-H gel model. Additionally, in terms of mechanical properties, while numerous studies have examined the uniaxial tensile stress–strain curve of models, few researchers have

validated its accuracy. This lack of verification hinders comparative studies between simulations and experiments at various scales. Likewise, it is important to explore the impact of scale effects on the mechanical properties of models at the nanoscale for comparison with experimental or simulation results at different scales.

In this work, corrected and uncorrected C-S-H gel models were constructed at different sizes to investigate the influence of model correction and scaling effects on the mechanical properties of C-S-H models.

2 Methodology

2.1 Model Construction

The model construction process was completed in Materials Studio 2023. First, the unit cell of tobermorite 11 Å was extended and orthogonalized to a supercell with a ratio of 5 × 8 × 1. For models 1–3, the silicon chains were broken according to previous research [4, 6]. More details on model construction can be found in reference [6]. In this article, the final calcium-to-silicon ratio in models 1–3 is set to 1.67, and the Q_n distribution is $Q_2/Q_1 = 0.2$. For models 4–6, no corrections were made. Therefore, they can also be regarded as the supercells of tobermorite 11 Å. Based on this, all the supercells were then extended at ratios of 1 × 1 × 1, 2 × 2 × 2, and 3 × 3 × 3. The basic information of the models can be found in Table 1. The initial configuration displays the model dimensions in the *x*, *y*, and *z* directions, with the *y* direction being the direction in which the silicon chains extend, and the *z* direction being the layering direction.

2.2 Molecular Dynamics

LAMMPS software was used to perform molecular dynamics simulations, and the reactive force field [7] was adopted in this study. The time step throughout the simulation is set to 0.25 fs. First, the initial model is energy minimized and then

Table 1 Model information

	Silicon chain	Magnification	Initial configuration (Å^3)
Model 1	Breakage	1 × 1 × 1	32.95 × 59.12 × 22.77
Model 2	Breakage	2 × 2 × 2	65.89 × 118.24 × 45.54
Model 3	Breakage	3 × 3 × 3	98.84 × 177.36 × 68.31
Model 4	No breakage	1 × 1 × 1	32.94 × 59.12 × 22.77
Model 5	No breakage	2 × 2 × 2	65.88 × 118.24 × 45.54
Model 6	No breakage	3 × 3 × 3	98.81 × 177.36 × 68.31

relaxed for 100 ps under the NPT ensemble, with the pressure set to 1 atmosphere and the temperature to 300 K. Subsequently, uniaxial tension was applied along the silicon chain (y) direction of each model, with the strain rate set to 0.01 ps^{-1}. Throughout the uniaxial tension process, the strain and pressure values in each direction at each time step were recorded. In addition, atomic trajectories were output every 1 ps, and OVITO was used for data visualization.

3 Results and Discussion

3.1 Stress–Strain Relationship

On a nanoscale, uniaxial tension differs from macroscale tension in that the accuracy of the directly output stress–strain curve is reduced due to pressure oscillations in various directions during the uniaxial tension process [8]. Due to the particularity of analyzing stress–strain curves in molecular dynamics, it is essential to consider the pressures/stresses in directions other than tension when conducting the uniaxial tension tests. This is necessary to avoid excessive pressure oscillations in non-tension directions that could impact the accuracy of the results. After filtering out data points with excessive pressure in the non-tension direction, the stress–strain curves were plotted. The filtered curves of models 1–3 and models 4–6 were presented in Figs. 1 and 2, respectively. It can be seen from the figure that although the pressure oscillation still exists, the pressures in the non-tension direction are much smaller than the pressure in the tension direction. Additionally, from model 1 to model 3, or from model 4 to model 6, it can be seen that the larger the size of the model, the smaller the amplitude of the pressure oscillation. This means that increasing the model size can also reduce the error caused by pressure oscillations. In general, models with larger sizes (or greater total number of atoms) more accurately simulate the uniaxial tension process. Comparing the stress in the tensile direction in Figs. 1 and 2, it can be observed that the tensile strength of the corrected model (models 1–3) drops significantly when compared to the uncorrected model (models 4–6). Because the strength of C-S-H at the microscale is about 100 MPa [9], which is smaller than at the nanoscale, and C-S-H exhibits rapid deterioration in strength as the scale increases, introducing defects in the model can indeed better simulate the amorphous structure of C-S-H. In this simulation, the stress–strain curves of models of various sizes showed minimal changes during the stress increasing stage, whether it was models 1–3 or models 4–6. Considering that the revised model can still be further optimized, the applicability of this inference in a wider range still needs to be further explored.

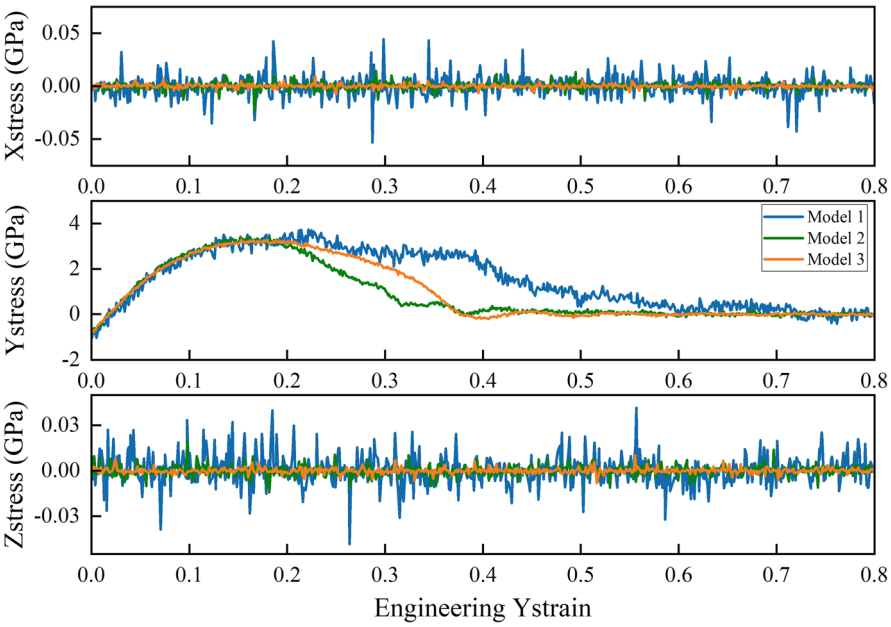

Fig. 1 Changes in stress/pressure in various directions with *y*-direction engineering strains during *y*-direction uniaxial tension in models 1–3

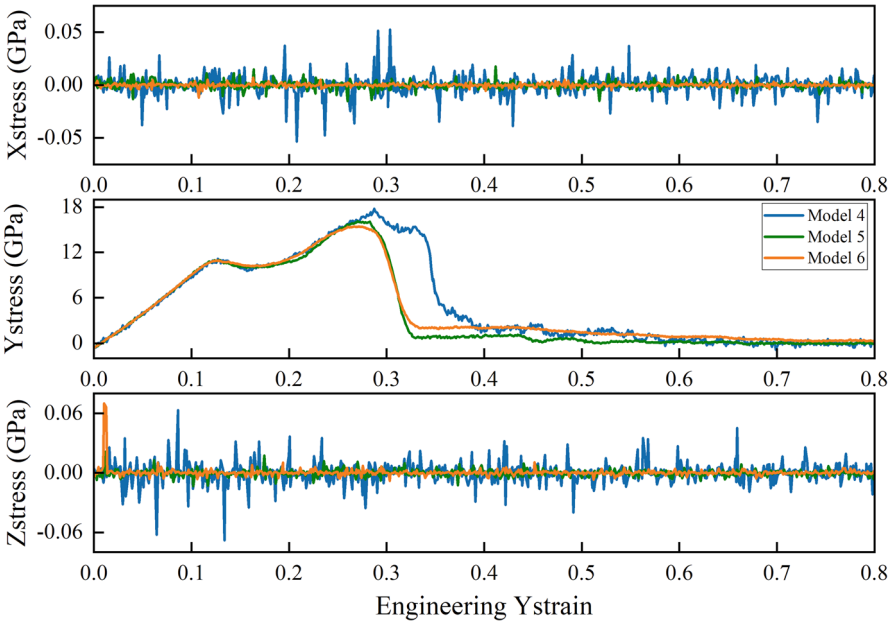

Fig. 2 Changes in stress/pressure in various directions with *y*-direction engineering strains during *y*-direction uniaxial tension in models 4–6

3.2 *Mechanical Properties of Models*

Observing the stress–strain curves of all models, it can be seen that when the strain value reaches 0.44, except for model 1, the other models have lost their load-bearing capacity and are in a state of fracture. Figure 3 shows the atomic trajectories of models 1–6 when the strain value is 0.44. The left side of Fig. 3 shows models 1–3. It can be observed that the fracture position in model 2 is at the end. This result indicates a failure in the experiment. In macroscopic experiments, uniaxial tensile force is typically applied only at the ends, whereas in nanoscopic simulations, pressure is uniformly distributed across the entire model, which may result in fractures at the ends. The tensile strength of model 2 is not significantly different from that of models 1 and 3; therefore, this tension process is undoubtedly effective. Considering the randomness that may occur during the molecular dynamics simulation process, a second simulation was conducted on the initial configuration of model 2. It was observed that the fracture position after tension was located at the center of the model. Figure 4 shows a snapshot of the atomic trajectory when the strain value is 0.44 during two uniaxial tension tests in model 2. It can be observed that, apart from the varying fracture positions, the crack shapes are nearly identical.

The elastic modulus, ultimate strength, and ultimate strain during the uniaxial tension process of models 1–6 were determined based on the stress–strain curves, and the results are presented in Table 2. Due to the unexpected fracture position of model 2, the initial configuration of model 2 was subjected to uniaxial tension twice, resulting in two sets of data. The underlined data corresponds to the uniaxial tension model in which the crack location occurs at the end. The elastic modulus is determined by linearly fitting stress and strain curves within the 0–0.05 strain range. The ultimate strength is the maximum stress that occurs during uniaxial tension, and the ultimate strain is the strain value when the maximum stress is reached. It can be seen from the two sets of data of model 2 that the fracture location will have a certain impact on the mechanical properties of the models. When the fracture occurs at the end, the elastic modulus is 45.29 GPa, and the ultimate strain is 0.15. When the fracture occurs in the middle, the elastic modulus is 43.58 GPa, and

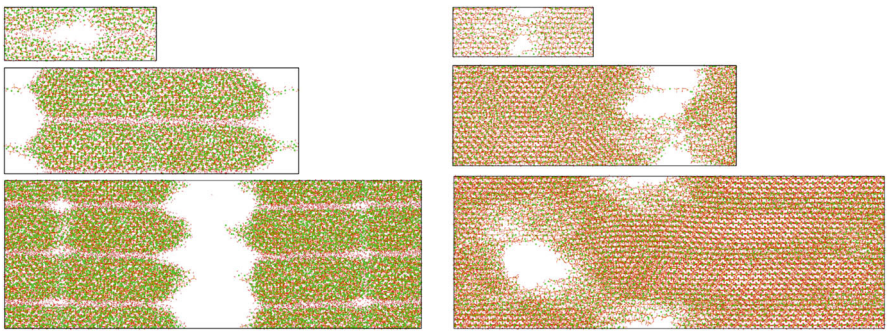

Fig. 3 Snapshots at strain 0.44 in models 1–6

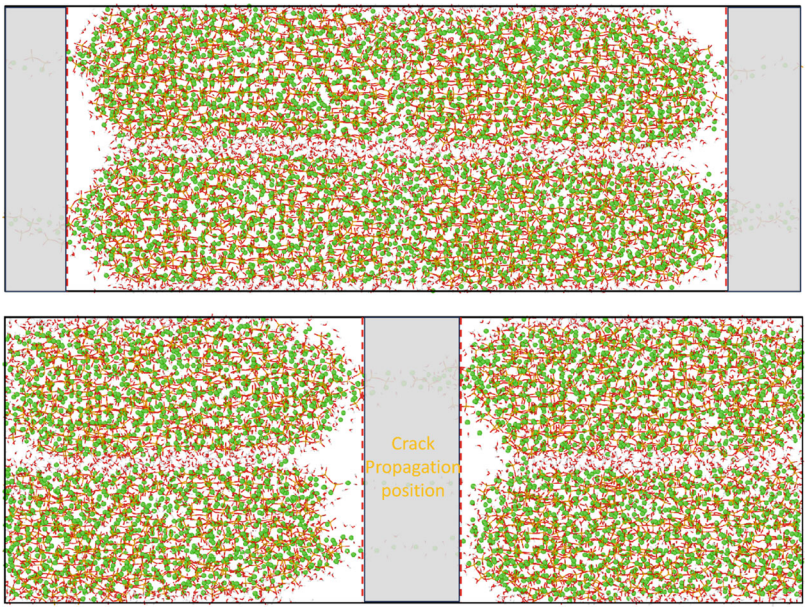

Fig. 4 Comparison of the fracture location after two uniaxial tensions of model 2 (at strain 0.44)

Table 2 Elastic modulus, ultimate strength, and ultimate strain in models 1–6

	Elastic modulus, E (GPa)	E_i/E_{i-1}	Ultimate strength, σ (GPa)	σ_i/σ_{i-1}	Ultimate strain, ε	$\varepsilon_i/\varepsilon_{i-1}$
Model 1	43.64	/	3.75	/	0.22	/
Model 2	*45.29*	/	*3.42*	/	*0.15*	/
	43.58	99.9%	3.42	91.2%	0.19	86.4%
Model 3	43.33	99.4%	3.29	96.2%	0.15	78.9%
Model 4	87.37	/	17.78	/	0.29	/
Model 5	88.77	101.6%	16.11	90.6%	0.27	93.1%
Model 6	89.25	100.5%	15.44	95.8%	0.27	100%

the ultimate strain is 0.19. The elastic modulus and ultimate strain values of the latter are between model 3 and model 1. This result is more consistent with the pattern of mechanical property degradation during scaling up in size. The occurrence of end fractures will not cause the simulation results to fail; however, it does affect the accuracy of the results. When comparing the mechanical properties of models, it is preferable to minimize differences in fracture locations.

According to the values in Table 2, it can be observed that the elastic modulus of the corrected model (models 1–3) is halved compared to the uncorrected model (models 4–6), bringing it closer to the experimental value [10]. The modification of

the model significantly reduces the elastic modulus, ultimate strength, and ultimate strain, with the ultimate strength showing the most significant decrease. With the same size, the ultimate strength of the modified model is 21.1%, 21.2%, and 21.3% of that before the modification, respectively. However, the change in elastic modulus caused by increasing the size of the model is not significant. In models 1–3, as the model size increases, these three parameters decrease slightly. However, the magnitude of this decrease is significantly smaller compared to the changes induced by altering the internal structure of the models. When the size increases, mechanical properties degrade. This means that the ultimate strain is more easily affected, while the elastic modulus degrades more slowly.

3.3 Stress–Strain Correction

The strain used in the above analysis is the engineering strain, and its formula is

$$\varepsilon_E = \frac{L_n - L_0}{L_0} \tag{1}$$

where L_0 is the initial length, and the L_n is the current length during tension. This formula overestimates the effect of initial length on strain but is widely used in macro-experiments because it is easy to calculate and the dimensional change is much smaller than the dimension itself, which ensures the high accuracy. On a macro scale, the engineering strain of common concrete structures is usually much less than 4%, and the disparity between the engineering strain and the true strain is minimal. At the nanoscale, the size of the structure is reduced, leading to simultaneous amplification of stress and strain values. In some simulations, the measured value of engineering strain can even reach 1.0 [11], while the actual strain at this time is around 0.69. In other words, if we want to compare stress–strain curves across scales, it will become unreasonable to continue using engineering strains at the nanoscale. In addition, the performance of C-S-H deteriorates rapidly during upscaling [9]. Therefore, the use of engineering strain also impedes drawing correct conclusions when studying scale effects. For the reasons mentioned above, when comparing stress–strain relationships across different scales, it is advisable to use true strains in molecular dynamics simulations instead of engineering strains. The formula for true strain is

$$d\varepsilon_T = \frac{dl}{l} \tag{2}$$

ε_T was obtained by integrating Eq. (2):

$$\varepsilon_T = \int_{L_0}^{L_n} \frac{dl}{l} = ln\left(\frac{L_n}{L_0}\right) \tag{3}$$

The necking phenomenon is not considered here. According to the expressions of engineering strain and true strain, the transformation relationship between the two strains can be derived:

$$\varepsilon_T = ln(\varepsilon_E + 1) \tag{4}$$

Observing the stress–strain curve of the above models, we can find that when the strain is 0 (i.e., when uniaxial tension has not yet begun), the stresses are all negative, which means that there is an undesired pre-compression at the beginning of the simulation process. Considering the definition of true strain (Eq. 2), i.e., the strain value at this moment is the superposition of the instantaneous strains at all previous moments. Therefore, the accumulation of strain can be calculated starting from when the stress is 0. The specific method is to translate the entire curve in the horizontal direction so that it passes the origin, thus eliminating the strain value accumulated in the preloading state. Obviously, the curve obtained in this way is more reasonable than the stress–strain curve obtained by forcing the data to fit through the origin. Taking model 3 with the more reasonable structural configuration and larger size as an example, the strain (including engineering strain, true strain, and corrected true strain) and stress curves are shown in Fig. 5. Comparing the various stress–strain curves, it can be observed that the curves generated using engineering strain and true strain tend to overestimate the deformation capacity and strain of the model during the uniaxial tension process. However, the elastic modulus and ultimate stress remained unchanged before and after the correction.

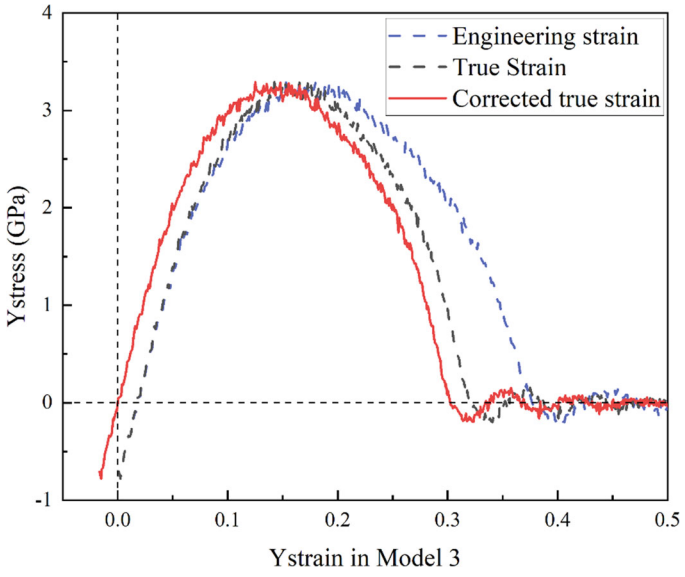

Fig. 5 Stress–strain curve correction diagram

4 Conclusions

In this paper, uncorrected and corrected molecular models with different sizes were built to study the influence of size effect and model structure. Several conclusions can be drawn as follows:

1. Larger-sized models exhibit smaller pressure oscillations in all directions, allowing for a more precise simulation of uniaxial tension processes.
2. The elastic modulus of models of different sizes but of the same type (either corrected or uncorrected) decreases slightly with increasing size. Within the scale range discussed in this paper, differences in stress–strain curves caused by size variations are mainly observed in the stress descent phase.
3. Significantly distinct stress–strain curves exist between the corrected structure and the structure obtained directly from the tobermorite supercell. The ultimate strength of the corrected model is approximately 21.2% of the uncorrected model.
4. Since pressure is uniformly applied to the models in all three directions, fractures occurring at the ends of the models in the tension direction do not invalidate the data. However, different fracture locations in the same models do affect the specific values of the model's elastic modulus and ultimate strain, with no impact on ultimate strength.
5. In uniaxial tension simulations, the strain in the stress–strain curve should represent true strain. After that, shifting the original stress–strain curve horizontally to pass through the origin ensures a more accurate stress–strain curve at the nanoscale.

1 Introduction

The construction industry stands out as a dynamic and economically robust sector. Yet it endures the dual distinction of being an intensive energy consumer and a prominent exploiter of global natural mineral resources. This duality results in important environmental effects and unsustainable practices. Despite estimable advances toward reducing natural resource depletion and encouraging the integration of several recycled and by-product materials, the dependence on virgin and non-renewable resources remains paramount. Rocks and clays, in their natural form or following manufacturing processes, are one of the pillars of construction materials and continue to play fundamental roles in the construction industry. Ordinary Portland cement (OPC) has been the primary binding material used in the production of pastes, mortar, and concrete [1], annually generating more than 1.6 billion tons

M. Kioumarsi, B. Shafei (eds.), *The 1st International Conference on Net-Zero Built Environment*, Lecture Notes in Civil Engineering 237,
https://doi.org/10.1007/978-3-031-69626-8_26

and 12 billion tons, respectively [2]. Despite its popularity and wide usage, OPC manufacturing emits substantial greenhouse gases, averaging 0.85 kg of CO_2 per kilogram of cement produced and accounting for around 8% of global CO_2 emissions [3]. Thus, exploring new cementitious and pozzolanic materials to entirely or partially substitute OPC becomes vital in reducing carbon footprints generated by the construction industry.

There are numerous supplementary cementitious materials (SCMs) developed as probable replacements for OPC, including fly ash [4, 5], slag [6], silica fume [7–9], Rice Husk Ash [10, 11], bagasse ash [12], and metakaolin [13]. The limited availability, and sometimes even the scarcity of these conventional SCMs in many regions of the world, especially in many developing countries, causes difficulties in their common and regular utilization in the cement concrete industry [14]. Meanwhile, natural pozzolans like natural clays [15], clay waste [16], and calcined clays [17] are commonly used as alternative pozzolans. However, compared to these alternatives, calcined clay stands out as the most promising pozzolanic material for blended Portland cement [18]. Clay pozzolan was generally prepared through thermal treatment of kaolinitic clay [19]. Other clays, such as illite [20], smectite [21], and bentonite [22], can also be used to prepare clay pozzolans.

Nevertheless, the calcined clay-blended cement's performance depends on various related parameters such as the mineralogical and chemical compositions, degree of amorphousness, dehydroxylation level, and the fineness of the calcined clay, alongside admixture content, water-to-binder (w/b) ratio, and portlandite (CH) content in the cement paste [1].

A previous study [23] showed that pozzolans derived from heat-treated clay can result in concrete with slightly lower mechanical properties than control concrete, in addition to some negative effects on workability. As the clay brick powder replacement rate increases from 5% to 25%, the 28-day compressive strength may be decreased by around 8–25% as [24] reported. Moreover, blended cement with calcined clay exhibits high resistivity to alkali-silica reactions, chloride diffusion, sulfates, and harmful environmental attacks [25].

Using calcined clay alone or in combination with limestone not only enhances mechanical and durability properties but can significantly reduce clinker usage in cement production by 30–50% without negatively impacting the technical properties [1]. Using calcined clay-blended cement and LC3 systems reduces fuel consumption by 650 MJ/ton and 730 MJ/ton, respectively, compared to OPC. Moreover, clay calcination consumes around 50% less energy than clinker production using the same fuel in India [26]. These alternative systems also significantly reduce CO_2 emissions by 26 and 33%, respectively, compared to OPC.

This study's target is to improve the sustainability of Portland cement, which serves as a cornerstone in the construction industry, while simultaneously addressing its status as one of the most environmentally detrimental constituents in cement-based materials.

2 Materials and Testing Procedures

2.1 Materials

Locally available raw and manufactured materials were used as components of mortar mixes studied in this research. Natural well-graded sand with grain size ranging from 600 μm to 150 μm as per ASTM C778-21 [27], a specific gravity of 2.82, and water absorption of 1.5% was used. Ordinary Portland cement (OPC) conforming to ASTM C150-22 [28] with a specific gravity of 3.14, specific surface air permeability of 327 m^2/kg, a normal consistency of 26%, and an initial setting time of 160 minutes was used in all mortar mixes as the main binder.

To keep the flow of all mortar mixes within the target value set, a high-performance superplasticizer (SP) admixture was used in a liquid state and added directly during the mixing. This SP is chloride-free, reddish in appearance with a specific gravity of 1.24, and conforms to BS-EN 934-2 [29] and ASTM C494/C494M-19 [30] types B, D, and G. The mixing water used has a pH of 7.8 and a TDS of 585 ppm. Raw clay from the northeast region of Oman was collected, screened, dried, ground in a ball mill to fine particles, and sieved to retain only the particles smaller than 75 μm.

2.2 Procedures

A series of materials characterization were conducted on both the raw and burnt clay. Raw clay was first characterized using X-ray Fluorescence (XRF) to arbitrate the major oxides and assess its suitability for use as a pozzolana. Thermogravimetric (TG) analysis was conducted to examine the clay's weight loss upon heating up to 1400 °C and to determine the probable suitable calcination temperature(s).

Mortar mixing was performed as per the guidance specified in ASTM C305-20 [31]. Following the mixing, fresh properties, including temperature, density, and flow as per ASTM C1437-20 [32], were measured. The hardened density, flexural, and compressive strengths were all tested after 28 days of curing in water. Compressive strength was tested on 50 mm cubes as per ASTM C109/109 M-21 [33], and flexural strength was tested on prisms of 40 × 40 × 160 mm as per ASTM C348-21 [34]. At 28 days of water curing, the porosity of the plain and modified mortar mixes was determined as per ASTM C642-21 [35]. A rapid chloride permeability test (RCPT) was carried out after 180 days of water curing to assess the mortar's resistance to chloride ions ingress. The test was carried out on mortar discs measuring 100 × 50 mm according to ASTM C1202-22 [36] and AASHTO T277-15 [37].

3 Results and Discussion

3.1 Physical Characterization of Clay-Pozzolan

The clay used had a specific gravity of 2.75, a Brunauer–Emmett–Teller (BET) surface area of 17,900 m^2/kg, and most of the particles (97%) have a size smaller than 75 μm. Scanning electron microscopy (SEM) images show that both OPC and CCF have angular and irregular shapes with rough surfaces. This is one of the factors that led to a reduction in mortar's flow when CCF replaces part of the OPC.

The thermogravimetric analysis of a raw clay sample showed that the dehydroxylation starts at around 450 °C, followed by an acceleration in the mass loss to reach around 12%. The TGA graph indicates that the transition phase, where the crystalline structure and chemical bonds in the clay are likely to occur, is at a temperature varying from 500 to 800 °C. During this stage, the clay structure transforms from crystalline to semi or non-crystalline. Based on this analysis, a calcination temperature of 700 °C was selected.

The crystal structure and mineralogical composition were examined using X-ray diffraction (XRD). The raw clay's XRD patterns show a sharp and intense peak mainly of four major minerals, including quartz, hematite, kaolinite, and calcite. In terms of oxide composition, the CCF clay is rich in silica, alumina, and iron oxide, with a sum of these three oxides exceeding 93%. This amount qualifies the CCF clay as a pozzolana as per ASTM C618-23 [38]. The burning of the clay at a temperature of 700 °C resulted in an XRD pattern with fewer peaks, lower intensity of the calcite peaks, and complete disappearance of kaolinite peaks. This indicates the calcined clay (CCF) transformation to a more amorphous powder material and a reduction in the degree of crystallinity of the heat-treated clay.

3.2 Fresh Properties of Mortar Mixes

The mortar mixes studied were all tested at fresh state for temperature, fresh density, and flow. The temperature of the freshly mixed mortars was immediately measured after the end of the mixing sequence. The temperatures recorded range between 24 and 27 °C. The inclusion of CCF led to a drop in the mortar's fluidity, as depicted in Fig. 1. To keep the mortar's flow within the targeted range (110–140%), an increase in the SP content was needed (Fig. 1). The higher the substitution ratio of CCF, the higher the SP demand. The relationship between blended mortar's flow and SP content is almost linear. In fact, the loss of fluidity exhibited by incorporating different amounts of CCF is attributed to the type of clay used, which is rich with hematite (Fe_2O_3) that accentuates the clay's water absorption. Additionally, the high surface area (17,900 m^2/kg) of the CCF requires a larger amount of water and/or SP to lubricate all the clay's ultrafine particles compared to the moderate fineness of OPC.

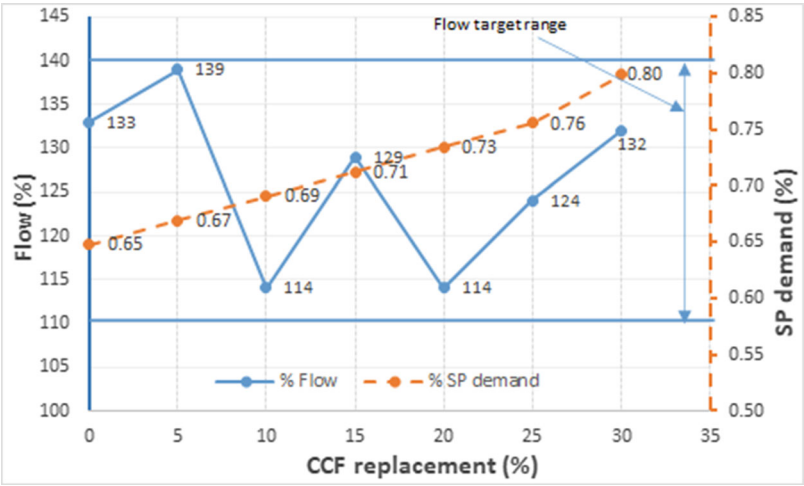

Fig. 1 Mortar's flow and SP demand function the CCF replacement level

The fresh density fluctuated from 2293 kg/m^3 for the control mortar mix to a maximum of 2400 kg/m^3 for the blended mix with 20% CCF. Generally, a slight reduction in the fresh density was found when the substitution ratio of OPC with CCF augmented from 0% to 5%, and 10%. At 15% replacement, the fresh density was equal to the control one, while at 20% replacement, the highest packing was reached with the maximum density. When the replacement level exceeds 20%, the density gradually reduces.

The change in density at a fresh state is likely to be affected by several parameters, including the initial materials' specific gravity, the mix's flow, and the compaction ability. Generally, because CCF has lower specific gravity compared to OPC, this can contribute to the observed fresh density reduction. Also, the lower the flow, the higher the density at the fresh state. The highly fluid mix is loose and, hence, less dense, as seen in Fig. 2.

3.3 Strength and Durability

The results of the 28-day flexural and compressive strengths development of the plain and modified mortar mixes with various percentages of the CCF are illustrated in Fig. 3. The results indicate that incorporating the CCF and increasing its content in the blended mortar mixes had slightly reduced the mortar's 28-day flexural strength from 36.4% to 9%.

However, regardless of the CCF replacement level, incorporating different percentages of the CCF significantly increased the blended mortar's 28-day compressive strength from 68.3% to 9.8%. The highest improvement of 68.3% was achieved

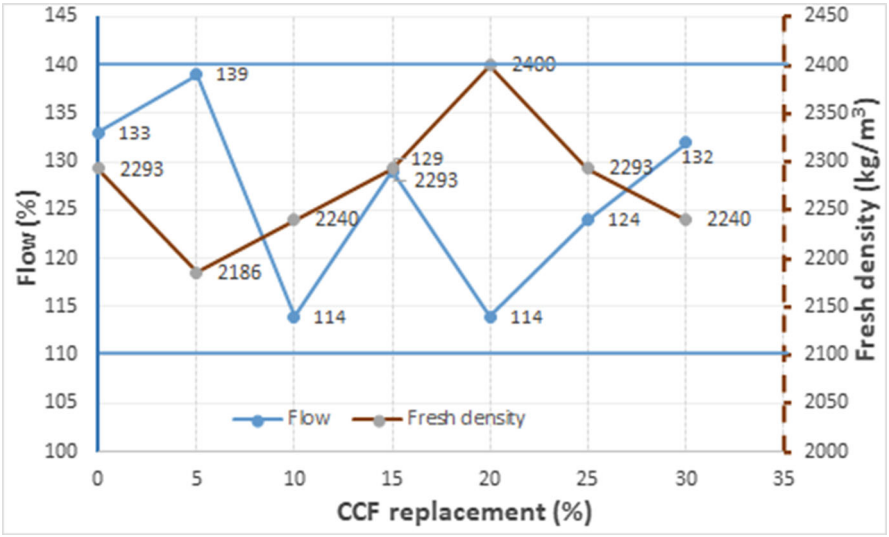

Fig. 2 Mortar flow and fresh density versus the CCF replacement level

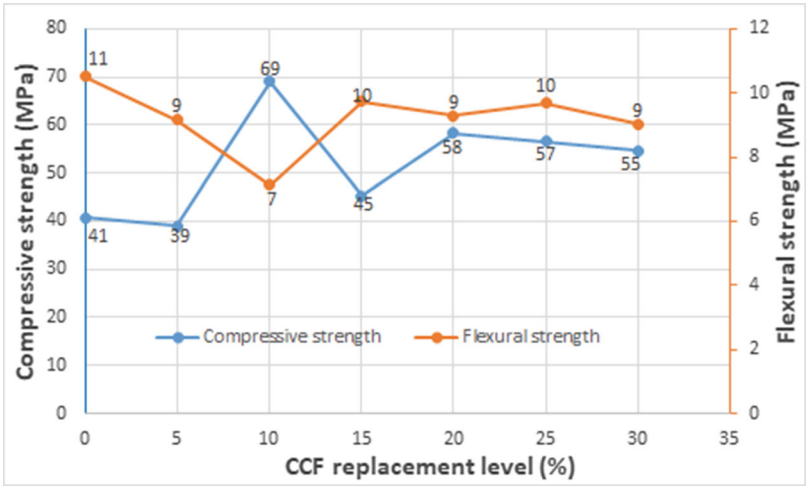

Fig. 3 Mortar's 28-day compressive and flexural strengths versus the CCF substitution level

when 10 wt.% OPC is replaced with CCF. Beyond 10 wt.%, the compressive strength kept higher than the control mortar but reduced gradually compared to the maximum strength reached at 10 wt.%. The strength enhancement of the modified cement mortar is due to the pozzolanic reaction between the amorphous silica-rich CCF and the portlandite of the OPC hydration reaction. The additional CSH formed fills and subdivides the larger capillary pores and, hence, increases mortar compactness and strength.

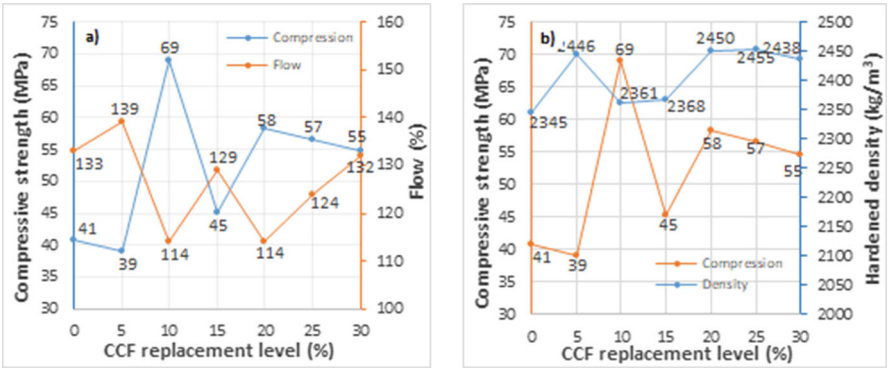

Fig. 4 Relationship between (**a**) the flow-compressive strength and (**b**) the density-compressive strength of mortar designed with various CCF replacement levels

For various replacement levels of OPC with CCF, Fig. 4 depicts the relationship between (a) mortar's flow-compressive strength and (b) hardened density-compressive strength. Generally, the compressive strength was inversely affected by the mortar's flow. The lower the flow, the higher the mortar's compressive strength. However, no apparent trend can be seen relating the mortar's density evolution to its compressive strength when rising the OPC substitution level with the CCF. All blended mortar mixes developed a higher density compared to the plain mortar. At a relatively low replacement ratio (0–15%), the density was moderate, ranging between 2345 kg/m^3 for the control mix to 2368 kg/m^3 for the blended mortar with a 15% replacement level. At a higher replacement ratio (20–30%), a significant increase in density was recorded. The higher density of blended mortar with CCF is mainly due to three major parameters, including (i) the presence of hematite in the CCF, (ii) the high fineness of CCF increased the packing density, and (iii) the pozzolanic reaction and the resulting CSH that fills the gaps and enhances the mortar's density.

Figure 5 illustrates the relationships between density-compressive strength and density-flexural strength. The results show a linear relationship with a good correlation relating the mortar's density and compressive strength with an *R*-squared value of 0.965 and a good correlation between the density and flexural strength with an *R*-squared value of 0.989.

On the other hand, permeable pore volume and chloride ions permeability are two important aspects of the durability of mortar, particularly when exposed to destructive environments such as the presence of chloride or other harmful substances. Figure 6 displays the effect of partially replacing OPC with various CCF content. It can be seen that, generally, both the porosity and permeability to chloride increase when rising the substitution ratio of OPC with CCF. The rate of decrease in permeability is accelerating with the increase in the substitution level, especially beyond 5%. However, porosity reduction is slightly affected by the increase in the CCF content in mortar.

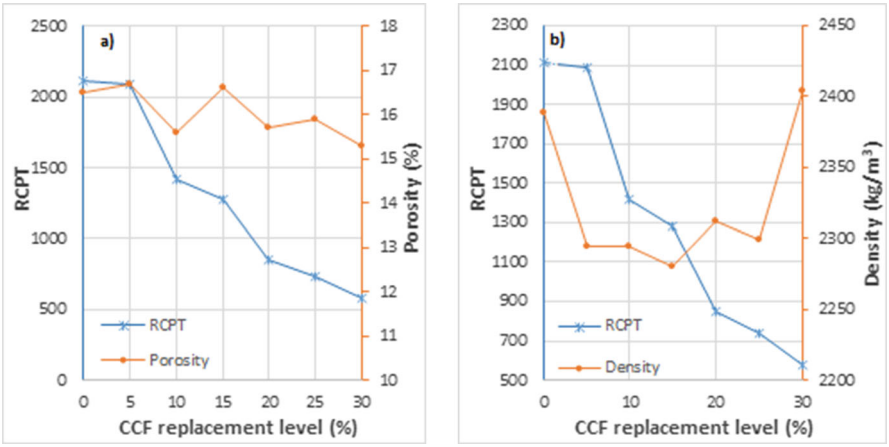

Fig. 6 Relationship between (**a**) RCPT-mortar's porosity and (**b**) RCPT-density of mortar designed with various CCF replacement levels

3.4 Environmental and Economic Assessment

With all its impacts on the quality of life and society and the continuous pressure on national and global economies, climate change has become a contemporary challenge for humanity. Reducing energy consumption, carbon dioxide emissions, raw minerals extraction, wastage generation, and rational usage of available

non-renewable natural resources are just some of the main criteria to reduce the environmental impacts of the construction industry. Producing clinker cement is known to generate from 850 to 1 ton of CO_2 per ton of produced cement. This high amount of CO_2 generated is due to the large energy consumption resulting from the calcination temperature of the raw materials used to manufacture clinker, which requires a temperature of around 1600 to 1400 °C. The present study used local clay (less carbon footprint caused by transportation) calcined at only 700 °C. This temperature is precisely half the temperature required for the manufacturing of clinker. Considering the actual clay calcination temperature compared to clinker cement, we can conclude that the energy required, and hence, the CO_2 generated by calcined clay, is half that caused by clinker cement. For each 1 ton of calcined clay, around 425 to 500 kg of CO_2 is generated.

Moreover, the clinker cement cost is mainly due to the energy used during the calcination. Reducing the required energy to half would also reduce the cost to half of the cost of cement, depending on the replacement level. The higher the cement replaced with calcined clay (CCF), the more significant the cost and carbon footprint reduction. Therefore, partially replacing OPC with CCF significantly contributes to environment-friendly concrete/mortar.

4 Conclusions

The findings of this study's experiments allow for the following conclusions to be made:

- The clay used (CCF) in this research work is classified as a pozzolana with a significant content (>93%) of the sum of the three main oxides (SiO_2, Al_2O_3, and Fe_2O_3). Moreover, the XRD analysis indicated that this CCF clay contains mainly four major minerals: quartz, hematite, kaolinite, and calcite.
- The physical properties of the CCF demonstrated a high fineness of 17,900 m^2/kg as a surface area and around 97% of particles passing 75 μm.
- The TG/DT analyses indicated that an optimum calcination temperature of around 800 °C combines enhancement in the mechanical and durability properties with sustainability and low environmental impact.
- The inclusion of various contents of CCF as an OPC partial substitute reduces the mortar's flowability, requiring an SP content increase to keep a satisfactory flow within the target of 110 to 140%.
- Except at a low substitution ratio (5%), the inclusion of CCF has significantly enhanced the compressive strength of mortar at 28 days. The highest strength improvement (68.3%) was obtained with a 10% replacement of OPC with CCF.
- A good correlation was found between the mortar's density and its compressive and flexural strengths, with an R-value of 0.965 and 0.989, respectively.
- The inclusion of CCF slightly reduced the permeable pores and significantly enhanced the mortar's resistance to chloride ions penetration.

- The environmental and economic assessment indicates great potential in reducing the final cost of the concrete/mortar and mitigating CO_2 emissions when partially replacing OPC with the CCF. The higher the replacement levels of OPC with CCF, the higher the reduction in cost and CO_2 emissions.

Acknowledgments His Majesty Trust Fund (HMTF) financially supported the research presented in this paper under the project grant number SR/ENG/CAED/21/01. The authors would like to express their appreciation and thanks for the funds provided.

1 Introduction

The construction industry consumes up to 40% of the global energy, generates about 30–40% of the total municipal solid waste, and emits about 25% of the total global CO_2 emissions [1]. To meet its carbon reduction targets and contribute to the transition to a net-zero built environment by 2050, it is crucial to use energy-efficient technologies and explore new CO_2 sequestration pathways. A promising approach to enhance the properties of cement composite involves accelerated mineral carbonation [2]. In this process, CO_2 reacts with calcium-bearing minerals to

form carbonates. This dual action not only improves the mechanical properties of cement composites but also leads to the permanent capture of CO_2 inside the material matrix [3]. However, carbonation at ambient or low-pressure conditions occurs slowly, thereby reducing the practicality of implementing it on an industrial scale. The concept is to explore cement material curing at high pressure, where the carbonation rate can be significantly enhanced through increased pressure.

High-pressure technology involving supercritical fluids is already well established as an energy-efficient technology, with high promise for implementation in the construction industry. Supercritical fluids are unique states of matter that possess properties of both liquids and gases. They are formed when a substance is subjected to high-pressure and temperature conditions, surpassing its critical point (Fig. 1). Their unique solvating power, enhanced mass transfer capabilities, and environmentally friendly nature make them valuable tools in numerous industries [4]. For example, supercritical fluid extraction allows the efficient extraction of valuable compounds from natural sources while preserving their quality [5]. Supercritical fluids are being extensively used for polymer processing including particle formation and encapsulation [6], foaming processes [7], enzymatic reactions [8], supercritical drying of aerogels [9], supercritical-fluid chromatography [10], for jet cutting [11], dry cleaning [12], for sterilization processes, and for powder coatings [13]. Supercritical fluids are frequently found in large-scale operations in petrochemical plants [14], as working fluid in advanced power cycles [15], and carbonation of well cement [16]. A comprehensive understanding of the carbonation process under supercritical conditions is essential for various applications in the construction industry, including CO_2 capture and storage [17], the treatment of recycled concrete [18], and the solidification of toxic waste in building materials [19].

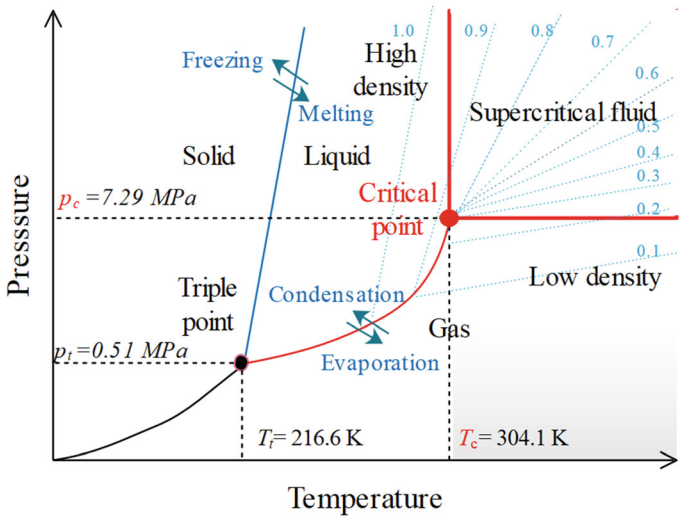

Fig. 1 P-T diagram for CO_2

This study presents the first investigation into the use of high-pressure carbonation of cement mortar mixed with a pozzolanic material, metakaolin. Mortar samples underwent treatment in a high-pressure reactor at 323 K and 15 MPa. The carbonation rate of the carbonation front and the carbonation rate of the cross-section, as well as the compressive and flexural strengths, were measured after 7, 14, and 28 days of exposure to supercritical CO_2. The specific surface area of hydrated mesoporous samples was assessed through N_2 desorption and absorption analysis. Morphological changes were measured with scanning electron microscopy with energy-dispersive spectroscopy (SEM-EDS).

2 Materials and Methods

2.1 Raw Materials

The typical ingredients used in the production of Portland cement mortar (PCM) samples were cement, sand, metakaolin, and water. The Portland cement was CEM II/B-M(LL-V) 42.5 N, known for its high resistance to sulfate attacks due to the clinker composition lacking tricalcium aluminate (C_3A), sourced from Salonit Anhovo d.o.o, Slovenia. A mineral additive, metakaolin (MK), with a mean particle size distribution (d_{50}) of 4.5 μm and density of 890 kg/m^3, supplied by Melanin d.o.o, Slovenia, was employed as a partial replacement for the Portland cement. Standard sand with particle sizes ranging between 0.08 and 2.00 mm was used to prepare the mortar samples (Normensand GmbH, Germany). The phenolphthalein indicator was provided by Sigma Aldrich, Germany. Carbon dioxide gas (3.5) was obtained from Messer d.o.o, Slovenia.

2.2 Samples Preparation and High-Pressure Carbonation Curing

The first set of PCM was prepared with a fixed water-to-cement ratio (w/c) of 0.5 and sand-to-cement ratio (s/c) of 3.0, followed by stirring for 5 minutes. Furthermore, metakaolin (MK) was incorporated as a supplementary cementitious material to create a second type of blended mortar sample, replacing 15% by weight of Portland cement (PCM+MK). The homogenized mortar in its green state was vibrated and poured into molds measuring 40 × 40 × 160 mm, adhering to Standard SIST EN 197-1 specifications. After 24 hours of regular curing, the samples were extracted from the molds and made ready for standard curing in water or high-pressure carbonation curing.

Carbonation was performed in a high-pressure reactor (Sitec AG, Zurich, CH) capable of operating at 150 MPa and 573 K. The CO_2 was pumped inside the reactor by a liquid high-pressure pump (NWA PM 101). The samples were treated at a

pressure of 15 MPa and a temperature of 323 K. The required moisture was provided in the reactor as there was water in the lower part of the reactor. Having moisture content is crucial for the carbonation process.

2.3 Characterization Methods

2.3.1 Compression and Flexural Tests

Prism specimens sized 40 mm × 40 mm × 160 mm were prepared for three-point bending flexural (σ_f) and compression (σ_c) strength testing. Compression and flexural strength were tested following Standard SIST EN 197-1. Compression was calculated according to Eq. (1):

$$\sigma_c = F_c / A_0 \tag{1}$$

where *Fc* represents the instantaneous load applied perpendicular to the specimen cross-section (N), and A_0 is the original cross-sectional area before any load is applied (mm^2). Three-point bending flexural (σ_f) was calculated according to Eq. (2):

$$\sigma_f = \left(1,5 \cdot F_f \cdot l\right) / b^3 \tag{2}$$

where F_f is the load at a given point on the load-deflection curve, (N), l is the distance between the supporting pins (100 ± 0.5 mm) and b is the prism side length (40 ± 0.2 mm).

2.3.2 Carbonation Rate

Carbonated mortar samples were quantified using phenolphthalein indicator. Non-carbonated region with a pH >10, the color changes to purple, while, in the carbonated area with pH <10, the color remains the same. Pictures of the sectioned sample areas were subsequently analyzed using the open-access image processing software, ImageJ [22]. The average carbonation rate and depth was calculated.

2.3.3 Nitrogen Adsorption/Desorption Method

Gas adsorption–desorption analysis was conducted to determine the pore volumes (cm^3/g), specific surface areas (m^2/g), and pore diameters (nm) of fractionated samples. The experiments were performed utilizing an ASAP 2020MP instrument (Micromeritics, Norcross, Georgia, US), with N_2 serving as the adsorptive gas.

2.3.4 Microstructural Analysis

The surface morphology and chemical composition of fractured mortar samples were analyzed using a Quanta 200 3D Scanning Electron Microscopy–Secondary Electron Imaging (SEM-SEI) device, manufactured by FEI Company in Hillsboro, OR, USA. The equipment was further equipped with FEI Sirion 400 NC energy-dispersive X-ray spectroscopy (EDS), also from FEI Company.

3 Results and Discussion

3.1 Compression and Flexural Strength

The compressive and flexural strength of cement mortar samples exposed to conventional curing and high-pressure carbonation for 7-, 14-, and 28-day test periods are depicted in Figs. 2 and 3. It is evident that the addition of 15 wt% MK significantly enhances the strength of the samples. Under conventional curing conditions, the compression strength increases from 59.34 MPa to 71.4 MPa, and the flexural strength increases from 7.76 MPa to 10.84 MPa at 28 days. The treatment under high pressure further enhances the strength of Portland cement mortars compared to conventional curing methods. For instance, SUP-PCM and SUP-PCM+MK samples carbonized with supercritical CO2 for 28 days show an 18.11% and 13.11% increase in compression strength, and a 31.06% and 10.18% increase in flexural strength, respectively. The increase in strength is attributed to the mineralization of CO_2, which reacts with portlandite ($Ca(OH)_2$) and/or calcium-silicate-hydrate (C-S-H) in the cement matrix, forming carbonates (CaCO3(s)) that enhance the strength at the interface transition zone (ITZ) [20].

SUP-PCM+MK treated under supercritical CO_2 showed a non-colored area indicating that the carbonation process had occurred. As presented in Fig. 4, the average carbonation rate SUP-PCM and SUP-PCM+MK samples increased with exposure time from 7 days up to 28 days.

Results suggest that with increasing time, more CO_2 was permanently mineralized in the mortar matrix. For example, the carbonation rate and depth increased from 25% and 3.2 mm to 33% and 5.4 mm, respectively. Surprisingly, significantly larger CO_2 uptake was observed in the mortar samples blended with 15 wt% of MK, where the carbonation rate increased from 40% at 7 days to 67% at 14 days and up to 78% at 28 days, suggesting almost complete carbonation.

3.3 Nitrogen Adsorption and Desorption Analysis

The nitrogen adsorption and desorption isotherms were utilized on mortar samples to provide information regarding the pore surface area. According to the IUPAC classifications, there are typically six types of adsorption isotherms [21]. Hysteresis loop can be observed in every sorption isotherm and could be classified as type V

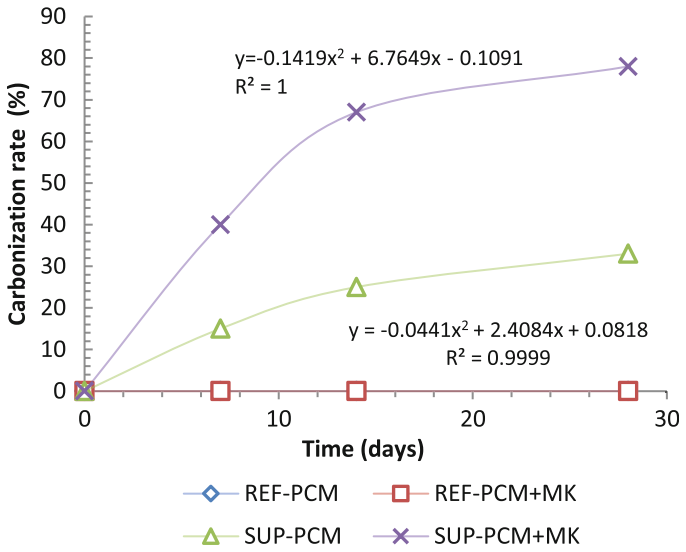

Fig. 4 Increased average high-pressure carbonation rate versus time

isotherms (Fig. 5). These isotherms represent a specific case of adsorption occurring in micro and/or mesopores, characterized by relatively weak interactions between the adsorbent and the adsorptive [22]. The BJH desorption pore volume versus pore size distribution revealed that hydrated mortar samples possess a complex pore system characterized by a significant amount of small gel pores (up to 3 nm) as well as large gel and mesopores ranging from 12 to 50 nm. Macropores are present to a lesser extent (Fig. 6)

Table 2 shows the BET surface area that was used to determine the internal specific area of pores and the average pore sizes of BJH. The specific surface area and quantity of absorbed/desorbed N_2 were slightly higher in the mortar samples containing 15 wt% of MK. Because capillary condensation and surface adsorption contribute to the amount of adsorbed water within the pore structure, the PCM-MK and SUP-PCM-MK samples absorbed more water, leading to higher carbonization rates. The BET surface area decreased upon exposure to supercritical CO_2, suggesting mineralization within the pore system.

3.4 SEM-EDX

SEM-EDX was used to provide a quick nondestructive determination of the elemental composition of mineral additive and carbonated samples.

Figure 7 presents the SEM-EDX analysis of the aluminosilicate mineral additive that was used to produce mortars. The powdery product consists of spillable size particles. Chemical analysis shows a typical representation of elements in MK powder such as silicon (Si) and aluminum (Al).

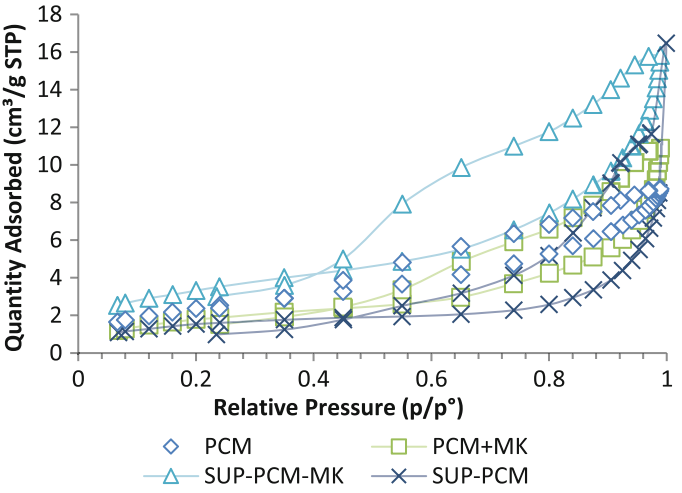

Fig. 5 Adsorption–desorption isotherms for mortar samples treated under atmospheric and supercritical conditions

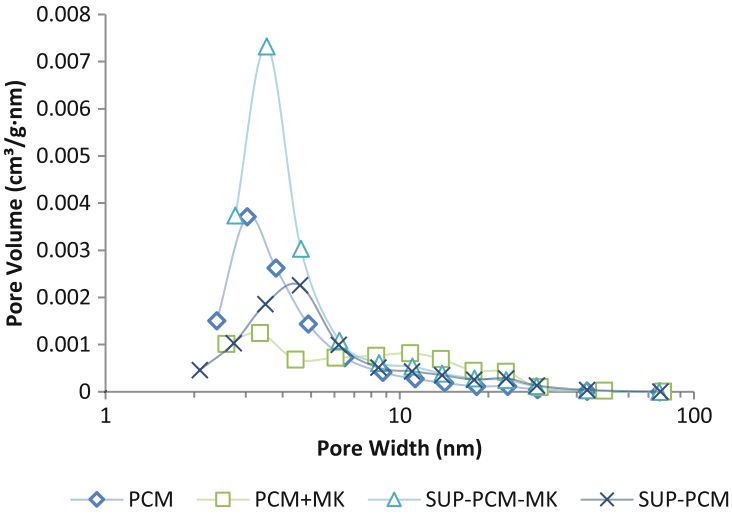

Fig. 6 BJH desorption pore volume for mortar samples treated under atmospheric and supercritical conditions

Figures 8 and 9 depict the SEM-EDX micrographs of mortar samples SUP-PCM and SUP-PCM-MK after exposure to supercritical CO_2. A distinct interface delineates the outer carbonized zone from the inner non-carbonated zone, with the carbonated zone exhibiting a rougher surface and crystal formation. Following exposure to supercritical CO_2, both samples' outer zones show a decrease in calcium (Ca) atomic percentage and an increase in carbon (C) atomic percentage compared to

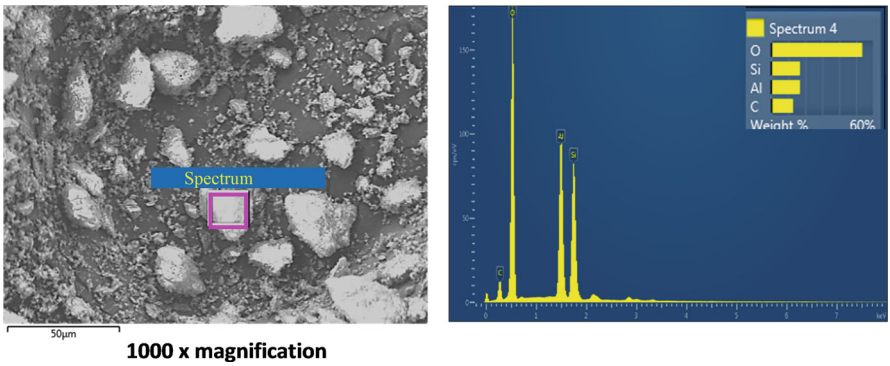

Fig. 7 SEM-EDX analysis of used mineral additive, metakaolin (MK)

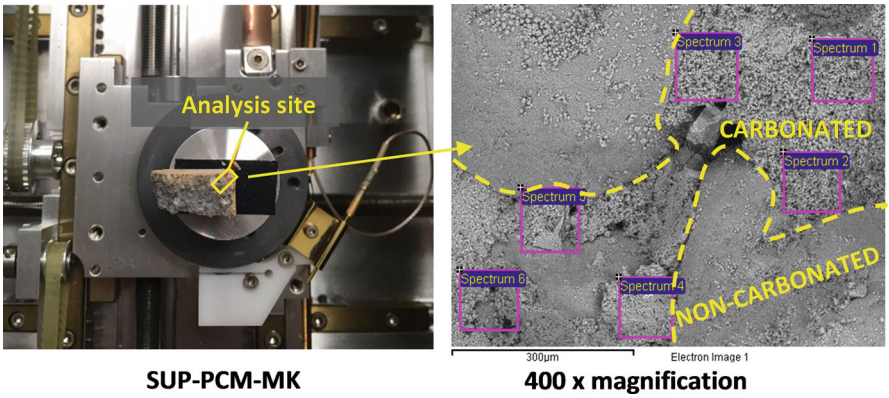

Fig. 9 SEM-EDX analysis of mortar SUP-PCM-MK with a distinguished interface that separates the outer carbonized zone and the inner non-carbonated zone

the non-carbonized inner zone, indicating the formation of $CaCO_3$ polymorphs. Additionally, both samples display a light brown crust on the surface. Table 3 presents the chemical composition of the SUP-PCM and SUP-PCM-MK spectra at 400× magnification.

4 Conclusion

The aim of this study was to investigate the potential of high-pressure carbonation to improve the strength and CO_2 utilization of Portland cement mortar. It was observed that the addition of metakaolin (MK), a supplementary cementitious material with pozzolanic properties, significantly enhanced both strength and CO_2 mineralization under supercritical conditions. These findings suggest promising prospects for the application of high-pressure carbonation in the construction industry, particularly for curing cement composites and recycled concrete where cement mortar is utilized on the surface.

1 Introduction

In demand for better construction materials, at the end of twentieth century, a novel class of concrete has been developed and referred to as ultra-high-performance concrete (UHPC). It exhibits extremely high strength, ductility, and durability [26]. The typical compressive strength of UHPC lies in the range of 120–200 MPa, its split tensile strength up to 20 MPa, and flexural strength up to 30 MPa [21]. The excellent properties are achieved using ultra-fine silica fume, steel fiber, and low water/binder ratio [9]. Durability of UHPC benefits from the dense matrix formed by carefully graded granular materials which makes UHPC resistant to water penetration, chemical attacks, and carbonation [27].

However, low water/binder ratio can lead to autogenous shrinkage up to 2000 to 3000 μm/m due to self-desiccation [17]. To mitigate the autogenous shrinkage, one of the effective methods is internal curing. It provides curing water internally that can participate in early-age chemical reaction in addition to base mixing water [20]. This mechanism can maintain the internal relative humidity (IRH) and thus mitigate the autogenous shrinkage. Superabsorbent polymer (SAP) and natural zeolite are two effective internal curing agents used in many studies [14, 15, 23]. SAP is typically cross-linked poly-electrolyte with acrylamide/acrylic acid or poly-acrylic acid. It can absorb water up to 1000 times of its own mass and gradually release the absorbed water when surrounding IRH is relatively low. The effectiveness of SAP as an internal curing agent is closely related to its chemical characteristics, its dosage and particle size, the water/binder ratio of UHPC [18, 28]. Researchers have divided results regarding the effect of SAP on compressive strength, some indicated an increase in compressive strength [24], and others reported a negative impact [8]. Natural zeolite is a natural pozzolan that is able to act as an internal curing agent similar to SAP particles. Zeolite particles can entrap water molecules in the cavities and channels in their honeycomb-like structure and gradually release it back to the cementitious matrix [14]. Moreover, natural zeolite is considered eco-friendly for several reasons. China currently possesses substantial natural zeolite deposits, estimated at over 3 billion tons. The current annual consumption rate is approximately 3 million tons [10]. To ensure responsible resource management, government oversees the extraction rates, labor safety, environmental impact and operational economic efficiency.

However, there are few efforts spent on studying their effects using the identical setup, that is, same raw materials, mixing method, curing condition and test specifics. Therefore, to facilitate a better visualized comparison of SAP and zeolite, this study aims to investigate the effect of both SAP and natural zeolite on shrinkage reduction, mechanical performance, micropore structure and hydration characteristics of UHPC. To this end, six mixtures were designed, where SAP was added at three different dosages, namely, 0.2%, 0.4%, and 0.6% of cement mass. Silica fume was replaced by zeolite particles at 25% and 50% by mass, respectively. Apart from early-age autogenous shrinkage, drying shrinkage was also recorded to provide a comprehensive understanding of dimensional stability of UHPC. Micropore structure was evaluated by mercury intrusion porosimetry (MIP) to explore its relation with shrinkage and compressive strength. The pore size distribution was supported by the T_2 profiles given by the low-field nuclear magnetic resonance (NMR). The tests and analysis conducted in this study shed a light on how SAP and zeolite influence shrinkage and other properties of UHPC under different dosages. The outcome of this study contributes to making a more sustainable UHPC with better dimensional stability.

2 Experimental Testing Program

2.1 Materials

The UHPC used in this study is a non-proprietary UHPC mixture that consists of ordinary Portland cement (OPC), silica fume (SF), natural zeolite (NZ), SAP, river sand (fine sand), quartz sand (coarse sand), superplasticizer (SP), and water. The OPC, SF and NZ are considered as binders. The median particle sizes of the OPC, SF, SAP, NZ, fine sand are 14.805 μm, 26.368 μm, 29.431 μm, 53.855 μm, and 353.257 μm, respectively. The particle size distributions of materials are shown in Fig. 1. The size range of coarse sand is 600–2000 μm. The OPC used in this study is type P·II52.5R. Steel fibers are not used to avoid the interference of steel fibers on shrinkage restraining. The SP used is provided by SIKA Co. Ltd. in form of solid powder.

2.2 Mix Design and Mixture Proportions

The mix design of this study adopts a non-proprietary mixture proposed by Karim et al. [13]. Minor modifications were made to optimize UHPC performance according to modified Andreasen and Andersen particle packing theory [11], as part of the efforts in adaption to local materials. The mixture proportions are shown in Table 1. For the reference mixture, the binder materials include Portland cement and silica fume, which account for 86.8% and 13.2% of total binder by mass,

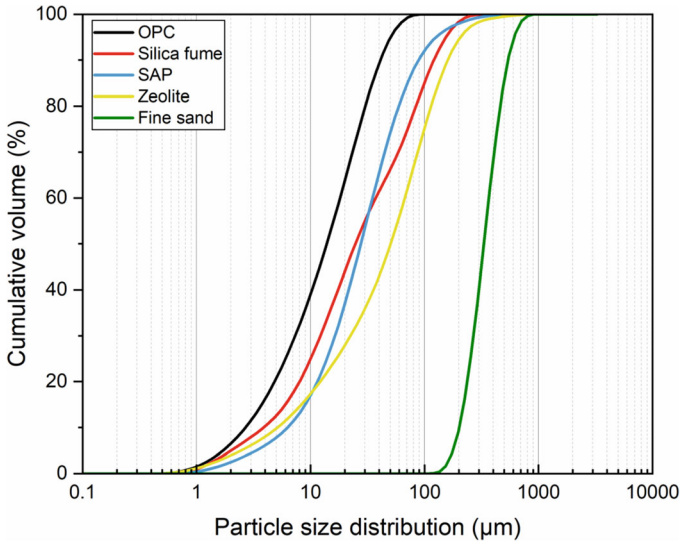

Fig. 1 Particle size distribution of raw materials

Table 1 Proportions of non-proprietary UHPC mixtures

Mix. ID	Materials (kg/m^3)									Eff. w/b	Total w/b
	PC	SF	NZ	SAP	Quartz sand	River sand	Water	Extra water	SP		
Ref	889.0	135.8	–	–	906.8	349.0	174.2	0.0	14.2	0.170	0.170
S0.2	889.0	135.8	–	1.8	906.8	349.0	174.2	29.2	14.2	0.170	0.198
S0.4	889.0	135.8	–	3.6	906.8	349.0	174.2	58.3	14.2	0.170	0.227
S0.6	889.0	135.8	–	5.3	906.8	349.0	174.2	87.5	14.2	0.170	0.255
Z25	889.0	101.9	33.9	–	906.8	349.0	174.2	5.3	14.2	0.170	0.175
Z50	889.0	67.9	67.9	–	906.8	349.0	174.2	10.6	14.2	0.170	0.180

respectively. The sand (filler) to cement ratio was 1.41:1, and the sand consists of 72.2% of quartz sand and 27.8% of river sand by mass. The water-to-binder ratio was 17.0% for the reference mixture. The amount of superplasticizer is 1.6% by mass of cement across all mixtures. Six mixtures of UHPC were designed in total (including the reference mix). Three of them were mixed with different dosage of SAP, namely, 0.2%, 0.4%, and 0.6% by mass of cement. They were named by the internal curing agent and its dosage, that is, S0.2 denotes the mix with SAP at dosage of 0.2%. Two of them were mixed with different levels of substitution of silica fume for zeolite, namely, 25% and 50% by mass of silica fume. Z25 denotes the mix with zeolite substitution level of 25%.

2.3 Mixing Procedure

The mixing and curing procedures followed ASTM C192 [3] unless specified otherwise below. All mixtures were mixed under 25 °C. First, all dry materials except cement were mixed for five minutes, SAP or zeolite included. Cement was then added to the dry materials and mixed for another five minutes. Water was slowly added for a duration of two minutes while mixing. Finally, the mortar was mixed for another eight minutes.

2.4 Test Methods

2.4.1 Autogenous Shrinkage

To measure the early-age autogenous shrinkage of UHPC mixes, about 185 ml of freshly mixed UHPC mortar was cast in a specialized plastic corrugated tube which can extend or shrink in length depend on its content without creating much resistance. The tube was then sealed and gently put on a dilatometer bench at 23 ± 2 °C in accordance with ASTM C1698 [6]. The length of the tube was recorded by the dilatometer every five minutes for up to 7 days. The result of every mixture is the average of three identical tests.

2.4.2 Drying Shrinkage

The drying shrinkage of UHPC mixtures were evaluated conforming to ASTM C596-23 [5]. For each mixture, three specimens were cast. After being moist cured in molds for 24 hours, specimens were removed from the molds and cured in lime-saturated water for 48 hours. At the age of 72 hours, specimens were removed from water and wiped with a cloth before being placed in air storage until the age of

28 days. Drying shrinkage measurements were recorded by a length comparator at the age of 3, 7, 14, 21, and 28 days. The averaged values of three specimens were used for each mixture.

2.4.3 Compressive Strength

Testing for compressive strength has been employed to evaluate the compressive strength of concrete samples. The test was conducted according to ASTM C109 [2] using a specimen size of 50 × 50 × 50 mm. The results were based on the average of three specimens. Immediately after casting, the specimens were covered with a plastic film, until they were removed from the molds at the age of 24 hours. The specimens were then kept in a dedicated moist curing chamber which maintains a temperature at 20 °C and a relative humidity at 95% as per ASTM C511 [4]. The specimens stayed in the chamber until they were tested at the age of 3, 7, and 28 days, respectively.

2.4.4 Mercury Intrusion Porosimetry

To obtain test specimens with dimension of 10 × 10 × 10 mm, UHPC cubes were cut with a concrete saw. Then the specimens were submerged in 99.9% isopropanol for 48 hours and were transferred in a vacuum chamber for another 48 hours to dry. The specimens were sealed before they were shipped to a third-party agency for the MIP test, which was conducted with pressure in range of 0.33–227.48 MPa. The MicroActive AutoPore V 9600 program was employed to obtain the pore size distribution.

2.4.5 Low-Field Nuclear Magnetic Resonance (NMR)

A low-field ^{1}H NMR instrument (Lime Echo Co. Ltd., Beijing, China) was used for the NMR experiments. With a constant magnetic field of 0.49 T and a 12 mm coil operating at 2 MHz, the Carr-Purcell-Meiboom-Gill (CPMG) sequence was applied and ^{1}H NMR relaxation data were processed and converted by the Polimar 2021 (Lime Echo Co. Ltd., Beijing, China) application into T_2 relaxation time component. The effective relaxing component of T_2 lies in the range of 0.01 ms to 1000 ms. The longer component of T_2 (100–10,000 ms) corresponds to water with higher degree of freedom, that is, in large pores and surface water. Shorter T_2 components represent gel water (0.01–1 ms) and capillary water (1–100 ms). After repeated trial experiments, the parameters of NMR experiments were optimized to balance the signal/noise ratio and the running time. The corresponding signal-to-noise ratio for measuring the water in the cement paste can reach 200:1. In this study, NMR tests have been conducted to obtain T_2 signal from UHPC samples at the age of 28 days. The samples were moist-cured per ASTM C511 [4] before test.

3 Results and Discussion

3.1 Shrinkage Remediation

3.1.1 Autogenous Shrinkage

Figure 2 shows the autogenous shrinkage of UHPC mixtures incorporated with SAP and zeolite particles. The reference mixture showed a shrinkage of 1360 μm/m in the first 24 h of hydration. The quick development of autogenous shrinkage of UHPC is related to the use of silica fume and the very low water/binder ratio [16]. The shrinkage of UHPC made with 0.4% of SAP was 1340 μm/m while S0.2 and S0.6 reached 1600 μm/m and 1770 μm/m, respectively. This could be due to that the extra water in S0.2 and S0.4 stimulated an accelerated rate of hydration that could lead to self-desiccation. S0.2 only had a total water/binder ratio of 0.198 which was not sufficient for the increased water consumption. The relatively high total water/binder ratio of S0.6 induced an even faster rate of hydration that quickly consumed the extra water and caused greater self-desiccation and thus, shrinkage. In other words, the total water/binder ratio of S0.4 (0.227) found the balance of increased hydration rate and the amount of extra water that resulted in a reduced early-age autogenous shrinkage. The autogenous shrinkage of S0.2, S0.4 and S0.6 at 7 days maintained the trend at 24 hours, where S0.4 reduced 2.8%, S0.2 and S0.6 increased 15.2% and 20.0%, respectively, when compared to the reference mixture. On the other hand, the UHPC mixtures containing zeolite particles exhibited lower autogenous shrinkage throughout the test duration. But the zeolite replacement level did not have significant effect on shrinkage reduction. At 7 days, the mixtures with 25% and 50%

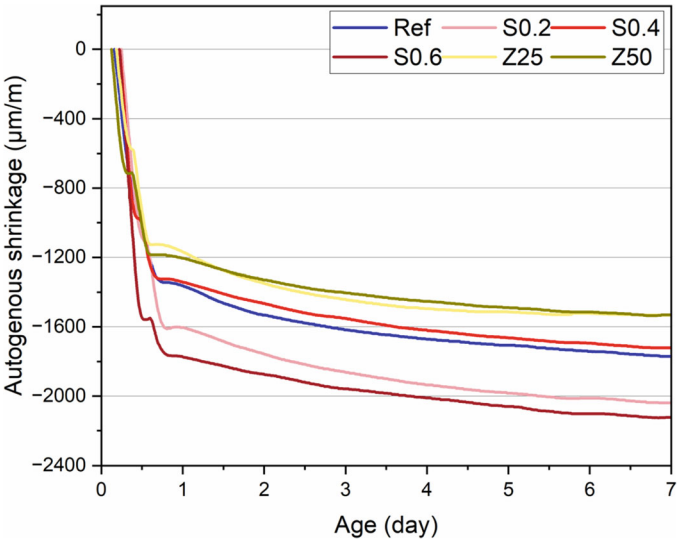

Fig. 2 Early-age autogenous shrinkage of UHPC mixtures

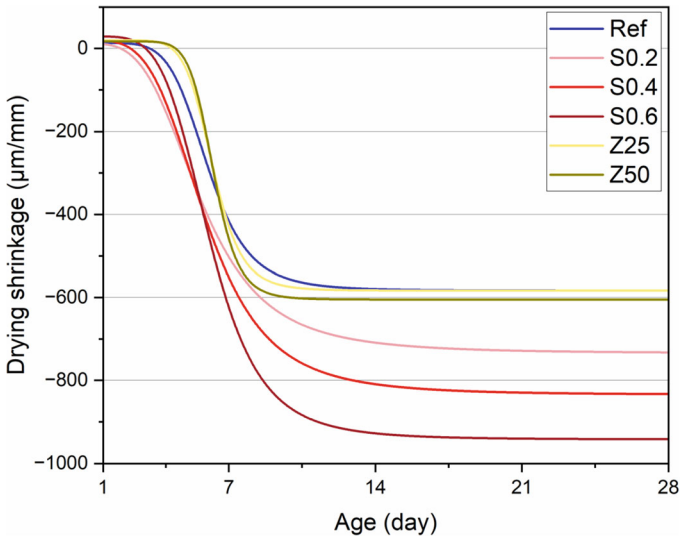

Fig. 3 Drying shrinkage of UHPC mixtures

zeolite replacement experienced 13.4% and 13.5% lower shrinkage than that of the reference, respectively. This could be due to that natural zeolite particles had a larger particle size and smaller surface area than those of silica fume, which make zeolite attract water slower and reduce the self-desiccation.

3.1.2 Drying Shrinkage

The results of drying shrinkage test of UHPC mixtures with SAP and zeolite particles at the different ages are shown in Fig. 3. The specimens were wet-cured under saturated lime water for the second and third days per ASTM C596 [5]. Drying shrinkage of all mixtures developed rapidly for the first seven days then increased slowly thereafter. Noticeably, the amount of shrinkage had a strong positive relation with the total water/binder ratio of the mixtures. The higher the total water/binder ratio, the greater the drying shrinkage, regardless of whether it contained SAP or zeolite particles. This attributes to the fact that more extra water introduces more capillary pores within the UHPC matrix and the rate of water evaporation mainly relates to the size of pore [19]. The increase in capillary pores of UHPC mixtures with high total water/binder ratio can be verified by the results of MIP test where there were more pores within the range of 200–4000 nm in specimens with high total water/binder ratio (Figs. 5 and 6). And this range lies in the range of capillary pores suggested by Aligizaki [1]. Therefore, for thin UHPC sections where drying dominates the total deformation, traditional external curing methods are still necessary to reduce drying shrinkage regardless of the use of internal curing agents, especially when the total water/binder ratio of the UHPC mixture is higher than 0.2.

3.2 Compressive Strength

The results presented in Fig. 4 show decreasing compressive strength of the UHPC with increased SAP dosage and higher zeolite replacement level. This pattern in compressive strength of the UHPC mixtures corresponds well with the pattern in total water/binder ratio as well as the pore size distribution indicated by MIP test shown in Figs. 5 and 6. The decrease in compressive strength of UHPC with SAP can be attributed to the porosity introduced by extra water and the void of SAP particles. Although SAP with small particle size ($D_{50} = 29.4$ μm) has been used, as suggested by Justs et al. [12], the SAP voids remained the largest defect in the UHPC matrix. On the other hand, UHPC mixture with zeolite replacing 25% of silica fume exhibited comparable compressive strength with the reference. This could be due to the fact that zeolite particles have similar pozzolanic reactivity to silica fume and can show internal curing effect without introducing excessive porosity. However, UHPC with increased level of zeolite replacement at 50% had noticeable decrease in compressive strength. Ramezanianpour et al. [25] explained that this can be due to silica fume having higher pozzolanic reactivity than natural zeolite and thus leads to richer C-S-H gel product and higher compressive strength. Despite having lower compressive strength than the reference mixture at 28 days, both SAP and zeolite mixtures exhibited earlier strength development. At seven days, S0.2, S0.4 and S0.6 reached 75.6%, 81.7%, and 83.1% of their 28-day strength, respectively. Z25 and Z50 reached 82.3% and 84.1%, where the reference mix was only at 65.9%. This could be due to the internal curing effect of SAP and zeolite particles that helped maintain a relatively high internal relative humidity (IRH) which provided sufficient free water to sustain the hydration process at early age.

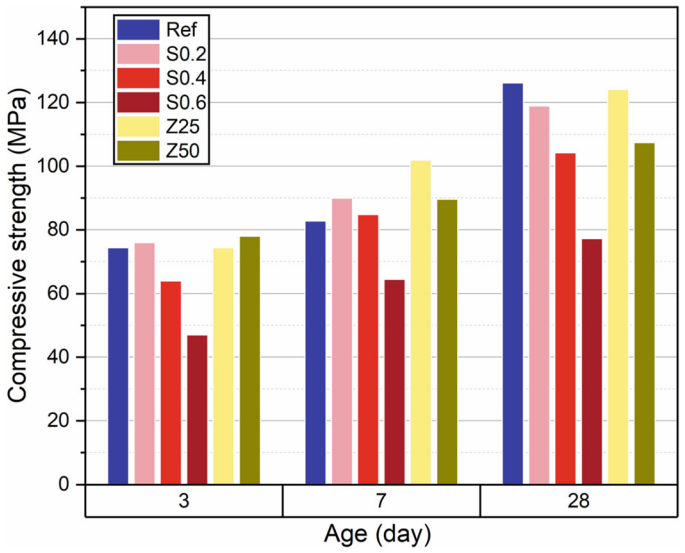

Fig. 4 Compressive strength of UHPC mixtures

3.3 *Pore Structure*

3.3.1 Mercury Intrusion Porosimetry (MIP)

Figure 5 shows the pore size distribution of UHPC incorporated with SAP at 28 days. As can be seen, the main peak lies within the ranges of 10–40 nm which corresponds to gel and capillary pores [1]. The critical pore size of the SAP mixtures was the same as that of the reference mixture. There were also substantial minor peaks existed in the range of 200–4000 nm which represents the large capillary pores. These were the pores induced by the extra water added for internal curing purpose. Noticeable change in pore structure were found between 200 and 4000 nm where UHPC mixtures with higher SAP content observed significantly greater pore volume, in other words porosity. Figure 6 shows the pore size distribution of UHPC with zeolite replacement. The zeolite mixtures had a generally similar pore structure to the reference mixture where only Z50 had a slightly higher pore volume at both the main peak (critical pore) and the minor peak (capillary pore). This is due to the extra amount of internal curing water added that is proportional to the level of zeolite replacement.

3.3.2 Nuclear Magnetic Resonance (NMR) at 28 Days

Figure 7 shows the transverse relaxation time (T_2) of the UHPC samples that has been moist cured for 28 days then saturated under pressured water. It can be seen that the pore size distribution of all groups presents a bimodal pattern. This pattern agrees

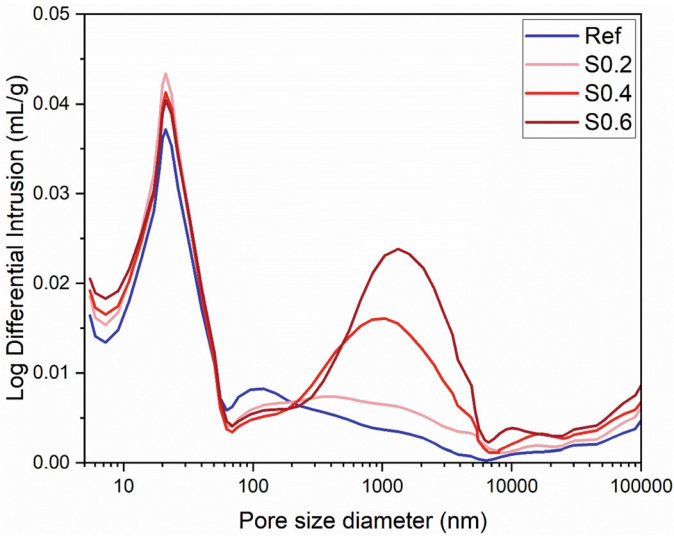

Fig. 5 Pore size distribution of UHPC mixtures with SAP

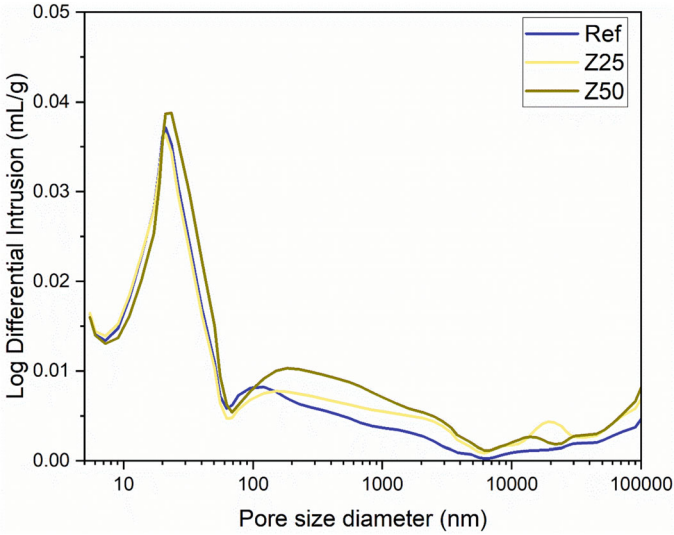

Fig. 6 Pore size distribution of UHPC with natural zeolite

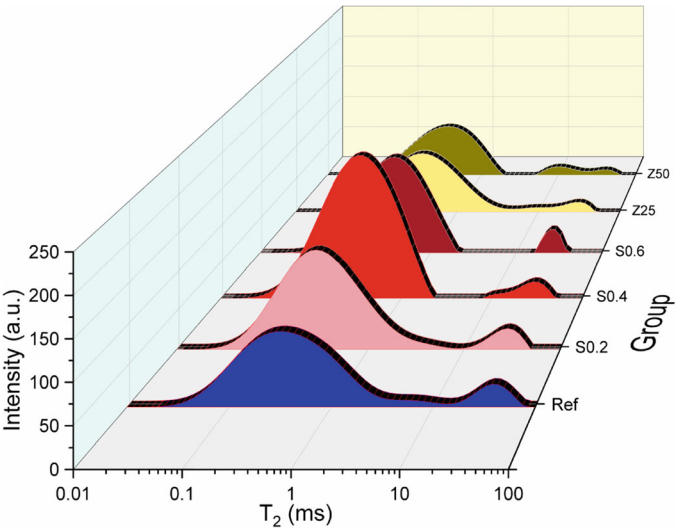

Fig. 7 Transverse relaxation time spectrum of UHPC samples at 28 days

with the findings of Muller et al. [22], where two T_2 distribution peaks were observed in the concrete samples that were first cured for 28 days then dried and saturated under water at a pressure of 300 bars. They reported that these two peaks corresponded to C-S-H gel pores and capillary pores, respectively. For the samples that had only been cured for 28 days and not saturated under pressure, four T_2

distribution peaks had been observed. In this study, with the increase of total water/binder ratio, the signal strength of the gel pore distribution signal (left peak) also increased in UHPC mixtures with SAP and zeolite replacement. For the capillary water distribution signal (right peak), as the dosage of SAP and extra water increased, the peaks appeared to be narrower and taller. This also held true for UHPC with zeolite replacement, which indicated that excessive extra water could lead to the generation of capillary pores in similar size and reduce the amount of smaller capillary pores. In general, the test results generated by ^{1}H NMR were consistent with the MIP test results in terms of modal pattern and the signal intensity of the gel pore relative to capillary peaks, as well as the relation of signal intensity to the different total water/binder ratio of each UHPC mixture. It can be advised that low-field ^{1}H NMR to be used to verify and complement the results of other pore size distribution evaluation methods.

4 Conclusions

This study evaluates the effect of SAP and zeolite incorporation on shrinkage behavior, mechanical performance and hydration characteristics of a non-proprietary UHPC. Compared to traditional UHPC, the reference UHPC in this study uses less cement and silica fume [7]. Additionally, the SAP/NZ modified UHPC can have higher early-age compressive strength and lower autogenous shrinkage which can reduce cracking and extend the expected lifespan, and thus, promote sustainability. Based on the test results and discussion, the following conclusions can be made:

- UHPC mixture added with SAP by 0.4% of cement mass and mixtures with zeolite replacement of 25% and 50% exhibited reduced early-age autogenous shrinkage by 2.8%, 13.4%, and 13.5% compared to the reference mixture at the age of seven days, respectively. However, UHPC mixtures with SAP at 0.2% and 0.6% dosages increased autogenous shrinkage by 15.2% and 20.0% at the age of seven days, respectively.
- UHPC mixtures with zeolite replacement of 25% and 50% exhibited slightly increased drying shrinkage by 0.16% and 2.4% compared to the reference mixture at the age of 28 days, respectively. On the other hand, all UHPC mixtures added with SAP showed increased drying shrinkage of over 23.4%.
- According to MIP and NMR analysis, increased SAP and zeolite content results in increased overall porosity of UHPC matrix, where SAP incorporation induces higher overall porosity than natural zeolite, especially in the range of capillary pores. But shift of the critical pore size has not been observed in any UHPC mixture in this study.
- Natural zeolite replacement slightly reduced compressive strength of UHPC where Z25 and Z50 reduced 28-day compressive strength by 1.6% and 15.1%, respectively. Notably, Z25 uses 25% less silica fume and effectively reduces

autogenous shrinkage while maintains compressive strength and drying shrinkage, which makes it a more sustainable mixture for further studies.
- By cross-verification of results of low field ^{1}H NMR test and MIP, hydration heat and TG tests, it is suggested that NMR test can facilitate analysis of hydration characteristics as well as micropore structure of UHPC matrix.

1 Introduction

Concrete is a composite material which has superior properties to overcome engineering challenges in the construction industry. It has a heterogeneous microstructure as it is composed of a combination of fine supplementary cementitious material, unreacted cement particles, hydrated products, filler materials, and fibers in various special length scales [1, 2]. In general, ultra-high-performance concrete is known for strengths beyond 120 MPa, higher ductility, high resistance to aggressive chemical environments leading to higher durability, and Young's modulus between 50 and 60 MPa [2]. The performance enhancement of ultra-high-performance concrete at very low water to binder ratios can be achieved by altering its microstructure with partial replacement of cement using low carbon supplementary cementitious materials such as, fly ash, silica fume, limestone, and slag with suitable quantities. For instance, the addition of pozzolanic materials assists the formation of pozzolanic calcium hydrate silicates in addition to the clinker hydration to support the strength while reducing the probability of alkali silica reactions, supporting durability

aspects. Further, by optimizing the particle size distribution of the cement paste, the packing density of the particles is improved and thus reduces the amount of void space in the cement restricting the permeability.

Ultra-high-performance concrete is recognized as reactive powder concrete since finer aggregates and particles provide more compacted strength to the structure. The benefits of finer particles in creating a more denser and compacted structure at micro-nano level with less voids ratio lead researchers to more concentrate on introducing inert nano materials such as graphene oxide [3, 4], graphite nanoplates [5], and carbon nanofibers [6] to improve long-term performance to reduced water sorptivity and permeability, reduced sulfate attacks, freeze thaw effects, etc. The low water to binder ratio makes concrete more prone to alkali-silica reaction causing delayed final setting time, reduced strength, and increased drying shrinkage and permeable voids. This can be controlled in ultra-high-performance concrete by partial replacement of cement with pozzolanic mineral admixtures such as fly ash (10–20%), blast-furnace slag, silica fume (15–30%) by reacting with calcium hydroxide to form calcium hydrate silicate and limiting the availability of alkalis to react with reactive silica [7]. The performance enhancement of ultra-high-performance concrete is greatly contributed by cement, and this leads to long term sustainability issues related to carbon emission. As a solution, carbon-neutralizing methods have drawn the attention of current studies to partially replace cement with phosphorous slag [8], a blend of nano-silica 2% and class F silica fume 10% [9], geopolymer as alkali-activated low carbon binder [10], fine aggregate replacement by mechanically activated pozzolanic gold tailings with a relatively wide particle size distribution (35% of micropowder) [11], and rice husk ash as a reactive filler to increase amorphous silica [12].

The qualitative investigation of microphases in concrete is possible nowadays with a variety of technologies up to atomic level. As discussed in the previous section, ultra-high-performance concrete designs can be altered with low carbon footprint materials and the design can be optimized by conducting a proper characterization at the smallest length scale to investigate the reason behind the macroscale strength improvement. Scanning electron microscopy (SEM) [13] and transmission electron microscopy (TEM) [14] can provide high-resolution images of the microstructure and capable of revealing the morphology of cement particles [15], the porosity of the cement matrix [16], and the interfacial transition zone [17] between the cement and aggregate. X-ray diffraction (XRD) can be used to precisely identify the crystalline phases present in the sample [18]. Acquiring accurate quantitative information from micro-nano scale is yet an emerging area of study for cementitious materials and essential to overcome engineering challenges in the future. The need for a proper framework to identify the cement microphases is mainly required to understand the underlying cause for any property change in the experiment, so the trial and error-based experiments can be carried out toward a profound direction.

This study exhibits the development of a framework to quantitatively identify the microphases of an ultra-high-performance cement paste consisting of 30% of ground granulated blast furnace slag, silica fume and fly ash altogether with 70% of ordinary Portland cement. The methodology is developed using the information from EDS-based chemical hypermaps, and microphase information is descriptively

elaborated in terms of volume fractions of microstructures and distribution of microphases. The image capturing for the chemical characterization was done in such a way that the inhomogeneity of the considered length scale is represented, and the accuracy of the microphase quantification is compared with an independent analytical hydration simulation software, Virtual Cement and Concrete Testing Laboratory (VCCTL).

2 Methodology

2.1 Overview

Chemical phase mapping of cement microstructure using EDS data combined with BSE imaging is a powerful tool when considering the quantification of hydrated and unreacted phases at microlevel. These microphase quantification outcomes were validated with theoretically simulated hydration outcomes from VCCTL and the briefed methodology involved is illustrated in Fig. 1.

2.2 Material Properties and Specimen Preparation

Specimens for the compressive strength test, elastic modulus, and chemical characterization experiments were prepared using the cement mix proportions listed in Table 1; 50 mm × 50 mm × 50 mm cubes were cast for the compressive strength test.

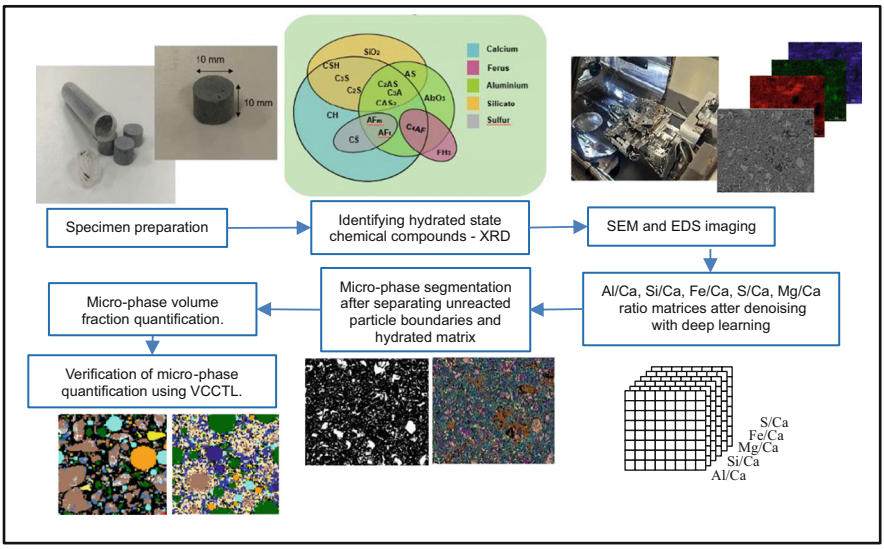

Fig. 1 Methodology of cement microstructure quantification and validation process

Table 1 Mix proportions of the cement paste

Component	Density (kg/m^3)	Weight (kg/m^3)
Ordinary Portland cement (OPC)	3100	1159
Ground granulated blast furnace slag	2860	361
Fly ash—Class F	2290	100
Silica fume	2180	116
Water	1000	385
Superplasticizer 1	1064	16
Superplasticizer 2	1000	3
Retarder	1080	3

The average compressive strengths on 7th and 28th days were 98 MPa and 141 MPa, and elastic modulus was 47 GPa on 28th day.

Specimen dimensions for the chemical characterization were 10 mm in diameter and 10 mm in height (Fig. 1). The hydration was stopped on the 28th day by submerging the specimen in isopropyl alcohol for 7 days to remove free water and afterwards the specimen was exposed to 100 °C temperature for 24 hours in the oven to evaporate the alcohol completely. Then, the observation surface of the specimen was polished and the final mirror like polish was achieved by using 1 μm diamond grit paper. Mirror like polishing of the observation surface was important to remove any surface irregularities that could interfere with chemical analysis. Then the polished surface was coated with carbon up to a thickness of 10 nm and provided a conductive surface to reduce the probability of getting hindered by the positive surface charge accumulation on the observation surface when using the scanning electron microscopy.

2.3 Chemical Composition Identification Using Semi-quantitative XRD

Chemical compound existence of crystalline structures can be accurately found using XRD analysis. Since amorphous compounds exist intermixed with crystalline compounds in hydrated cement, a semi-quantitative XRD analysis was conducted to identify the existence of crystalline compounds. This experimental qualitative identification of chemical compounds from XRD facilitates seeking existing microphases from EDS hypermaps, especially because EDS hypermaps do reveal any information about the potential phases in the mix. In this study, Bruker D8 Advance instrument was used for the XRD analysis, and diffractometer was operated at 40 A and 40 kV. The radiation was CuKα with an angular range of 85° 2θ. Total scan was done for 1 hour with no temperature control. Hydrated cement sample was powdered for this analysis and initial crushing of the sample was done using a mortar and pestle followed by XRD Mill McCrone milling for 5 minutes. Fig. 2 shows the identification of chemical compounds.

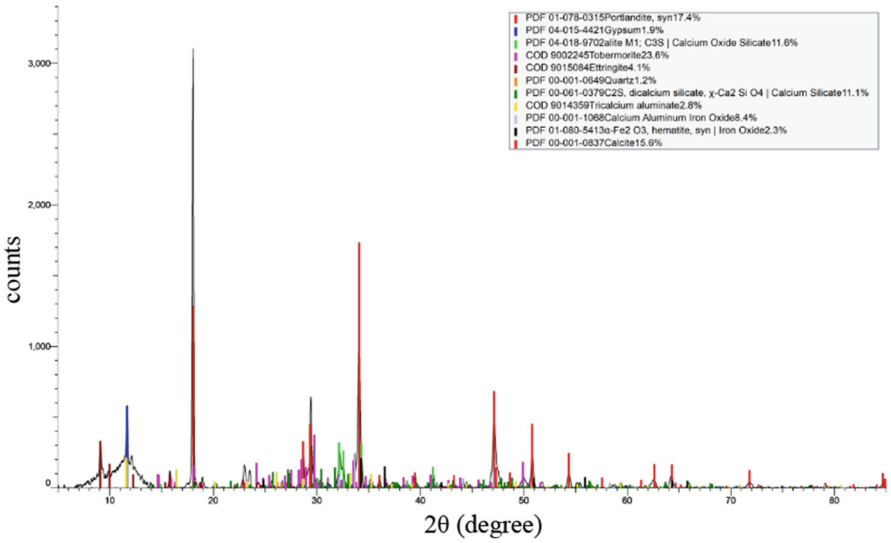

Fig. 2 Phase composition identification using XRD semi-quantitative analysis

2.4 Chemical Data Acquisition by Energy Dispersive Spectroscopy Combined with Scanning Electron Microscopy

Inhomogeneity at nano scale is governed by calcium silicate hydrate, and the Representative Volume Element (RVE) length at nano-level is 1 μm [19]. Considering the scale separation principle in multi-scale modeling, the RVE length at microscale can be taken as 100 μm and the smallest inhomogeneity would be 1 μm. Therefore, in this study the EDS image capturing was done with a resolution of 365 × 319, optimizing the observation of the smallest dimension to 0.74 μm while covering a frame sufficient to represent the inhomogeneity at microlevel.

To quantitatively identify microphase volume fractions along with their topographical distribution, EDS imaging was used. When it comes to EDS map generation, there are two types of maps. EDS maps generated using the characteristic x-ray intensity due to the abundancy of elements are called "intensity maps" and the EDS intensity maps corrected for atomic number, absorption, fluorescence effect are called "quantitative maps." Since the focused interest of this study prefers accurate quantitative chemical compositional outcomes for comparison purposes, quantitative map acquisition with no energy normalization was performed after calibration for both beam and energy measurements.

Generally, elemental concentration maps are noisy, and the noise could be reduced as much as possible using denoising methods such as non-local means (NLM), total variation, wavelet thresholding, etc. With the recent rise of artificial

Table 2 Chemical boundary tolerances to segment microphases

Microphase	Si/Ca	Al/Ca	S/Ca	Mg/Ca	Fe/Ca
Calcium hydrate silicate	$0.5 \pm \xi$	$0.25 \pm \xi$	–	–	–
Portlandite/$CaCO_3$	<=0.20	<=0.20	–	–	–
Ettringite	–	$0.35 \pm \xi$	$0.5 \pm \xi$	–	–
Unreacted cement	$0.3 \pm \xi$	<=0.7	–	–	$0.1 \pm \xi$
Slag	$0.8 \pm \xi$	$0.4 \pm \xi$	–	$0.3 \pm \xi$	–
Silica fume	>50.0	<=3	–	–	–
Fly ash	>1.0	>1.0	–	–	$1.0 \pm \xi$

intelligence applications, data preprocessing functions such as data augmentation, data normalization, feature extraction pretrained models are now available. The denoising Network function in MATLAB creates a deep convolutional neural network for image denoising, which is based on the DnCNN (denoising convolutional neural network) architecture. The network consists of several convolutional layers, followed by batch normalization and ReLU activation, and is trained using a mean squared error loss function to minimize the difference between the denoised and clean images.

To carry out a meaningful microphase segmentation, qualitative phase information from XRD was required to reveal the potential phases of the sample. Considering the possibility of a considered microphase in the mixture being composed of a number of elements depending on the function specific mix-design, it is always advisable to compress the chemical data into data numerical matrices (double type) rather than depending directly on the chemical concentration maps (uint8). Since calcium is the most abundant element in any cement mixture, double type matrices can be developed to represent atomic ratios with respect to Ca using respective EDS maps, for instance Si/Ca, Al/Ca, Fe/Ca, S/Ca, etc. Based on the stoichiometries of the compounds from XRD outcomes (Table 2), the stoichiometric boundaries for microphases can be defined to facilitate the phase segmentation considering the required number of ratio matrices to accurately identify the microphase. This selection can be graphically demonstrated in a 2D ratio plot as shown in Fig. 2, in such a way that a selected point in the 2D ratio plot represents a pixel from the segmented phase map, indicating a particular Si:Al:Ca ratio depending on the microphase stoichiometry.

3 Results and Discussion

This section describes the results of the experimental phase identification analysis carried out in terms of segmented phases, volume fractions, and chemical composition distribution of phases. Further, the hydration outcomes from VCCTL software are used to compare the reliability of the experimentally gathered phase information.

3.1 Phase Segmentation

The expected outcome from the phase segmentation is to visualize the microphase distribution over a two-dimensional plane using EDS images taken from random locations which represent the inhomogeneity of the cement microstructure. The primary task to achieve this outcome from a collected image is to identify the locations of the pixels (pixel IDs) belonging to a particular phase which satisfies the chemical boundary requirements listed in Table 2. A representation of chemical composition distribution of each individual pixel can be illustrated in a ratio plot as shown in Fig. 3.

Once required phases were identified using the stack of chemical ratio matrices, a separate empty RGB map with similar resolution to the BSE image was generated, to store separate RGB colors for each individual phase. Figure 4 shows the segmentation of phase mappings from the 28th day hydration representative areas captured.

It is evidently clear that the slag particle capturing in S28_0 image is comparatively lesser than other specimens. Further, the Portlandite intermixed $CaCO_3$ region seems to be gathered around porous areas and the reason for this might be the reduction of water in these pore areas. Slag particles tend to react slowly over the time and since these specimens are at their 28th day hydration, majority of the slag particles remain as it is. Darker areas represent the porosity intermixed with cracks and these cracks might be due to the polishing effect and dehydration effort to stop the hydration on 28th day using the oven.

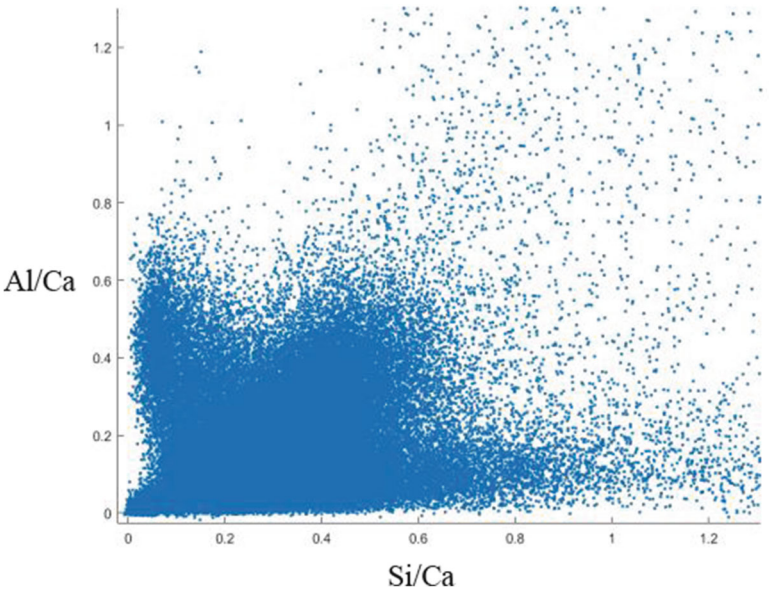

Fig. 3 Si/Ca vs. Al/Ca element distribution in identified phases

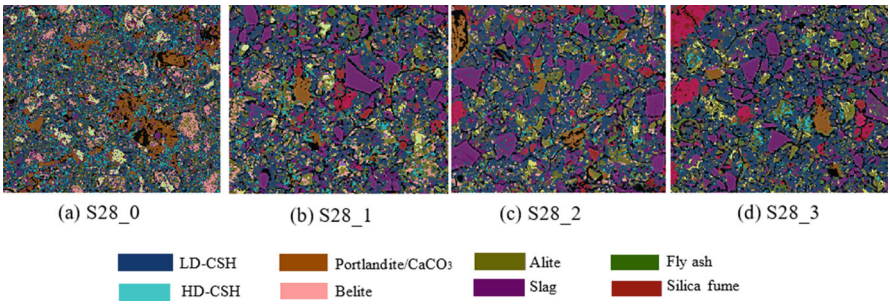

Fig. 4 Segmented phase mapping from random locations representing 28th day hydration

3.2 Hydration Simulations Through Virtual Cement and Concrete Testing Laboratory

VCCTL is a cement hydration simulation software which can model the hydration of raw cement constituents with real particle shapes in a 3D space. Further, this software facilitates the hydration simulations with supplementary cementitious materials which paves the way to modeling zero carbon cement mixes revealing theoretical mechanical and transportation properties, upon feeding particle size distributions and chemical composition of raw materials along with dispersion effects due to superplasticizers. Different cement types and other raw cementitious materials in the VCCTL database have been fed by statistical outcomes from a significant amount of SEM/EDS images of 800 magnification over a region of 200 μm × 200 μm [20]. VCCTL has demonstrated precise simulation capabilities for different cement hydrations such as ultra-high-performance concretes [21, 22], blended cements [23], and other normal strength concretes [24].

Simulating the hydration of 0.22 w/b ratio cement paste was done in VCCTL by defining the physical and chemical properties of constituents in the mixture. The cement mixture microstructure and hydrated microstructure are presented in Fig. 5.

It is reported that when preparing databases for different cementitious materials with a significant number of SEM/EDS images for each material, a standard deviation of 3% to 7.5% has been observed [20].

3.3 Microphase Volume Fractions

The microphases from the chemical image analysis precisely reveal the hydration information at microlevel. The unreacted clinker amount is comparatively higher in S28_0 location and the Portlandite/$CaCO_3$ mixed phase is also comparatively higher. This might be due to the lack of free water for hydration in this area. Further, slag fraction remains low in S28_0 location and this represents the non-homogenous mixing of particles in the cement matrix.

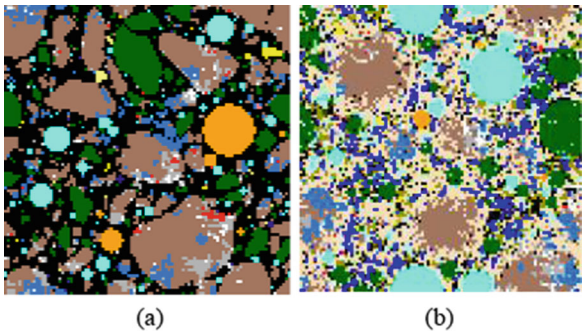

Fig. 5 Cement mixture microstructure (**a**) and hydrated microstructure (**b**) from VCCTL simulation

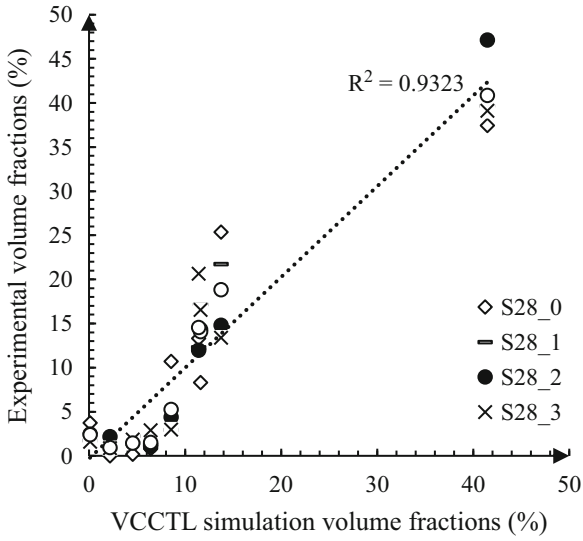

Fig. 6 The correlation between experimental vs. VCCTL microphase quantification

The back scattered electron imaging with higher resolution (1024 × 884) was used to identify the porosity together with cracks, and using an algorithm, the cracks were separated from porosity. The s.d. values from the experiment are within 6% and the linear regression analysis in Fig. 6 shows the mean values from the experimental microphase analysis lies closely near the zero-error line. This result could be more robustly verified with a significant number of sample analysis. Further, larger unreacted particles hold higher s.d. values comparatively to that of smaller particles. This represents the phase heterogeneity sensitiveness within the considered length scale. Reacted phases with high volume fractions also do have a high s.d. compared to less abundant reacted phases (Table 3).

This study shows that VCCTL program can also be used to conduct parametric studies once a control specimen is validated. VCCTL is capable of predicting mechanical and transportation properties from the obtained microphase information. Although most of the studies do confirm that the simulation is correct for generating

Table 3 Volume fractions (%) of hydrated and unreacted cement products

Microphase	S28_0	S28_1	S28_2	S28_3	Mean	Standard deviation (s.d.)	VCCTL simulation
Unreacted cement	25.362	21.757	14.838	13.398	18.839	5.677	13.734
Slag	8.311	17.185	14.359	16.563	14.105	4.048	11.608

phase quantifications but when it comes to predicting mechanical properties, the software underestimates the material properties to a certain extent [24]. If nanoindentation results could be combined with the microphase volume fractions, that would be an alternate method to homogenize the mechanical properties at microscale.

4 Conclusions

The microphase identification of hydrated cement pastes is an essential area of study to overcome many civil engineering challenges. This chapter investigated the feasibility of using EDS chemical hypermaps to develop a MATLAB-based image processing model to identify the existence of microphases in an ultra-high-performance concrete blended with low carbon supplementary cementitious materials in terms of their volume fractions and phase distribution on the 28th day of hydration. A novel algorithm is proposed to develop RGB microphase segmented maps using any desired number of elemental ratio matrices with respect to the most abundant element, Ca. These elemental ratio matrices were developed after denoising with a pretrained deep learning algorithm built in MATLAB. The following are the conclusions from the study.

- The MATLAB inbuilt deep learning denoising algorithm was effective in reducing the noise of chemical maps. Therefore, pixel by pixel Si/Ca, Al/Ca, Mg/Ca, S/Ca, Fe/Ca ratio extraction to segment microphases was accurately done.
- The chemical ratios were stored in numerical matrices (double type) similar to the size of BSE image. Therefore, it facilitated the extraction of any number of required chemical ratios for a given microphase at a considered pixel location with no restriction.

- The phase segmentation volume fractions were in good agreement with the theoretical hydration simulation program—VCCTL outcomes ($R^2 = 0.93$).
- There is commercially available software for phase segmentations with expensive licensing but do require expertise to post process after data acquisition for correct phase segmentation. But this simplified method can be customized/modified for a novel cement paste to get its microphases identified with no post processing time after the feeding quant EDS elemental maps and BSE image.
- It is recommended to improve the robustness of the statistical analysis for the volume fractions by analyzing a larger number of locations from the same specimen. However, the analysis time and cost could impose constraints to this experiment, and they could be detoured if powerful silicon drift detectors can be used EDS instruments to improve the sensitivity, speed, and resolution of the scanning.
- The interfering of heterogeneity within the considered length scale with the volume fractions could be recognized as one of the limitations in this method. The volume fraction of larger unreacted phases was observed to extend the standard deviation up to 6%.

non-recyclable tires being abandoned annually [1]. Improper dumping of these tires in landfills has been shown to cause severe environmental pollution and economic damage, as well as fire-related accidents and the release of pollutant gases. Moreover, the dumped tires create breeding grounds for disease-carrying insects and animals, leading to the spread of infectious diseases [2]. In response to these challenges, considerable efforts have been made to advance waste disposal methods and implement effective waste management strategies [3]. Dumping tires in landfills is now undesirable due to the depletion of available space, leading many countries to enforce strict regulations against such practices. Various strategies have been developed to mitigate tire dumping, including reusing waste tire crumbs in asphaltic concrete, incorporating them into concrete mixtures, incinerating them for steam generation, and utilizing them in plastic and rubberized products. Used tires are repurposed as a fuel source in cement production and for constructing synthetic reefs in ocean habitats [4, 5]. Recycling waste tires in the concrete industry not only helps preserve landfill space but also offers additional benefits such as reducing the demand for natural resources, transportation and production energy costs, carbon dioxide emissions, and increasing the lifespan of concrete structures [6]. Several studies [7–9] have shown that integrating recycled tire materials into concrete mixtures creates more eco-friendly concrete, which has a reduced carbon footprint, is more cost-effective, and consumes less energy than conventional concrete formulations.

The alkali-activation technique (using one or two-part alkaline activator solution) has been devised to create high-performance geopolymer concretes, resulting in lower greenhouse gas emissions than cement-based traditional concrete production [10–14]. Several studies have indicated that calcium in fly ash significantly affects the geopolymer materials' final hardened properties and compressive strength [15, 16]. Calcium oxide reacts with sodium-aluminum-silicate (N-A-S-H) gels to form calcium-silicate-hydrate (C-S-H) gels [17]. These two gels coexist and greatly influence the hybrid compounds of cement and alkali-activated aluminum-silica [18, 19]. Earlier studies have employed synthetic gels to examine the effects of elevated pH levels on distinct gel constituents. Notably, the generation of C-S-H gel was significantly affected by the presence of aluminate in the solution [20]. Furthermore, aqueous calcium has been observed to alter N-A-S-H gels, exchanging sodium ions with calcium ones, thereby leading to the genesis of (N,C)-A-S-H gels [20, 21]. However, the precise mechanisms underlying the synthesis of these gels and further advancements remain fully understood.

The ceramic industry generates significant amounts of waste annually, resulting in a large portion in landfills. However, reusing these wastes in concrete presents a win-win situation. It addresses the ceramic industry's waste problem while promoting more sustainable concrete [22]. Global ceramic tile production exceeds 10 million square meters per year [23]. According to a survey, approximately 15–30% of this production is wasted in the ceramic industry. Currently, this waste is not being reused, but it is accumulating over time. The percentage of waste increases due to ceramic damage during storage, transportation, construction, and house renovations. Additionally, the cost of deposition processes is rising due to restrictions on landfill

usage. Consequently, industries need to explore alternative solutions, such as recycling these waste materials into valuable products.

This experiment aims to develop several types of high-performance geopolymer concrete incorporating tile ceramic waste powder (TCWPs) and discarded rubber tire crumbs (DRTCs). The effect of both material's inclusion of geopolymer matrix on workability and strength performance is evaluated. To achieve this aim, various assessments were conducted, including slump tests for fresh concrete and evaluations of compressive, splitting tensile, and flexural strengths. The influence of curing duration on strength development was also examined, with specimen testing occurring at intervals of 3, 7, and 28 days.

2 Methodology

2.1 Materials

To create geopolymer concrete samples, a total of nine materials were utilized, including GBFS, TCWPs, river sand, crushed stone, and fine and coarse DRTC materials, alongside sodium hydroxide, sodium silicate, and water. GBFS and TCWPs were combined to form a dual-component binder, adjusting the proportions of calcium oxide relative to silica and aluminum oxides. Meanwhile, river sand and crushed stone served as the primary fillers (acting as fine and coarse aggregates) and were subsequently substituted with fine and coarse DRTCs. An alkaline activator solution, essential for initiating the geopolymer reaction, was concocted from sodium hydroxide, sodium silicate, and water. To determine the chemical makeup of GBFS and TCWPs, X-ray fluorescence (XRF) analysis was employed, see Table 1. Regarding physical characteristics, TCWPs were characterized by a specific gravity of 2.61, a surface area of 12.2 m^2/g, and a median particle size of 35 μm, while GBFS had a specific gravity of 2.9, a surface area of 13.6 m^2/g, and a median particle size of 12.8 μm.

Natural aggregates with specific properties were selected for this experiment to create geopolymer specimens. The fine aggregates comprised washed river sand, which exhibited a water absorption rate of 2.2%, a specific gravity of 2.65, and a maximal particle diameter of 4.75 mm. Conversely, the coarse aggregates utilized crushed stone, characterized by a water absorption rate of 1.2%, a specific gravity of 2.67, and a maximal particle size of 10 mm. Regarding the DRTC materials, the rubber aggregates were categorized according to the ASTM C136 standard. The details regarding the water absorption rates, specific gravities, and the maximum sizes for both fine and coarse DRTC particles are outlined in Table 2.

Table 1 GBFS and TCWPs chemical composition using XRF spectrometry data (mass%)

Materials	CaO	SiO2	Al2O3	MgO	Na2O	Others	LOI
GBFS	51.8	30.8	10.9	4.6	0.5	1.2	0.2
TCWPs	0.02	72.6	12.2	1.0	13.5	0.6	0.1

Table 2 Water absorption, specific gravity, and maximum size of utilized aggregates

Type of aggregates	Water absorption, %	Specific gravity	Maximum size, mm
Natural river sand	2.2	2.65	4.75
Natural crushed stone	1.2	2.67	10
Fine DRTCs (1–4 mm)	–	1.34	4
Coarse DRTCs (5–8 mm)	–	1.37	8

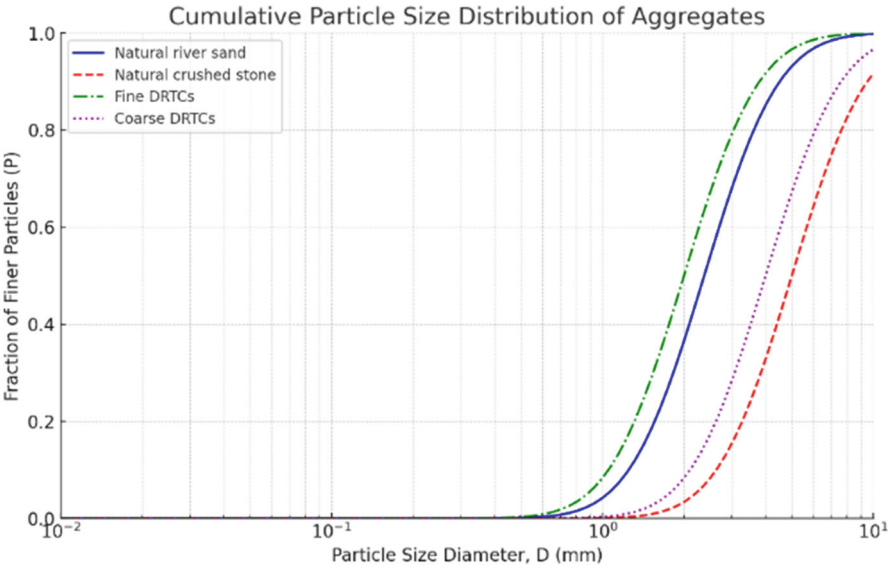

Fig. 1 Cumulative particle size distribution curves of aggregates used in this study

Figure 1 displays the cumulative particle size distribution curves corresponding to the aggregates detailed in Table 2.

2.2 Mix Design of Geopolymer Concrete

Eight distinct concrete mixes were devised to examine the impact of incorporating TCWPs and DRTCs into the geopolymer concrete matrix as substitutes for GBFS and natural aggregates (see Table 3). Initially, five mixes were created to assess the effect of replacing GBFS with TCWPs on the workability and strength characteristics of the envisioned geopolymer concrete. A control sample was established with a geopolymer binder blend consisting of 70% GBFS and 30% TCWPs. Subsequently, geopolymer mixes were prepared with TCWPs replacing GBFS at increments of 40, 50, 60, and 70%. The quantities of river sand and crushed stone were maintained constant across all mixes. Based on the results from this initial phase, the mix

Table 3 Mixes design of geopolymer concrete with various levels of TCWPs and DRTCs

	Binder, kg/m^3		Natural aggregates, kg/m^3		DRTCs, kg/m^3	
Mix code	GBFS	TCWPs	River sand	Crushed stone	Fine	Coarse
GPC_1	293.7	125.7	721	995	0	0
GPC_2	251.4	167.6	721	995	0	0
GPC_3	209.5	209.5	721	995	0	0
GPC_4	167.6	251.4	721	995	0	0
GPC_5	125.7	293.7	721	995	0	0
GPC_6	209.5	209.5	684.9	945.3	18.2	25.4
GPC_7	209.5	209.5	648.9	895.5	36.5	50.9
GPC_8	209.5	209.5	612.8	845.8	54.7	76.3

demonstrating a compressive strength exceeding 35 MPa at three days was chosen for further experimentation. In other words, the selection criteria for further experimentation were established based on early strength development. Specifically, among the initial mixes, the one that achieved a compressive strength exceeding 35 MPa at the early age of three days was chosen for subsequent detailed study. In the second phase, DRTCs were used to substitute 10, 20, and 30% of the volume of natural aggregates. During the formulation of these geopolymer concrete mixes, the molarity of sodium hydroxide, sodium hydroxide to sodium silicate ratio, and the proportions of alkaline activator solutions were kept constant at 4 M, 0.75, and 0.45, respectively.

2.3 Test Procedure

Following ASTM C579 guidelines, cube molds for the geopolymer concrete, each side measuring 100 mm, were prepared to evaluate compressive strength. Cylindrical molds, 100 mm in diameter and 200 mm in height were utilized for the splitting tensile strength test. Concrete beams of dimensions 100 mm by 100 mm by 500 mm were used to assess flexural strength. Engine oil was applied to the molds prior to casting to ensure the molds could be easily stripped. A dual-component alkaline activator solution, measured by weight, was concocted by mixing sodium hydroxide (4.0 M) and sodium silicate thoroughly at least 24 hours before casting to allow it to cool down to room temperature, reducing the exothermic heat produced during mixing.

The mixing process commenced with blending the fine and coarse aggregates, including river sand, crushed stone, and rubber, in their dry states for 3 minutes to achieve a homogeneous mixture. This was followed by adding the GBFS and TCWPs binary mixture, which was mixed for an additional 5 minutes in a concrete mixer. The alkaline activator solution was then added to kick-start the geopolymerization process, with the mixing continuing for another 5 minutes. The

freshly mixed geopolymer concrete was then transferred into the pre-lubricated molds in two layers, compacting each layer with a vibrating table for 30 seconds to remove air pockets.

Post-casting, the geopolymer concrete specimens were left to cure at room temperature (around 27 ± 1.5 °C) and 75% relative humidity for 24 hours. After this initial cure, the specimens were de-molded and kept in the same ambient conditions until their testing dates at 3, 7, and 28 days. Tests for the slump, compressive strength, splitting tensile strength, and flexural strength were performed by ASTM C143, ASTM C109, ASTM C496, and ASTM C78 standards, respectively, with the average values from three specimens being used to determine the geopolymer concrete' s fresh and hardened characteristics.

3 Results and Discussion

3.1 Fresh Properties and Compressive Strength Development

Figure 2a demonstrates the notable effect of replacing GBFS with TCWPs on the workability of the formulated concrete. The results show a progressive increase in slump value with a higher percentage of TCWPs substituting for GBFS in the geopolymer mixture. As the TCWP content escalated from 30% to 40, 50, 60, and 70%, the slump values correspondingly ascended from 85 mm to 92, 110, 122, and 136 mm. The increase in the content of TCWPs and the reduction of GBFS in concrete workability have been attributed to their effects on chemical reaction rate, plasticity, and mixture's workability, as reported in previous studies [24, 25]; this affects the chemical reaction rate and increases the plasticity of the mixture, which improves the concretes' workability.

Figure 2b showcases the influence of substituting natural fine and coarse aggregates with DRTCs on the workability of the engineered concrete. Replacing natural aggregates with 10, 20, and 30% DRTCs led to a reduction in slump values, descending from 110 mm to 102, 90, and 78 mm, respectively. This drop in slump

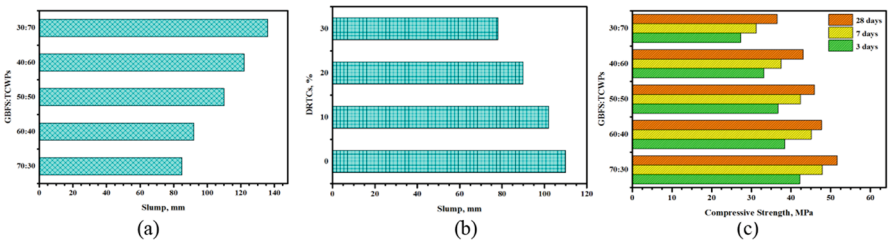

Fig. 2 Workability performance of geopolymer concrete containing TCWPs as GBFS replacement (**a**), Effect of DRTCs content on the workability of proposed geopolymer concrete (**b**), and Effect TCWPs as GBFS replacement on compressive strength development of proposed geopolymer concrete at 3, 7, and 28 days (**c**)

values is linked to the greater water absorption capacity and smaller particle sizes of DRTCs compared to river sand, which negatively impacts the workability of the proposed concrete mixture, thereby diminishing the slump values. A previous study [26] found that the varied morphologies of DRTCs aggregates increased friction among the components of concrete mixes, leading to lower workability when high replacement levels were used. Likewise, concrete mixtures with increased proportions of rubber crumbs exhibited reduced workability, attributable to their more significant specific surface areas and enhanced roughness. Another study [27] observed reduced workability performance with increased DRTCs content as a substitute for river sand.

Before adding DRTCs as aggregate substitutes, the impact of replacing GBFS with TCWPs on geopolymer concrete strength was studied, see Fig. 2c. Results showed that as TCWPs content increased, compressive strength decreased, yet it generally rose with longer curing times. Initially, strength dropped significantly with higher TCWPs levels but all mixtures eventually exceeded 35 MPa in compressive strength after 28 days. The decline in strength is linked to a lower calcium oxide content from TCWPs, altering the chemical balance and slowing down the formation of strength-contributing calcium silicate hydrate (C-S-H) gels [28].

Figure 3 illustrates the effect of substituting natural fine and coarse aggregates with DRTCs on the compressive strength of the designed concrete over curing periods of 3, 7, and 28 days. A consistent pattern of rising compressive strength was noted across all geopolymer concrete samples as the curing time extended from

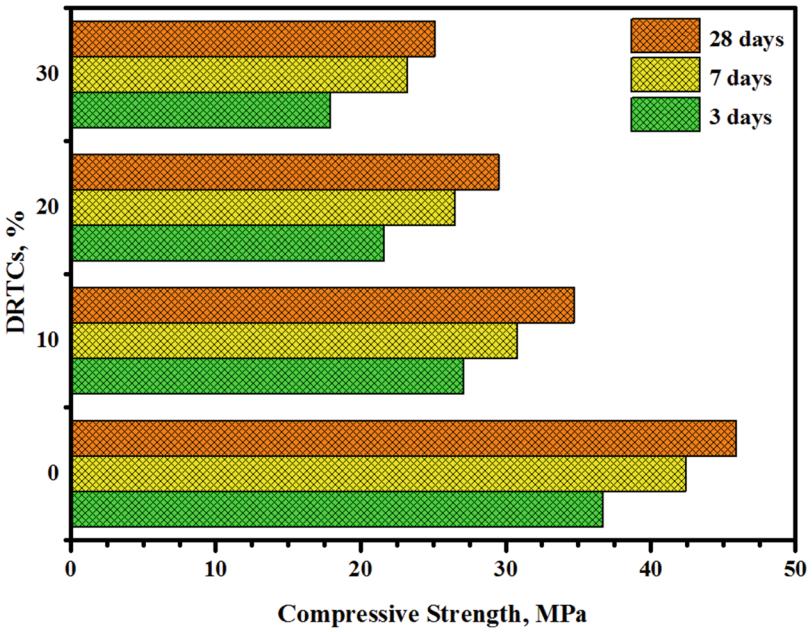

Fig. 3 Influenced compressive strength by DRTCs as fine and coarse aggregate replacement

3 to 28 days. Nonetheless, integrating DRTCs negatively impacted the compressive strength, showing a decrease in values as the DRTC content was augmented from 0% to 10, 20, and 30%.

Specifically, at a curing age of 3 days, replacing natural aggregates with 10, 20, and 30% DRTCs decreased compressive strength from 36.7 MPa to 27.1, 21.6, and 17.9 MPa, respectively. This trend continued at seven days of age, with strength values reducing from 42.4 MPa to 30.8, 26.5, and 23.2 MPa as the DRTCs content increased to 10, 20, and 30%, respectively. By 28 days of curing, the specimens exhibited a lower percentage of strength loss compared to those at 3 and 7 days, with strength values declining from 45.9 MPa to 34.7, 29.5, and 25.1 MPa upon substituting natural aggregates with 10, 20, and 30% DRTCs, respectively.

The decrease in compressive strength can be linked to the smoother texture of rubber aggregates compared to the rougher surface of natural aggregates. This smoothness diminishes the bonding efficacy at the junctions between the cement pastes and rubber particles, decreasing concrete strength as the quantity of rubber in the mix escalates. Other studies [7, 29] have supported these findings, indicating that WRTCs have a negative impact on concrete strength. Similar trends have been reported in several studies [30, 31], demonstrating the negative effect of DRTCs content on strength development.

3.2 *Splitting Tensile Strength*

Figure 4a highlights the effect of substituting different proportions of TCWPs for GBFS on the splitting tensile strength of geopolymer concrete after a curing period of 28 days. The results demonstrate that the inclusion of TCWPs results in a

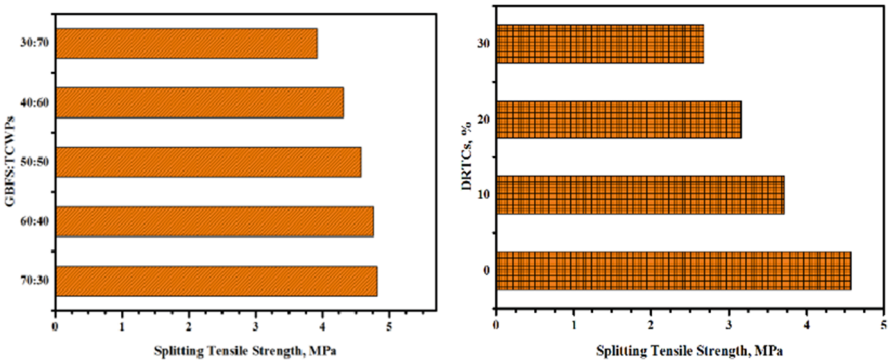

Fig. 4 Effect of TCWPs on geopolymer splitting tensile strength after 28 days of curing age (**a**), and Effect of DRTCs on splitting tensile strength of proposed geopolymer concrete after 28 days of curing age (**b**)

diminished splitting tensile strength, with a more significant decline noted with higher replacement levels.

Specifically, substituting GBFS with 40, 50, 60, and 70% of TCWPs decreased tensile strength from an initial value of 4.82 MPa to 4.76, 4.58, 4.31, and 3.92 MPa, respectively. This trend can be attributed to the fact that the strength of geopolymer binders is enhanced by the presence of calcium-based materials, such as calcium oxide, which contributes to the formation of additional C-S-H (Calcium Silicate Hydrate) and C-A-S-H (Calcium Alumino Silicate Hydrate) gels alongside the N-A-S-H (Sodium Alumino Silicate Hydrate) gel. The reduction in tensile strength values with an increase in the level of TCWPs as a replacement for GBFS in the proposed geopolymer matrix is thus explained by the diminished presence of these calcium-enriched materials, which are crucial for strength development [32].

Figure 4b showcases the effects of varying levels of DRTCs as a replacement for natural fine and coarse aggregates on the splitting tensile strength of geopolymer concrete. The results significantly impact tensile strength as the proportion of DRTCs increases. Specifically, substituting natural aggregates with 10, 20, and 30% of DRTCs led to a notable decrease in tensile strength values, dropping from an initial value of 4.58 MPa to 3.71, 3.16, and 2.68 MPa, respectively.

The observed trend underscores a reduction in splitting tensile strength as the incorporation of DRTCs increases. This reduction in tensile strength is linked to inadequate adhesion at the interfaces between the rubber granules and the cement pastes, leading to early failure of the specimens even after a brief curing duration. This phenomenon highlights the difficulties in using DRTCs as replacements for aggregates, particularly concerning preserving the structural integrity and performance of geopolymer concrete [33]. The type and quantity of rubber particles also contribute to the failure, as significant distortion creates a lack of rigidity in the rubberized granules [26, 34].

3.3 Flexural Strength

The impact of TCWPs content as a replacement for GBFS on the flexural strength of geopolymer concrete was evaluated, with the findings presented in Fig. 5a. These findings align with the trends noted in both compressive and splitting tensile strengths at a 28-day curing period, wherein an elevation in the content of TCWPs within the geopolymer matrix corresponds to a modest decline in flexural strength.

The integration of 40, 50, 60, and 70% TCWPs led to a sequential reduction in flexural strength, dropping from an initial value of 1.73 MPa to 1.61, 1.54, 1.42, and 1.29 MPa, respectively. This pattern suggests that the efficiency of the geopolymerization process, heavily dependent on the calcium oxide content, decreases with the rising proportion of TCWPs, culminating in lower strength gains, especially at the early stages of curing. Additionally, the decline in flexural strength is partly due to an increase in the amount of unreacted or partially reacted silicates and a diminished presence of the Calcium Silicate Hydrate (C-S-H) phase, which plays a pivotal role in the strength development of geopolymer concrete [35].

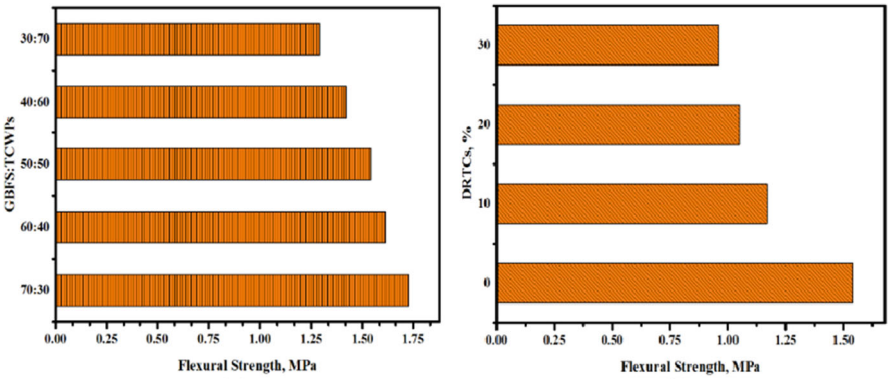

Fig. 5 Flexural strength of geopolymer concrete containing various levels of TCWPs as GBFS replacement (**a**), and flexure strength of geopolymer concrete prepared with various levels of DRTCs as a fine and coarse aggregate replacement (**b**)

Figure 5b illustrates the flexural strength outcomes for geopolymer concrete samples that incorporate DRTCs as replacements for natural fine and coarse aggregates. An inverse correlation was noted between the flexural strength of the geopolymer concrete and the amount of DRTCs used. Specifically, as the replacement level of natural aggregates with DRTCs increased to 10, 20, and 30%, there was a corresponding decrease in flexural strength values, from an initial 1.54 MPa down to 1.17, 1.05, and 0.96 MPa, respectively.

The observed reduction in flexural strength is mainly due to the poor bonding between the rubber particles and the matrix of TCWPs-GBFS pastes in the concrete. Including rubber results in creating voids within the matrix, consequently lowering the concrete's overall density. This effect significantly contributes to the decrease in flexural strength, underscoring the challenges of optimizing performance in geopolymer concrete when replacing traditional aggregates with DRTCs [36]. Additionally, the smooth surface of rubber granules hinders bonding with the geopolymer paste [37, 38].

4 Conclusions

This study explored the development of geopolymer concrete with suitable mechanical properties for various construction applications, utilizing tile ceramic waste powder and discarded rubber tire crumbs as replacements for slag and natural aggregates. The findings of this research are summarized as follows:

(i) *Workability*: The addition of tile ceramic waste powder positively affected the workability of the proposed geopolymer concrete. As the level of slag replacement by tile ceramic waste powder increased, so did the workability, reaching

up to 136 mm compared to 85 mm in the control mix. Conversely, incorporating discarded rubber tire crumbs into the geopolymer matrix decreased workability, with a 30% inclusion of rubber aggregates resulting in a loss of strength greater than 25%. This reduction in workability is attributed to the rubber crumbs' excessive fineness and absorption capacity.

(ii) *Compressive Strength*: The inclusion of tile ceramic waste powder and discarded rubber tire crumbs negatively impacted the development of compressive strength in geopolymer concrete at both early and late ages. The trend showed that increasing the content of these materials in the geopolymer matrix led to a decrease in strength.

(iii) *Compressive Strength of Tile Ceramic Powder Mixes*: Specimens prepared with tile ceramic powder as a replacement for slag exhibited acceptable compressive strength after 28 days of curing, with values exceeding 35 MPa. However, increasing the replacement content from 30% to 70% decreased strength from 51.6 MPa to 45.9 MPa, respectively.

(iv) *Impact of Rubber Aggregates*: Replacing natural fine and coarse aggregates with 10, 20, and 30% rubber aggregates resulted in a more than 40% strength loss compared to control specimens. This significant decrease in strength is primarily due to the formation of widened, weaker, and highly porous bond zones, which led to poor adhesion between the rubber particles and the binary binder pastes.

(v) *Tensile and Flexural Strengths*: Similar to the compressive strength results, the inclusion of tile ceramic waste powder and discarded rubber tire crumbs in the geopolymer matrix decreased the splitting tensile and flexural strengths of the tested specimens.

1 Introduction

The quest for sustainability within the construction industry has increasingly spotlighted the significance of reducing the carbon footprint associated with concrete mix designs. Concrete, one of the most widely used construction materials globally, plays a pivotal role in the sector's environmental impact, mainly due to its intensive carbon dioxide emissions from cement production and aggregate use. Innovations in concrete mix design, including incorporating various fibers and alternative materials, offer a promising avenue to enhance structural performance while significantly mitigating environmental footprints. By reducing the carbon footprint through thoughtful mix designs, the construction industry can make substantial strides toward sustainability goals, contributing to the global effort to combat climate change, reduce energy consumption, and promote environmental stewardship. This approach aligns with the urgent need for eco-friendly construction practices.

Following the need to reduce carbon footprints in concrete mix designs, integrating fibers into concrete presents a transformative approach to achieving enhanced material properties and environmental benefits. Synthetic fibers such as polyvinyl alcohol (PVA), alkali-resistant Glass (AG), and polypropylene (PP), among others, have been increasingly adopted to improve concrete's strength, durability, and crack resistance properties. These fibers reduce traditional cement content and steel reinforcing bars, indirectly reducing CO_2 emissions associated with cement and steel production. Moreover, using fibers in concrete not only aids in achieving a more sustainable construction material by enhancing its lifespan and reducing the need for repairs but also opens possibilities for incorporating recycled and bio-based fibers, further aligning with eco-friendly construction practices. This broader adoption of fibers signifies a shift toward more resilient and sustainable construction methodologies, where the performance benefits of fiber-reinforced concrete are leveraged to meet the dual goals of structural integrity and environmental responsibility.

Therefore, this study aims to illuminate the focus of enhancing structural benefits while simultaneously addressing the environmental impacts of incorporating fibers in concrete mix design. By carefully balancing the addition of fibers such as PVA, AG, and PP, the study delves into the realm where improved mechanical properties and durability of concrete do not come at the expense of the environment. By evaluating the benefits and impacts of these fibers, the study contributes to the evolving discourse on sustainable construction, advocating for innovations that ensure the longevity and resilience of infrastructure without compromising environmental integrity. This endeavor aims to foster a construction paradigm where environmental and structural considerations are balanced and synergistically advanced, heralding a new era of eco-conscious and structurally sound building practices.

2 Properties of Fibers Used for Concrete Structures

Fiber-reinforced concrete (FRC) is a composite material that has evolved significantly over time, incorporating distinct fibers to bolster concrete's structural characteristics and longevity. These fibers are often classified into two main categories: macrofibers and microfibers, differentiated primarily by size. Microfibers, characterized by their low diameter and high aspect ratio (length to diameter), are typically shorter than 18 mm, whereas macro fibers are more substantial, with a length exceeding 18 mm. This distinction is critical as microfibers and macrofibers are pivotal in mitigating cracking and enhancing the concrete's structural integrity throughout its service life. They achieve this by increasing resistance to plastic and drying shrinkage cracking, significantly reducing crack widths, and improving the concrete's ability to absorb energy and withstand impacts [1, 2].

Including fibers in concrete is not merely for structural enhancement; it fundamentally transforms the mixture's durability and resilience. The spectrum of fibers

utilized in FRC includes metallic (notably steel), glass, synthetic, and natural fibers, each bringing unique properties to the concrete mix. The length of these fibers varies widely, ranging from 10 mm (approximately 3/8 inch) to 75 mm (about 3 inches), allowing for a tailored approach to reinforcing concrete based on specific engineering and construction requirements [3].

Carbon steel fibers, widely recognized as the predominant metallic fibers in concrete applications, are available in various forms such as straight, hooked end, crimped, or flat shapes, designed to optimize their mechanical interlock and bonding with the concrete matrix, enhancing tensile strength and crack resistance. In contrast, stainless steel fibers are specifically chosen for environments where corrosion is a significant concern, as their inherent resistance to rust and degradation makes them ideal for ensuring the longevity of concrete structures in harsh conditions [4, 5].

On the other hand, glass fibers, sourced from natural minerals or rocks, are utilized in concrete for their superior mechanical properties; silica and basalt glass fibers are notable examples, with basalt fibers often preferred for their higher elastic modulus and tensile strength, as documented in past studies [3, 6].

In synthetic fibers, materials such as PP, PVA, nylon, polyolefin, carbon, polyethylene, polyester, acrylic, and aramid stand out. These fabricated fibers are essential for controlling concrete shrinkage and temperature-induced stresses, making them suitable for environments prone to chemical exposure and corrosion [7, 8]. However, it is important to note that synthetic fibers enhance durability and resistance to environmental factors. However, they generally do not contribute as significantly to concrete's compressive and flexural strengths as their metallic counterparts. The selection of fiber type for concrete reinforcement is thus a strategic decision influenced by a blend of factors, including mechanical properties, cost considerations, specific demands of the construction project, and prevailing environmental conditions. As pointed out in [1], choosing fiber is crucial for optimizing the performance and sustainability of concrete and cementitious composites in varied applications.

Incorporating synthetic fibers into concrete has recently garnered significant attention in the construction sector, particularly for its potential to fortify the material's durability under adverse environmental conditions. Acknowledged for substantially enhancing concrete's mechanical attributes and longevity, synthetic fibers have become a focal point in the quest for more robust construction materials.

This study thoroughly investigates the design of concrete mixes reinforced with synthetic fibers, focusing on the roles and impacts of PVA, PP, and AG fibers. By thoroughly examining these fibers' contributions, the study aims to elucidate their influence on concrete performance, particularly in enhancing strength, durability, and sustainability. By understanding the specific benefits and functionalities of PVA, PP, and AG fibers within concrete matrices, this analysis seeks to uncover the pathways through which synthetic fiber reinforcement can lead to the development of construction materials that are not only more durable and capable of withstanding harsh environmental challenges but also contribute to the sustainability of the construction industry.

2.1 Polyvinyl Alcohol Fibers

PVA fibers, as shown in Fig. 1b, have consistently demonstrated an ability to augment concrete's durability properties. A study by [9] subjected FRC composites made with varying PVA fiber contents (ranging from 0% to 1.5%) to extreme wet-thermal and chloride salt conditions. It was discerned that a PVA fiber content of 0.3% was optimal for compressive strength, while 0.6% maximized flexural strength. There were noteworthy enhancements, with a 67% increase in maximum flexural strength and a 30% rise in residual compressive strength compared to the non-fiber counterparts. Similarly, it was reported in [10] that blending 1.0 vol.% PVA fibers with 1.0 wt.% nano-SiO_2 in cement mortar can considerably improve its resistance to various deteriorating agents, including chloride-ions. This combination also positively influenced mechanical strength and frost resilience [11], further underscoring the durability of PVA fibers under seawater exposure, observing that even after a decade, the fibers remained robust, offering crack suppression benefits, particularly near rebars. Lee et al. [12] provided additional insights, suggesting that integrating PVA fibers into specific concrete types can considerably mitigate chloride ion and water penetration.

2.2 Polypropylene Fibers

PP fibers, as shown in Fig. 1a, have demonstrated multifaceted benefits and limitations. Wang and Chen [13] indicated that PP fibers could enhance the durability of concrete under freeze-thaw cycles and maintain its residual mechanical properties up to 400 °C. However, it could compromise concrete's strength properties, especially at higher temperatures. Further reinforcing these findings, it was found that concrete with up to 0.15% PP fiber content exhibited minimal water absorption and commendable resistance to chemical attacks [14]. Haq et al. [15] extended the understanding, suggesting that an optimal inclusion of PP fibers in certain concrete mixtures could enhance water absorption, permeability, and resistance to chloride-ion penetration. Nevertheless, Resende et al. [16] highlighted some limitations.

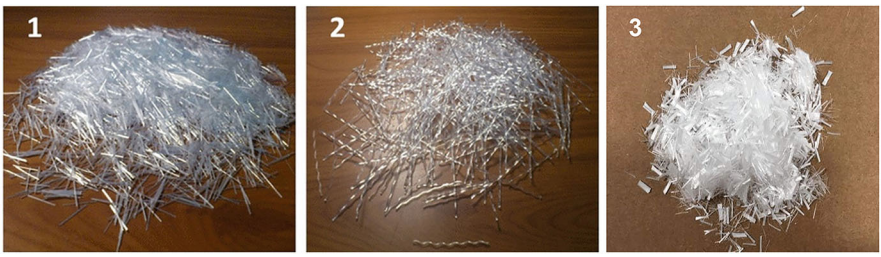

Fig. 1 (**a**) PP, (**b**) PVA, and (**c**) AG fibers

When exposed to a temperature spectrum of 25 to 800 °C, high-strength concrete containing PP fibers consistently revealed greater water absorption than its fiber-free counterpart.

2.3 Glass Fibers

Glass fiber-reinforced concrete (GFRC) presents distinct advantages in construction materials. Research by [17] demonstrated that GFRC initially shows superior carbonation resistance compared to ordinary portland cement (OPC). Despite reducing this resistance over time, GFRC still surpasses OPC in crucial aspects such as reduced porosity and enhanced resistance to chloride-ion penetration. These findings are corroborated by [18], which noted that increasing the glass fiber content in concrete significantly curtails chloride-ion penetration, a benefit primarily due to the robust bond between the fibers and the concrete binders. Experimental studies further highlight the advantages of GFRC, notably its increased resistance to acid attacks compared to steel fiber-reinforced concrete. This resilience is particularly significant in environments where concrete is exposed to corrosive substances. Additionally, even in high volume fractions, glass fibers contribute minimal weight to structural members, a stark contrast to the denser steel fibers, thereby not substantially increasing the self-weight of structural components. Moreover, as shown in Fig. 1c, glass fiber enhances the concrete's durability in terms of fatigue and impact resistance, akin to steel fibers, but with the added benefit of being cost-effective. This makes GFRC not only a financially viable option but also beneficial for improving the flexural tensile strength of concrete, thus offering a comprehensive suite of enhancements to concrete's structural performance. Overall, GFRC stands out for its cost-efficiency, improved mechanical properties, and reduced environmental impact, making it a compelling choice in modern construction practices. Its capacity to enhance the longevity and resilience of concrete structures while mitigating the environmental footprint underscores the importance of further research and adoption in the construction industry.

3 Environmental Impact of Fibers

The environmental impact of the construction industry is a significant concern, primarily due to the extraction, processing, and transportation of raw materials, which contribute to substantial pollution levels and high energy consumption. In the context of this research, using PVA, PP, and AG fibers in concrete necessitates a closer look at their environmental footprint [19].

3.1 Polyvinyl Alcohol Fibers

PVA, denoted chemically as $(C_2H_4O)n$, is a synthetic fiber known for its high strength, initially developed to replace asbestos in asbestos cement products. Despite its advantageous properties, PVA fibers are less prevalent in the construction industry than other concrete fibers, primarily due to their higher cost. Their limited availability in the concrete fiber market means they are sourced from select suppliers. Regarding environmental impact, producing PVA fibers involves processes that can contribute to CO_2 emissions. These emissions stem from the energy-intensive nature of synthesizing PVA, which involves polymerizing vinyl acetate into polyvinyl acetate and then hydrolyzing it to form PVA. This process typically requires significant amounts of energy, often derived from fossil fuels, leading to the generation of CO_2.

Moreover, the raw materials used in the production of PVA, such as ethylene (a petrochemical product), further contribute to its carbon footprint through the emissions associated with petrochemical processing. While PVA fibers can enhance the structural integrity and durability of construction materials, their production's potential CO_2 emissions must be considered in the broader context of sustainable construction practices, assessing whether their performance benefits outweigh their environmental costs [1, 3].

3.2 Polypropylene Fibers

PP fibers, as synthetic materials, undergo a complex and energy-intensive production process. The journey begins with the procurement of raw materials. These materials are primarily derived through the thermal cracking of fuels like naphtha and liquefied petroleum gas, necessitating sophisticated techniques to maintain their liquid state during storage. The domestic supply contributes the remaining 20%, separating propylene from propane at local facilities.

The manufacturing process then advances to the purification stage, where all raw materials are meticulously cleansed of impurities to ensure the stability and quality of the polypropylene production. Post-purification, the material enters polymerization reactors where polypropylene is synthesized. Following polymerization, the product undergoes degassing to expel residual hydrocarbons, leading to the extrusion phase. Here, polypropylene is mixed and melted, combined with additives, and formed into pellets, readying for consumer distribution.

For the fibers to be used in construction, they are further processed through specialized machines that shape and size them appropriately for integration into concrete. Within the concrete matrix, polypropylene fibers contribute to the structural integrity and durability of the material, not posing significant environmental concerns during the structure's service life. However, the environmental

implications become pertinent at the structure's end of life, where the disposal or recycling of polypropylene fibers can lead to environmental challenges, emphasizing the need for sustainable end-of-life management practices [19, 20].

3.3 Glass Fibers

Glass fibers, derived from naturally occurring minerals or rocks and primarily consisting of $(SiO_2)n$ monomers, are produced through a process that begins with melting raw materials like silica sand, limestone, and soda ash, along with recycled glass, at temperatures ranging from 1400 to 1600 °C to form molten glass. This molten glass is refined to eliminate bubbles and achieve uniformity before extruding through tiny orifices in a platinum-rhodium alloy bushing, creating continuous filaments. Depending on the production method and intended application, glass strands can be engineered to disperse into microfiber form upon contact with water or remain integral macro fibers. Manufacturing glass fibers is an energy-intensive process that incurs significant CO_2 emissions, primarily due to the high temperatures required for melting the raw materials, often utilizing energy from fossil fuels. The subsequent refining and fiberization processes also add to the carbon footprint, although modern advancements in production technology and energy efficiency are helping to reduce these environmental impacts. In construction, glass fibers are valued for creating robust, lightweight materials, but their environmental footprint includes the CO_2 emissions from their production phase. Utilizing recycled glass in manufacturing can diminish energy consumption and lower CO_2 emissions. Despite the carbon emissions associated with their production, glass fibers play a crucial role in promoting energy-efficient and durable construction, which can lead to a reduction in the overall CO_2 impact throughout the lifecycle of a building. Thus, while glass fiber production produces CO_2 emissions, their application in sustainable construction practices has the potential to balance out these initial environmental costs, contributing to a more sustainable construction industry [1, 3, 21, 22].

3.4 Carbon Footprint Assessment of Mix Designs

In the mix design study focused on concrete beams reinforced with PVA, PP, and AG fibers, an in-depth analysis was conducted to evaluate the environmental impacts, particularly CO_2 emissions associated with these materials. The study methodically integrated these fibers at two distinct concentrations—0.25% and 0.50%—and assessed six beams for each type, dividing equally among the specified percentages. Each fiber type's total usage in the beams amounted to 1.14 kg, allowing for a direct comparison of their respective CO_2 emissions.

Table 1 Synthetic fiber options and their various CO_2 emissions

Fibers	Percentage	Total number of beams	Percentage	Total number of beams	Total weight of fibers used in all beams (kg)	CO_2 emissions per kg (CO_2-kg/kg)
AG	0.25	3	0.50	3	1.14	2.04 [23]
PP	0.25	3	0.50	3	1.14	1.85 [23]
PVA	0.25	3	0.50	3	1.14	2.70 [24]

The mix included AG fibers at the aforementioned percentages was explored for reinforced concrete, with six beams collectively. The total CO_2 emissions for AG, calculated from an emission factor of 2.04 kg CO_2/kg of fiber, were approximately 2.33 kg CO_2 for the entire set of beams. This figure delineates the carbon cost of employing AG fibers in concrete reinforcement. PP reinforced concrete followed a similar experimental setup. Here, PP fibers demonstrated a lower environmental impact, evidenced by a CO_2 emission factor of 1.85 kg CO_2/kg, culminating in total emissions of around 2.11 kg CO_2 for the total fiber quantity. This denotes a comparatively lesser environmental footprint for PP fibers under the same testing conditions.

PVA fibers, utilized likewise in the beam compositions, emerged as the most environmentally taxing, with the highest CO_2 emission factor of 2.70 kg CO_2/kg. The cumulative emissions for PVA fiber reached approximately 3.08 kg CO_2, marking it the most impactful on the environment among the fibers evaluated. The above assessment is also illustrated in Table 1.

This comparative assessment of CO_2 emissions sheds light on the diverse environmental implications of incorporating these fibers in concrete construction. Despite all fibers enhancing concrete's structural attributes, their environmental ramifications vary significantly. PP fibers, in particular, stand out as the most environmentally benign option, emitting the least CO_2. This study's findings are critical in the broader context of sustainable construction practices. While the CO_2 emissions from these fibers are considerably lower than those from major construction sources like cement production and steel reinforcing bars and fibers production, they are nonetheless consequential and warrant careful consideration in the environmental footprint analysis of construction projects. Emphasizing sustainability, the research advocates selecting construction materials that fulfill structural requirements and align with environmental sustainability goals. Reducing CO_2 emissions, even in smaller quantities, is imperative in the construction industry's pursuit of a reduced carbon footprint. The urgency of these reductions becomes apparent when considering the current CO_2 concentration in the Earth's atmosphere, which stands at approximately 415 ppm, or 0.0415%. This level marks a 48% increase from the beginning of the industrial era and a 12% rise since the start of this millennium [25]. Therefore, as demonstrated in this study, the nuanced evaluation of materials' environmental impact is essential for advancing sustainable construction methodologies and achieving long-term ecological balance in the industry.

4 Conclusions

In conclusion, this study has thoroughly examined the integration of synthetic fibers such as PVA, PP, and AG fibers into concrete mixes, highlighting their potential to reduce the construction materials' carbon footprint and contribute to achieving net-zero goals. The comprehensive analysis, encompassing these fibers' production processes, application, and end-of-life phases, underscores their role in sustainable construction practices. The comparative life cycle assessment conducted within this study reveals that while all tested fibers enhance the mechanical properties of concrete, thus improving durability and resilience, PP fibers stand out for their lower CO_2 emission profile. This finding is instrumental in advocating for a more environmentally conscious selection of materials within the construction industry, pointing toward preferable choices of fibers in pursuing sustainability. The mix design and CO_2 emissions analysis results confirm the necessity of integrating energy-efficient manufacturing processes and promoting the use of recycled materials to further mitigate the environmental impact of construction activities.

traditional concrete comes with a hidden cost to the environment [1]. A key component of concrete, ordinary Portland cement (OPC), is a major culprit behind greenhouse gas emissions, particularly carbon dioxide (CO_2) [2]. Concrete production has critical environmental impacts, essentially in the form of carbon emission (CE) and embodied energy (EE) [3–5]. A method called Life Cycle Assessment (LCA) can be used to track and assess these environmental effects throughout concrete's entire lifespan, from when the raw materials are first collected to when the concrete reaches the end of its useful life [6–8]. The production of concrete may be a highly energy-intensive process that depends on the combustion of fossil fuels, basically in the form of coal and natural gas. This combustion discharges CO_2 into the environment, contributing to worldwide climate change. So, concrete production can produce a significant portion of global carbon emissions [9, 10].

Sources of CEs from concrete production include raw material extraction, cement production, and transportation. One effective strategy to reduce CEs is using alternative cement formulations. Incorporating alternative cementitious materials like fly ash [11–14], slag [15–18], silica fume [19–22], etc., can decrease the carbon footprint of concrete by lowering the amount of clinker needed.

The second factor, EE, refers to the total amount of energy consumed throughout the life cycle of a concrete product, including the energy used in raw material extraction, manufacturing, transportation, and construction. Due to its energy-intensive manufacturing process, concrete retains high energy and contributes significantly to overall energy consumption in the construction industry [23, 24]. Similar to CE, the energy sources involved in concrete include raw material extraction, cement production, and transportation. Therefore, recycling and reuse, local content, and energy efficiency can be considered as mitigation strategies.

Recognizing this environmental impact, researchers and engineers are actively exploring new materials and techniques to make concrete more sustainable. This quest for eco-friendly concrete solutions involves several approaches:

- Reducing reliance on OPC: A crucial part of this effort involves finding replacements or ways to use less OPC in concrete production. Here, we explore some promising strategies:
  - Supplementary cementitious materials (SCMs): When added to concrete mixes, these materials can partially take the place of OPC while still helping the concrete set and harden [25]. A prime example is fly ash, a leftover material from burning coal. Fly ash is particularly attractive because it's plentiful and relatively inexpensive. Fly ash is derived from pulverized coal combustion during power generation and is characterized by its pozzolanic properties, making it a valuable additive in concrete production. The incorporation of fly ash serves several purposes in enhancing the performance and sustainability of concrete. Initially, these materials act as a cementitious binder by reacting with the calcium hydroxide ($Ca(OH)_2$) produced during cement hydration, leading to the formation of additional calcium silicate hydrate (C-S-H) gel [26]. This reaction improves the overall strength and durability of the concrete. Secondly, the fine particles of fly ash fill the voids between cement

grains, leading to denser concrete with lower permeability. Because of this denser structure, the concrete becomes more resistant to damage from chemicals, sulfates, and alkali-silica reaction [27]. Moreover, the use of fly ash helps reduce the heat of hydration during concrete curing, which is beneficial for large concrete placements and in mitigating thermal cracking [28].
  - Geopolymers: These innovative binders, activated by alkaline solutions, have a smaller carbon footprint than OPC [29]. Geopolymers can be formulated using industrial byproducts like fly ash or even natural materials. While still under development, geopolymers hold significant promise for the future of sustainable concrete production.
  - Alternative binders: Researchers are exploring various alternative binders derived from agricultural waste [30] or industrial processes [31]. These binders can potentially offer significant environmental benefits while meeting the performance requirements for concrete applications.

- Enhancing concrete performance: Another key strategy involves developing concrete formulations with improved performance. This can lead to using less concrete overall for a project, indirectly reducing the environmental impact. For example, self-compacting concrete (SCC) offers several advantages over traditional concrete [32]:
  - Easier to work with: SCC flows freely under its weight, eliminating the need for vibration during placement. This translates to faster construction times and potentially safer working conditions.
  - Reduced noise pollution: Since vibration isn't required, SCC placement generates less noise pollution than traditional concrete.
  - Improved quality control: The self-compacting nature of SCC leads to better filling of forms and less segregation of materials, resulting in improved quality control.

Additionally, by incorporating certain fibers into the concrete mix, researchers aim to improve the durability and lifespan of the concrete, potentially leading to less maintenance and longer infrastructure lifespans [33–36].

This investigation explores the environmental impact of SCC reinforced with fibers and incorporating Class-F fly ash. While SCC offers well-documented improvements in workability and construction efficiency, a key question regarding its sustainability remains. Specifically, this study focuses on comparing how SCC production affects the environment throughout its entire lifecycle, compared to regular concrete. This assessment involves evaluating the potential environmental trade-offs linked to higher cement content, which is often necessary for SCC mixtures, and the use of chemical admixtures to achieve self-compacting properties.

The current investigation builds upon a foundational study by one of the authors [36], which focused on how well SCC containing class-F fly ash and reinforced with fibers works and how it responds to stress.

The previous work serves as a solid foundation for the current research, enabling us to investigate the environmental implications of selected fiber reinforcement strategies within the framework of incorporating fly ash as a partial substitute for OPC. By employing a LCA, a well-established method for comprehensively evaluating the environmental footprint of a product or process, this study aims to offer a clear understanding of the environmental impact of SCC with blended fiber reinforcement throughout its entire life cycle, encompassing raw material extraction, production, transportation, construction, use phase, and ultimately, demolition and waste disposal. The findings of this paper will provide valuable knowledge to the ongoing discussion on sustainable construction materials. By measuring the environmental impact of SCC with class-F fly ash and blended fiber reinforcement, this research can inform decision-making processes within the construction industry, guiding the selection of materials and techniques that minimize environmental burdens while maintaining structural integrity and performance.

2 Methodology

This study builds upon a foundational investigation by one of the authors [36] to establish the methodological framework for assessing the environmental impact of fibrous SCC with class-F fly ash. The prior work, which focused on characterizing the workability and mechanical response of SCC, provides a strong foundation for the current research. Key aspects of the methodology, including the utilization of established material properties and the adoption of the mixture design and specimen preparation procedures, are drawn from [36] to ensure consistency and minimize repetition.

2.1 Material Properties

The current investigation utilizes the well-defined material properties meticulously characterized in the previous study by [36]. That study provides comprehensive details on the constituent materials employed in this investigation, including:

- OPC
- Class-F fly ash
- Fine aggregates (limited to a maximum size of 2.36 mm)
- Clean tap water, free from any harmful impurities
- Carboxylate-based high-range water reducer (HRWR)
- Micro steel fibers
- Polyvinyl alcohol (PVA) fibers

Readers are directed to the aforementioned publication for a more in-depth understanding of the individual material properties [36]. Here, the focus is on how these materials are strategically used to assess the environmental impact of the reinforced SCC.

2.2 Mixture Design and Specimen Preparation

The base mixture design adopted here was directly adapted from [36] (as presented in Table 1), ensuring consistency in material composition and fresh concrete properties. This selection allowed for a focused evaluation of the environmental impact introduced by the blended fiber reinforcement. As detailed in [36], the base mixture consisted of OPC, water, and aggregates in a specific ratio of water to cement (0.38). A high-range water reducer was employed to attain the desired workability characteristics for SCC. Varying dosages and combinations of micro steel fibers and PVA fibers were incorporated into the base mixture design to investigate their combined effect on the environmental performance of the SCC. As outlined in [36], three volume fractions (0.5%, 1.0%, and 1.5%) of both fibers were explored in separate mixture series. The blended fiber approach aimed to leverage the synergistic benefits of both fiber types, as discussed in [36]. Micro steel fibers were expected to enhance the post-cracking behavior and tensile capacity, while PVA fibers were anticipated to mitigate plastic cracking and improve spalling resistance. The specific dosages and combinations of fibers were carefully chosen, considering the findings from [36] and aiming for a balance between desired mechanical performance and potential environmental impact.

Table 1 Concrete mix properties [36]

No.	Mix identification	Cement (kg/m^3)	Fine agg. (kg/m^3)	Fly ash (%)	Micro steel fiber (%)	PVA fiber (%)

2.3 Life Cycle Assessment

The initial phase of LCA involves establishing its purpose and boundaries, defining the production system based on a functional unit and system scope. In this research, the functional unit was defined as 1 cubic meter of concrete utilizing varying proportions of cement, fly ash, micro steel fibers, and PVA fibers. Additionally, the environmental comparison considered the impact of compressive strength and service life. The subsequent stage of LCA, known as Life Cycle Inventory (LCI), involves gathering necessary data (input and output inventory of materials within the system) aligned with the study's objectives. Following the inventory analysis, the Life Cycle Impact Assessment (LCIA) aids in assessing and interpreting environmental impacts within the established goals and scope.

To assess the environmental impact, we focus on two key factors: Global Warming Potential (GWP) and EE. GWP is designed to quantify the impact on the greenhouse effect caused by human emissions and absorptions. Typically, LCAs utilize GWP over a 100-year timeframe. GWP enables the calculation of a single index, expressed in grams of CO_2 per functional unit of a product, representing the quantity of CO_2 with equivalent global warming potential over 100 years (Eq. 1):

$$\mathrm{GWP} = \sum\nolimits_i m_i \times \mathrm{GWP}_i \tag{1}$$

This calculation considers the mass (in kilograms) of each material used (represented by m_i) and its GWP_i. GWP_i indicates how much a specific material contributes to warming the planet over 100 years, similar to how 1 kg of CO_2 does. The specific GWP_i values for each material are listed in Table 2 [37].

In the same way, Eq. 2 was applied to calculate the amount of EE as MJ per 1 m^3 concrete prepared according to the concrete mix design.

$$\mathrm{EE} = \sum\nolimits_i m_i \times \mathrm{EE}_i \tag{2}$$

The CO_2 emissions and EE due to binder materials (cement, fine aggregate, fly ash, steel fibers, and PVA fibers) were extracted from different studies, as listed in Table 3 [38–40]. As observed, the significant amount of CEs caused by conventional concrete production is directly related to the amount of cement in the composition [41].

Table 2 Global warming potential equivalency factors

Flow (i)	GWP_i (CO_2-equivalent)
Carbon dioxide (CO_2, net)	1
Methane (CH_4)	23
Nitrous oxide (N_2O)	296

Table 3 Carbon emission and embodied energy of concrete components (per 1 kg)

Items	CO_2 (kg)	Energy (MJ)
Cement	0.912	5.5
Water	0	0
Fine agg.	0.0139	0.0048
Fly ash	0.004	0.1
Steel fiber	1.5	1.01
PVA fiber	3.6	106.54

3 Results

In this section, the findings of the compressive capacity of concrete as a mechanical index are presented first. Then, the results related to the carbon emitted and the energy consumed to make 1 m^3 of concrete (as environmental indexes) are presented. In the following, the above indexes are compared.

3.1 Compressive Strength

A previous study by one of the authors [36] investigated the influence of fibers and fly ash on the compressive strength of SCC. The results aligned with existing literature, demonstrating a trade-off between the effects of fibers and fly ash. Figure 1 presents the compressive strength of specimens. While adding fibers can increase CS by limiting crack growth (bridging effect), it can also introduce porosity, potentially reducing CS. This study observed a significant CS increase with micro steel fibers (16.45% for 1.5% content) attributed to their uniform dispersion, rough surface, and high elastic modulus. Conversely, PVA fibers (1.5% content) led to a 9.16% decrease in CS, likely due to their smooth surface and lower stiffness compared to steel fibers. On the other hand, the incorporation of class-F fly ash resulted in a decrease in CS (15% and 8% for 5% and 10% replacement ratios, respectively) due to its slower pozzolanic reaction rate.

3.2 Sustainability Potential

The results of carbon emissions of all specimens are displayed in Fig. 2. In the first sample as a control test, the values of fly ash, steel fibers, and PVA fibers are equal to zero, and the concrete sample consists of 850 kg of cement and 1550 kg of fine aggregates. In this case, the carbon emission is about 796 kg CO_2. In samples 2–5, with cement and fine aggregates remaining constant, two types of fibers were added as a percentage of cement (without fly ash). By using 1.5% PVA fiber, the amount of carbon emission has been significantly increased to 862 kg CO_2. According to

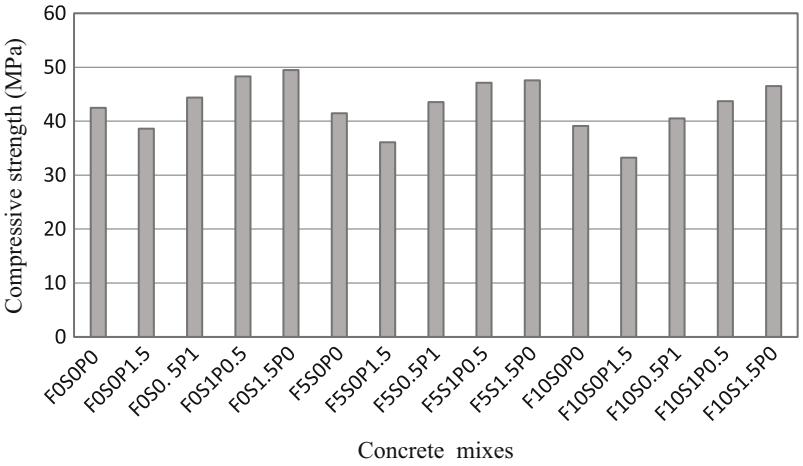

Fig. 1 Compressive strength of specimens

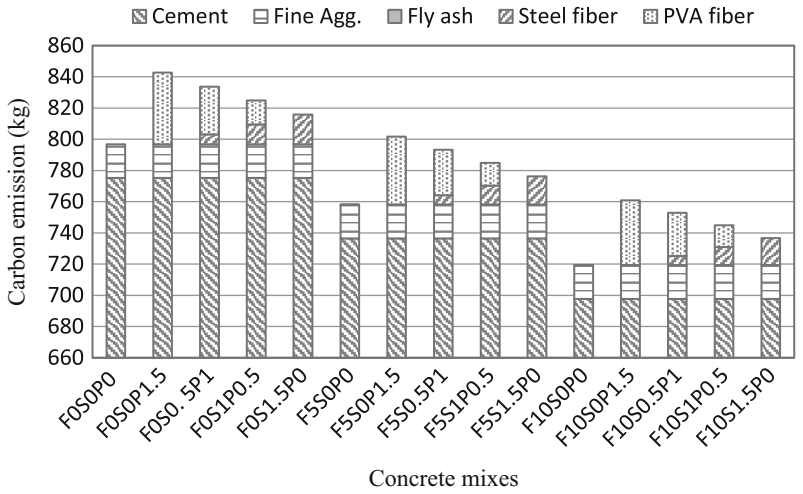

Fig. 2 Carbon emission value of concrete mixes (F: Fly ash; S: Steel fiber; P: PVA fiber)

Table 3, the carbon emission of PVA fiber is higher than other components. However, by reducing the PVA fiber and increasing the percentage of micro steel fiber usage, the amount of carbon emission has decreased. As the carbon emission varied from 842 to 815 kg CO_2.

In samples 6–10, the amount of fine aggregate remained constant, while the amount of cement was considered constant with a smaller amount. In addition, the amount of fly ash was added as a percentage of the used cement and fixed. Different amounts of micro steel and PVA fibers have been investigated in these samples by

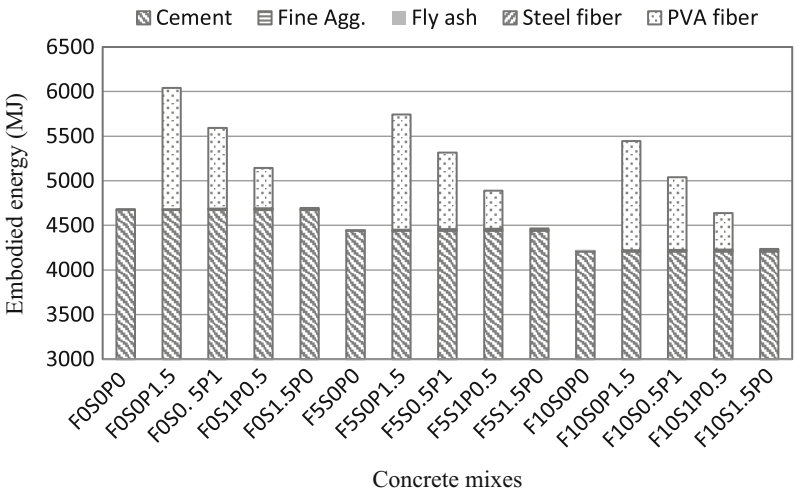

Fig. 3 Embodied energy value of concrete mixes (F: Fly ash; S: Steel fiber; P: PVA fiber)

applying fly ash. Again, it was concluded that PVA fibers have more carbon emission content than micro steel fibers. On the other hand, by reducing cement and replacing it with different types of fibers, carbon emission content has decreased significantly compared to tests 2–5. In tests 10–15, the same trend can be seen well, and the positive effect of replacing cement with PVA and micro steel fibers has been confirmed. So, in the last test with 765 kg of cement, 1550 kg of fine aggregate, 10% fly ash, and 1.5% micro steel fibers, the lowest amount of carbon emission equal to 736 kg as CO_2 was obtained. As the main result, micro steel fibers have an effective reduction in carbon emission compared to PVA fibers.

Figure 3 shows the results related to the energy consumed during the production of 1 m^3 of concrete for all specimens according to the concrete mix design (Table 1). Based on the consumption amount of the materials and the embodied energy values of each material (Table 3), it is observable that first cement and then PVA fibers had the greatest impact on the amount of EE. In different samples, the amount of EE has decreased with the reduction of cement and PVA fibers. On the other hand, considering the high energy value of PVA fibers, it is not logical to replace cement with this type of fiber.

Based on the results of using two types of micro steel and PVA fibers, and their influence on the amount of EE and GWP, it can be concluded that the use of micro steel is more effective. The inclusion of PVA fibers not only failed to reduce EE and carbon emissions but also had a detrimental effect on concrete compressive capacity. As mentioned previously, adding 1.5% PVA fibers decreased compressive capacity by approximately 9%. In contrast, the use of micro steel fibers significantly impacted concrete capacity. Therefore, it can be concluded that incorporating PVA fibers does not positively influence the mechanical or environmental properties of the concrete as intended.

4 Conclusion

The assessment of concrete's life cycle is crucial for comprehending and mitigating its environmental impact during production. By taking into account EE and carbon emissions throughout the concrete life cycle, stakeholders in the construction industry can make informed decisions to advance sustainability and diminish carbon emissions and overall carbon footprint. Implementing sustainable practices such as using alternative materials, adopting energy-efficient production techniques, and reducing carbon emissions will diminish the environmental effect of concrete making and contribute to a more sustainable built environment. In this study, mechanical and environmental indicators for self-compacting concrete were considered. For this purpose, compressive strength, global warming potential (as carbon emission), and EE were investigated for concrete samples reinforced with micro steel and PVA fibers. It should be noted that in the present investigation, fly ash was utilized as a substitute for part of cement. The findings showed that reducing the amount of cement, as expected, resulted in a significant reduction in environmental indicators. Additionally, the use of micro steel fibers improved the mechanical characteristics of SCC. Also, the fact that there is less CO_2 emission and EE compared to PVA fibers has had a significant influence on increasing the mechanical index and reciprocally reducing the environmental indexes on concrete.

1 Introduction

Every year, earthquakes cause a lot of destruction and damage to civil infrastructures, further leading to economic and life losses. Many regions in countries like India, Japan, Nepal, and the United States have frequent seismic activities. For example, the Gorkha earthquake in 2015 resulted in damage to more than half a million buildings and subsequently life loss in Nepal [1]. Such events show the necessity of advancing seismic design techniques for structures. Especially for commonly used burned clay brick masonry structures in earthquake-prone areas, they are at risk of multiple failure modes. Mercimek [2] and Canditone et al. [3] have shown the common shear failure resulting from cracks along mortar joints under earthquakes. Flexural [4] and diagonal tension failure [5] have also been reported as predominant failures in masonry structures. Moreover, out-of-plane and in-plane failures are major failures in masonry under lateral dynamic loads.

Traditional construction practices are unable to provide sufficient resistance to masonry structures under seismic activities. Inadequate material bonding, irregular structural configuration, insufficient reinforcement, heavy constructions, and not implementing seismic standards are some of the main reasons that lead to seismic failure of structures. Therefore, the development of seismic design of civil infrastructures and their strengthening are required, especially in these regions. Various strengthening techniques are adopted in design practices for new construction and existing structures. Strengthening with synthetic fiber-reinforced polymer (FRP) composites (i.e., carbon and glass FRP composites) in different forms, such as fabric, bars, and laminates as embedded and externally bonded reinforcement have been proposed as effective methods [6], to enhance the performance of structures under earthquake loadings. The strengthening provides resistance to the in-plane and out-of-the-plane failures of the masonry under seismic vibrations. However, the production of synthetic composites and their use in construction further lead to an increase in greenhouse gas (GHG) emissions. Moreover, disposal of such materials becomes another challenge to environmental safety.

Therefore, in this study, locally available natural fiber elements are proposed as a sustainable and cost-effective alternative to synthetic FRP composites for the strengthening of buildings. Saini et al. [7] have presented a detailed study on the strengthening of structures with various natural fibers in different forms. The use of sisal, jute, and flax in the form of short fibers in earthen brick, ropes to strengthen block masonry, and fabric to strengthen a masonry wall have been demonstrated [7]. Similarly, the enhancement in seismic resistance of an adobe wall with palm fibers has been obtained [8]. The effectiveness of hemp fiber composite grids in masonry panels and hemp ropes in adobe walls in increasing ductility has been reported by Menna et al. [9] and Abdulla et al. [10], respectively. Bitar et al. [11] also reported a significant increase in flexural strength at a 2.0% reinforcement ratio of flax fabric in masonry. The advantages of flax [12] and coir [13] fiber composites, i.e., high strength and less internal stress in composites, and durability and wear resistance, respectively, make them a suitable option for FRP strengthening.

However, there is no study that shows the seismic behavior of FRP composite strengthened a full-scale building. Therefore, in the present study, the efficacy of strengthening with flax and coir FRP composites on the seismic performance of a masonry building with opening is investigated. The seismic analysis of a structure has different components, which include modal, linear, and nonlinear dynamic analyses to assess the accurate seismic behavior of a structure [14]. Generally, the seismic response of the structure is evaluated in the form of displacement, acceleration, drift [14], and stresses [15, 16] to get a wholesome idea of the dynamic behavior of the structure required in new construction and in retrofitting of the structure against earthquake. Therefore, the main objectives of this study are: (a) to investigate the seismic behavior of a realistic building with openings designed for seismic loads and (b) to assess the effectiveness of flax and coir FRP composites in strengthening the building under earthquake load.

2 Numerical Modeling

A finite element (FE) model of a two-story unreinforced masonry building with openings considering fixed boundary conditions at the base is developed in ETABS® [17]. The concrete columns and beams are modeled as a frame, reinforcement bars in columns and beams are as a uniaxial bar element, and slab and masonry walls are modeled with shell elements. A macro modeling approach, continuum homogeneous modeling, is implemented for the masonry walls. In the study, the mortar is taken as an integrated part of the masonry and not modeled separately [18, 19]. An efficient mesh size of 25 mm is considered after a mesh convergence study. The FRP composite is also modeled with shell elements and considered perfectly bonded to masonry walls. The front elevation of the building has four windows and one door opening, and the back elevation has five window openings, as shown in Figs. 1 and 2.

2.1 Design of Building

The building with plan dimensions, length of 8.68 m, and width of 4.5 m, is provided with 0.23 m thick load-bearing brick masonry walls considered as per NBC guidelines [20], shown in Fig. 1. The size of the square window and door are taken as 1.219 m and 2.134 m long with 0.914 m width. A 0.125 m thick roof slab is provided in the building. Furthermore, lintel and sill seismic bands at heights of 2.134 m and 0.914 m from the base, respectively (see Fig. 2), are included in the design as per the NBC guidelines [20]. The flax and coir composites taken for strengthening the brick masonry walls of the building are designed using ACI 440 guidelines [6]. The FRP composites with 0.125 m width and 0.15 m thickness are applied externally on the masonry wall in a grid configuration (spacing less than 0.8 m), illustrated in Fig. 2.

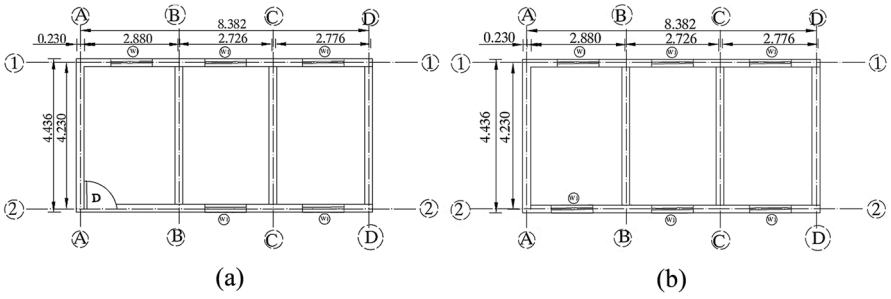

Fig. 1 The plan view of (**a**) the ground floor and (**b**) the first floor of the building considered in this study

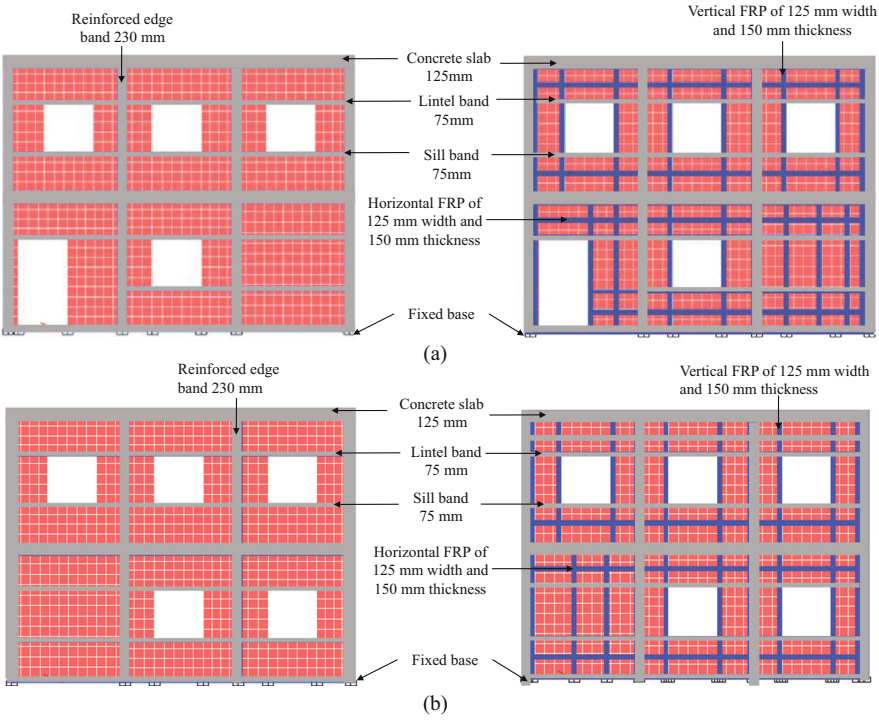

Fig. 2 Masonry buildings considering seismic bands, (**a**) front view and (**b**) back view strengthened without and with FRP composites

2.2 Material Properties

Masonry, concrete, and steel reinforcement are taken as isotropic materials, and FRP composites are considered to be orthotropic materials. The material properties of brick masonry and reinforced concrete used for columns and beams are considered as per NBC guidelines [20], as presented in Table 1. Moreover, the material properties of flax [12] and coir [13, 21] FRP composites are considered from the literature (see Table 2).

2.3 Permissible Stresses in Masonry

The permissible stresses in unreinforced masonry are estimated as per IS 1905 [22]. The design parameters of a masonry unit with 10 MPa are taken as thickness (t), 75 mm and width (w), 110 mm with mortar type M1. The permissible compressive stress ($f_c = f_b \times k_s \times k_a \times k_p$) in masonry depends upon basic compressive stress (f_b), 0.96 MPa, stress reduction factor (k_s), 0.43 (for a slenderness ratio of 27), area

Table 1 Material properties of brick masonry, concrete, and steel reinforcement adopted in the study

S. N.	Properties	Brick masonry	Concrete	Steel reinforcement
1.	Modulus of elasticity (MPa)	2112	22,360.68	200,000
2.	Poisson's ratio	0.3	0.2	–
3.	Density (kN/m^3)	19.2	25.0	76.97
4.	Co-efficient of thermal expansion (1/°C)	3.1×10^{-6}	13×10^{-6}	11.7×10^{-6}
5.	Shear modulus (MPa)	812.31	9316.95	891.25

Table 2 Material properties of flax and coir FRP composites used in the study

S. N.	Properties	Flax composite [12]	Coir composite [13, 21]
1.	Modulus of elasticity (MPa)	22,300	2139
2.	Poisson's ratio	0.44	0.2
3.	Density (kN/m^3)	12.18	7.24
4.	Co-efficient of thermal expansion (1/°C)	1.08×10^{-6}	1.2×10^{-6}
5.	Shear modulus (MPa)	1150	891.25

reduction factor (k_a), and shape modification factor (k_p), 1.0 (for height/width ratio ≤ 0.075). The area reduction factor ($k_{a\ =}\ 0.7 + 1.5A$) depends on the area of the section (m^2), A, and results in 0.71 magnitude. The permissible compressive stress results in 0.29 MPa and the permissible shear stress ($\tau_0 = 0.1 + f_d/6$) depends upon compressive stress due to dead loads (f_d), 0.17 MPa, resulting in approximately 0.13 MPa.

3 Results and Discussion

Modal and linear time history analyses are performed to assess the seismic behavior of masonry buildings without and with flax and coir composites.

3.1 Modal Analysis

A modal analysis of the masonry buildings without and with FRP composite strengthening is performed in this study. The P-Delta effect is insignificant, so it is not considered in the study. The major modes, time periods, and frequencies obtained are listed in Table 3. The mass participation of 92.15% and 91.45% is observed for respective translational Modes 1 and 2, whereas rotation is reported in mode 3. Mode 4 and Mode 5 have showed 7.82% and 8.53% mass participation in translational direction, respectively.

Table 3 Results of the modal analysis of the masonry building without and with flax and coir FRP composites strengthening

Mode	Building without strengthening		Building with flax composite		Building with coir composite	
	Time period (s)	Frequency (Hz)	Time period (s)	Frequency (Hz)	Time period (s)	Frequency (Hz)
1	0.131	7.622	0.099	10.13	0.124	8.052
2	0.118	8.472	0.094	10.655	0.115	8.723
3	0.099	10.063	0.079	12.656	0.096	10.469
4	0.057	17.590	0.042	23.808	0.054	18.613
5	0.046	21.661	0.037	26.807	0.045	22.107

It is observed that the strengthening of buildings with flax FRP composite results in an 8.33% reduction in the fundamental time period and an 8.96 % increase in the frequency of the building, as compared to that of the building without strengthening. Similarly, adding the coir FRP composite leads to a reduction of 2.78 % in the fundamental time period and a increment of 2.54 % in the frequency of the un-strengthened building, respectively. The increase in the fundamental frequency indicates enhancements in the stiffness of the building and subsequent seismic performance. The flax FRP composite has higher stiffness and strength than the coir FRP composite, resulting in higher enhancement in the stiffness of the structure. However, both composites have low density, leading to negligible increment in the mass of the structure. Thus, both lightweight biocomposites are preferred for strengthening structures due to the effective enhanced structural performance of the masonry structure.

3.2 Time History Analysis

Further, to compare the seismic performance of the building without and with FRP composites, a uniaxial linear time history analysis of the building where the seismic load is applied in the direction of X is performed.

The response spectrum is considered per NBC recommendations for zone IV (zone factor 0.24) and soil type 2 ground conditions, where the response reduction factor, 3, the importance factor, 1, and 5% damping are taken. The acceleration time history of ground motion from the 1940 Imperial Valley earthquake ground motion data recorded at El Centro station with a peak ground acceleration of 0.281 g (see Fig. 3), is applied to the structure. The seismic response is measured in terms of peak shear force and story drift, presented in Table 4. Moreover, the peak base shear and acceleration time histories are depicted in Fig. 4. The fundamental frequencies of the building without strengthening and with coir composite are very close, resulting in similar mode shapes and vibrations of the masonry building. However, due to the

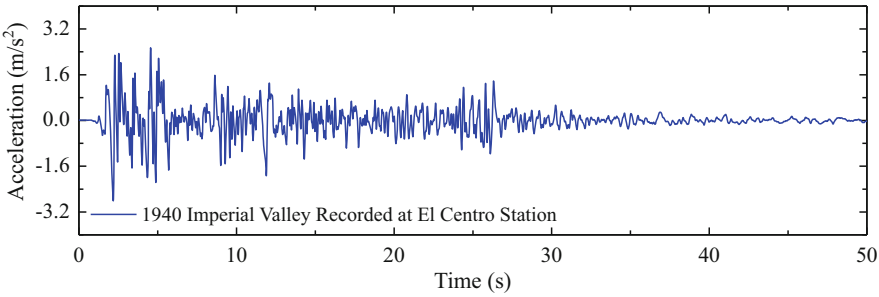

Fig. 3 The ground motion time history recorded at El Centro in the 1940 Imperial Valley Earthquake

Table 4 Response of the building without and with flax and coir FRP composites strengthening subjected to the earthquake ground motion

Response	Building without strengthening	Building with flax composite	Building with coir composite
Shear force (kN)	62.23	34.82	48.60
Peak drift ratio (%)	0.26	0.19	0.24

increase in the stiffness and strength of the building with flax FRP composite, the dynamic behavior of the structure changes compared to the structure without FRP composite.

It is observed that the tensile strength and stiffness enhancement due to strengthening with flax and coir FRP composites lead to 44.1% and 21.9% reduction in peak shear forces, respectively. Moreover, the overall reduction in floor acceleration response at the first story and roof level is reported due to flax and coir composite strengthening, respectively. Similarly, 28.6% and 8.8% reductions in peak deflection of the building due to the addition of flax and coir composites are obtained, respectively. This indicates a notable improvement in energy dissipation and reduction in kinetic energy, resulting in minimizing the impact of seismic forces on the building. The peak drift reduces to 0.19% and 0.24% with flax and coir FRP composites, which also presents the reduction in deformation of the building. These findings showcase the evident impact of flax and coir FRP composites on the seismic resistance of the building.

3.2.1 Stress Distribution

Stress distribution across the two-story buildings reveals a distinct pattern around the openings, where the highest stress concentration at the corners of the openings is obtained, resulting in localized failures in the masonry walls on both the front and back sides of the structure. The discontinuity in stress distribution is caused by openings in the wall, which further leads to stiffness reduction and seismic

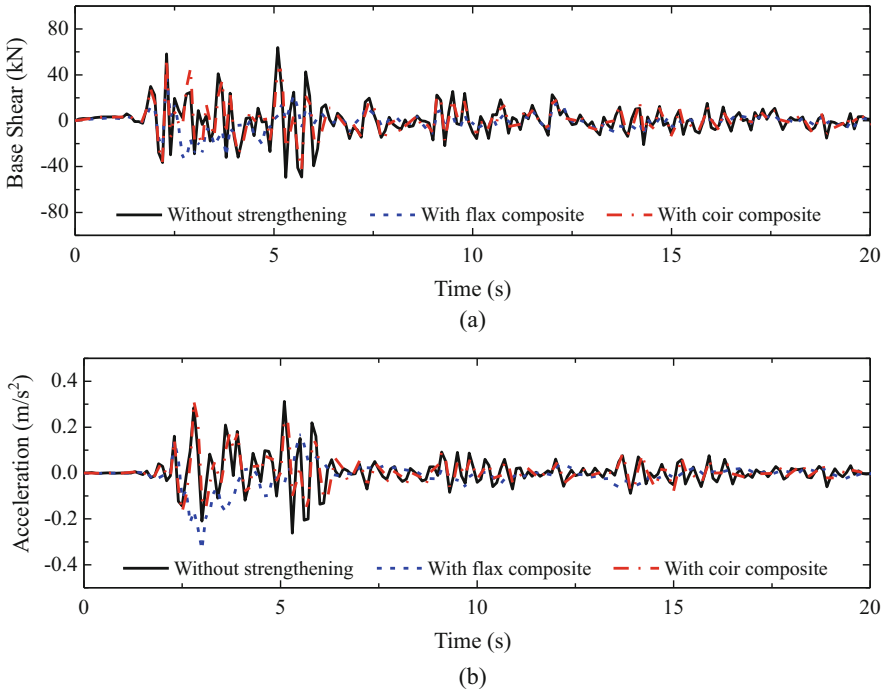

Fig. 4 The peak response time histories of the building without and with flax and coir FRP composites strengthening under the earthquake ground motion, (**a**) base shear and (**b**) acceleration

Table 5 Principal stresses in the masonry buildings without and with flax and coir FRP composites strengthening subjected to the earthquake ground motion

Stress	Building without strengthening (MPa)	Building with flax composite (MPa)	Building with coir composite (MPa)
Normal stress in the longitudinal direction (S11)	0.32	0.27	0.37
Normal stress in transverse direction (S22)	0.75	0.29	0.59
Shear stress in the in-plane direction (S12)	0.3	0.25	0.28

vulnerability of the structure. Therefore, the natural FRP composites are provided around openings as per ACI 440 [6] to reduce the stresses, as shown in Table 5.

It is observed that cracks propagate from corners of the openings diagonally under seismic load. The provided seismic bands also help restrict the stresses to a region (see Figs. 5, 6, and 7). The major stresses are longitudinal (S11) and transverse (S22) normal stresses, and in-plane shear (S12) stress, compared in Figs. 5, 6, and 7, respectively.

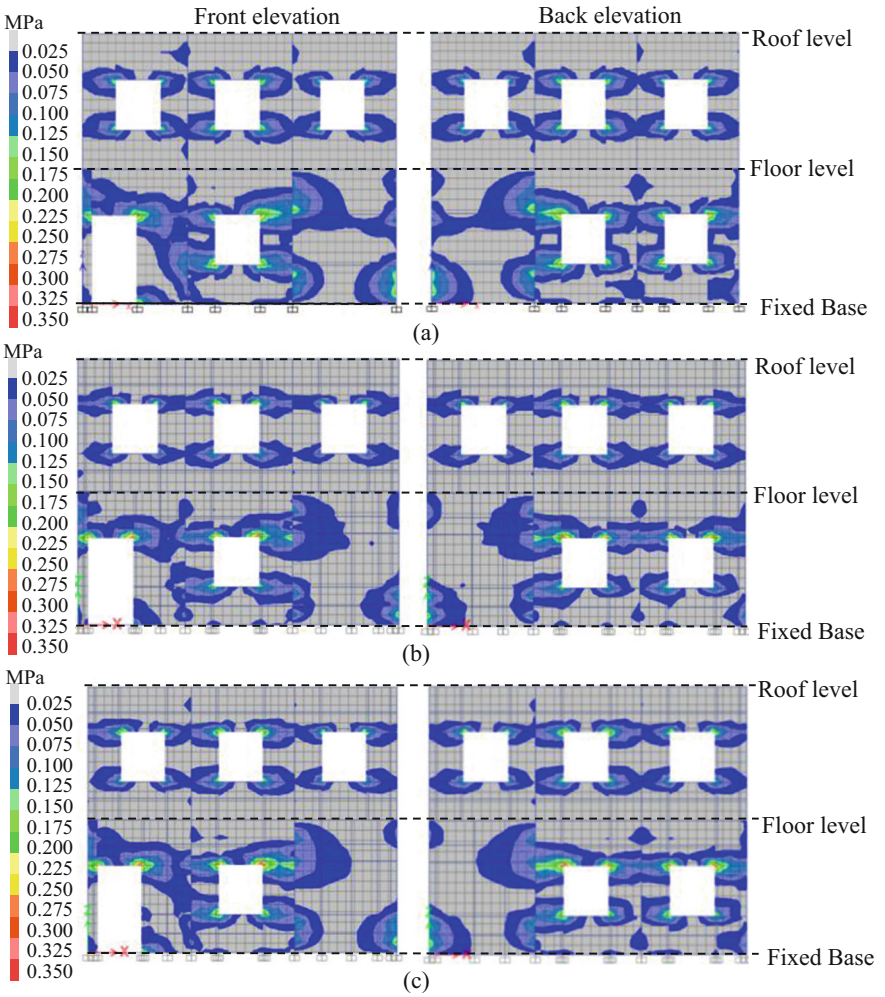

Fig. 5 Longitudinal normal stress (S11) in the building, (**a**) without strengthening, (**b**) with flax FRP composite, and (**c**) with coir FRP composite under the earthquake ground motion

The exceedance of stresses beyond permissible stresses in the case of the building without strengthening is clearly visible. The remaining normal (S33) and shear stresses (S13 and S23) are found insignificant; therefore, not presented here. The highest exceedance is observed for in-plane shear stress (S12) beyond permissible shear stress. This comparative analysis highlights the efficacy of FRP composites in strengthening structural weak points. It illustrates that flax FRP composite stands out as a more effective option for improving the seismic resilience of buildings, particularly by addressing stress concentrations around openings. The strengthening with flax and coir FRP composites results in a reduction of the longitudinal normal stress

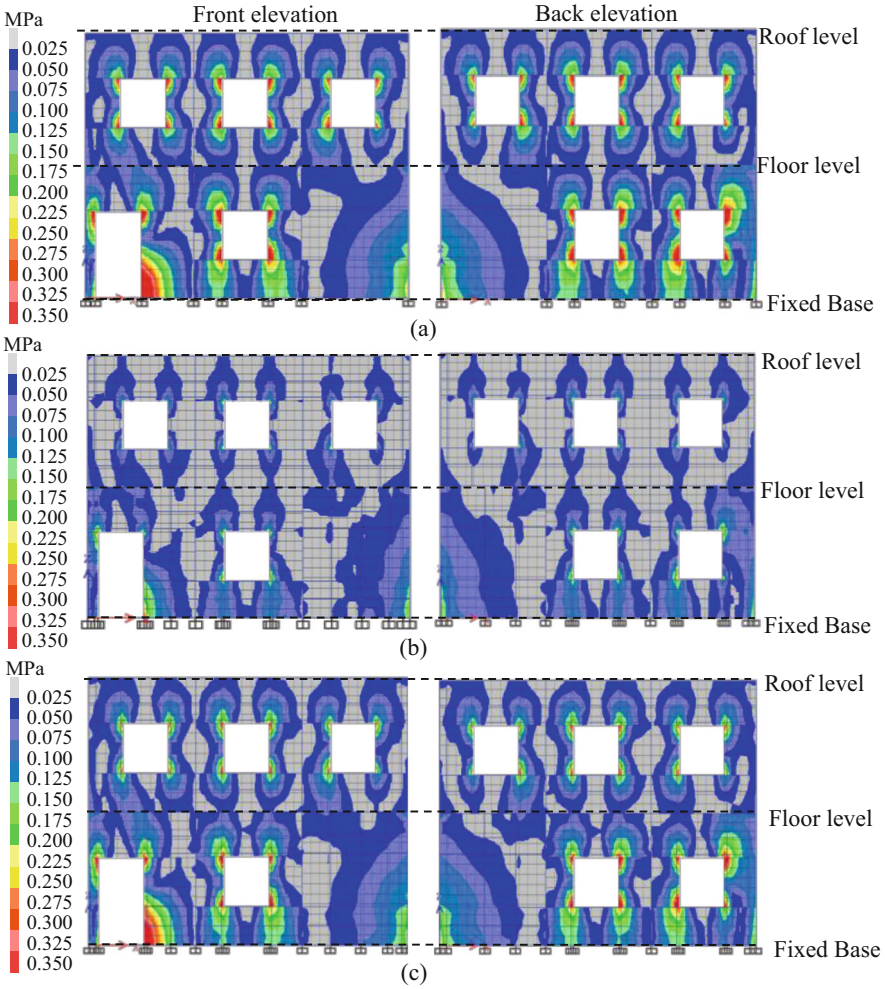

Fig. 6 Transverse normal stress (S22) in the building, (**a**) without strengthening, (**b**) with flax FRP composite, and (**c**) with coir FRP composite under the earthquake ground motion

by 15.6% and approximately insignificant, whereas in transverse normal stress by 61.34% and 21.34%, and in in-plane shear stress by 16.67% and 6.67%, respectively. Both flax and coir FRP composites can reduce the stresses in the masonry wall. However, the current grid configuration with coir FRP composite is not sufficient to reduce stresses and to keep them within the permissible stress limits. On the other hand, the current grid configuration with flax FRP composite sufficiently reduces the normal stresses than the permissible compressive stresses.

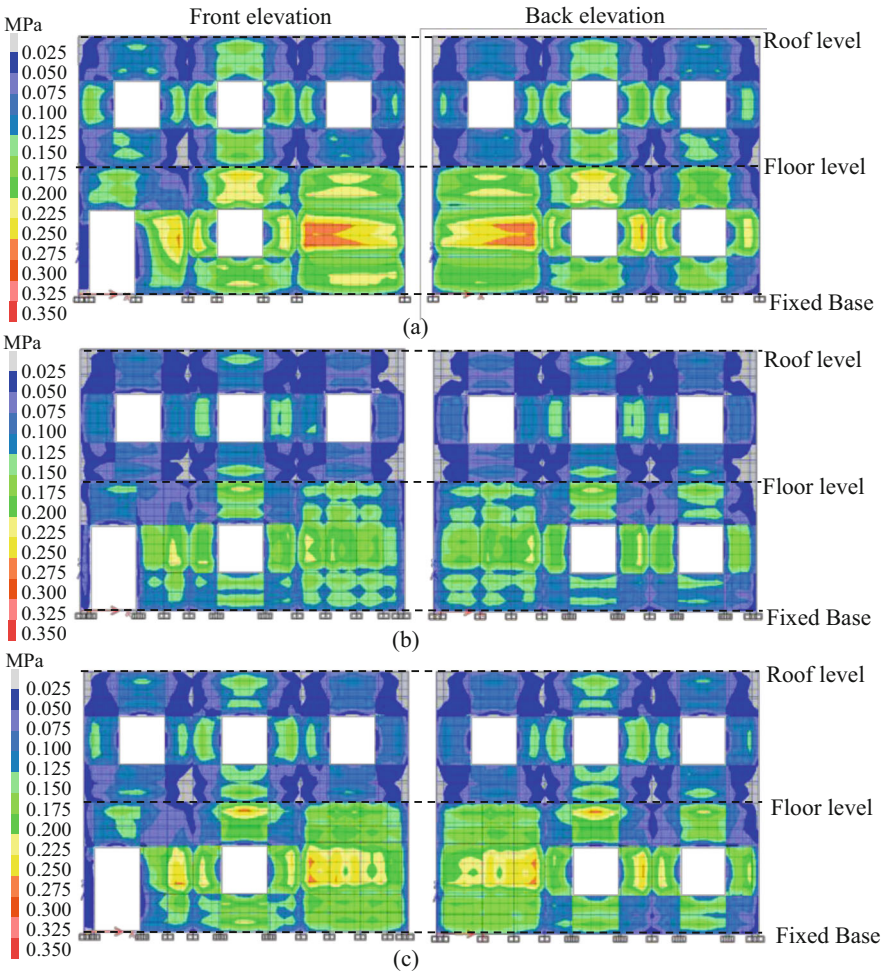

Fig. 7 In-plane shear stress (S12) in the building, (**a**) without strengthening, (**b**) with flax FRP composite, and (**c**) with coir FRP composite under the earthquake ground motion

However, to restrict the shear stress in buildings (to keep within the limit of permissible shear stress), various configurations of strengthening strategies and ways to increase in the stiffness (i.e., design dimensions, treatment of fibers) of composites are further required to be investigated as future scope of study. The design of the composites to strengthen the unreinforced masonry walls is considered as per the ACI 440 [6] recommendations, which are proposed for strengthening with synthetic FRP composites. Therefore, the same design guidelines may not work for strengthening of structures with natural fiber-based composites due to their lesser stiffness and strength than synthetic FRP composites, which reflects the need of new design guidelines for natural fiber-based strengthening techniques.

4 Conclusions

In this study, the seismic performance of two-story unreinforced masonry buildings (designed as per Nepal national building code guidelines)without and with flax and coir fiber-reinforced polymer (FRP) composite strengthening is assessed. A finite element model of the brick masonry building is developed and further, strengthened with the externally bonded FRP composites designed as per ACI 440 recommendations. Modal and time history analyses are conducted to show the efficacy of the natural fiber-based composites in strengthening structures under seismic forces, for advancing their broader adoption in earthquake-prone regions. The major conclusions drawn based on the findings of the study are listed as follows.

1. Strengthening with natural fiber-reinforced polymer composites in the form of externally bonded wrapping in a grid configuration, especially around openings of the unreinforced masonry walls of the building, as per ACI 440 guidelines, can help in reducing the seismic response of the building significantly.
2. The externally bonded wrapping with flax FRP composites for strengthening the masonry building is the most effective in enhancing the seismic resistance of the structure by reducing the base shear, peak acceleration, and stresses under earthquake ground motions.
3. The wrapping configuration in grids with the current design of flax and coir FRP composites for strengthening masonry walls is not sufficient to prevent the exceedance of in-plane shear stress compared to the permissible shear stress for unreinforced masonry under seismic load.
4. The design guidelines for strengthening of masonry structures with externally bonded synthetic FRP composites, i.e., carbon and glass FRP, may not be perfectly valid for the case of strengthening with natural FRP composites. Therefore, there is a need to develop new design standards and guidelines for strengthening masonry structures with natural fiber-based elements.

The study of integrating environmental considerations into structural engineering practices contributes to the development of sustainable strengthening methods for brick masonry structures globally.

1 Introduction

Integrating electrospun micro- and nanofibers into traditional construction materials, such as cement and lime composites, offers a promising avenue for enhancing their mechanical properties and structural integrity. Fibers with diameters in the micron and sub-micron range possess unique attributes, including elevated surface area, flexibility, and strength, making them ideal candidates for reinforcing construction

materials [1, 2]. Electrospinning, a widely utilized process for generating ultrafine fibers from various materials, is pivotal in producing micro- and nanofibers for construction applications [3].

The electrospinning process typically involves three main components: a high-voltage power supply, a polymer solution reservoir equipped with a syringe and a small diameter needle, and a conductive collector [4]. Electrospinning generates a charged polymer jet from the solution, which solidifies into microfibers upon reaching the collector surface [2]. This process can be adapted to vertical [2, 4] or horizontal setups, each offering distinct advantages in terms of fiber orientation and production efficiency [5]. Vertical setup has gained the attention of many researchers because of its simplicity and flexibility in blending fibers with cementitious materials [1, 2, 4, 6].

In construction materials, producing microfibers involves careful consideration of various parameters, including polymer concentration, solvent selection, and electrospinning parameters such as voltage, needle diameter, tip–collector distance, and flow rate. These parameters significantly influence the morphology and properties of the resulting microfibers. For instance, higher polymer concentrations produce thicker fibers, while lower flow rates result in thinner fibers with greater polarization [5]. Additionally, the distance between the needle tip and collector surface is crucial in facilitating proper fiber formation and evaporation of solvent [5, 7].

The literature shows that researchers have used a variety of polymers to produce micro- and nanofibers and blend them with cement to increase the mechanical properties, for instance, Nylon 66. The addition of Nylon 66 has been credited with an increase of 41% and 33% in tensile strength and compressive strength, respectively [8]. Other studies reported that Nylon 66 could increase tensile and compressive strength by 25%, 75%, and 7% respectively [1].

This study focuses on understanding and optimizing the electrospinning parameters essential for tailoring microfiber-reinforced composites to specific construction applications by systematically investigating production methods and materials for creating electrospun microfibers. Furthermore, different blending processes between microfibers and cementitious materials are examined and compared. Finally, results from preliminary mechanical tests are reported, analyzing the resulting structural and mechanical properties of microfiber-reinforced cement composites.

2 Materials

2.1 Chemicals and Reagents

The micro-fibers used in this study were obtained by electrospinning using the polymer Cellulose Acetate (CA) (Sigma-Aldrich, from Schnelldorf Distribution density: 1.3 g/ml). Acetone, $(CH_3)_2CO$, was the solvent used in the electrospinning process to obtain cellulose acetate fibers (VWR International, density: 0.792 g/ml).

In addition to CA, the literature indicates that several other polymers are promising candidates for the reinforcement of cement materials. The choice of CA for this study, over other relevant chemicals, is due to safety constraints since the use of alternative polymers required the use of toxic solvents, which was not feasible in the laboratory premises available for this work.

2.2 Solution of CA

The CA solution was prepared by dissolving cellulose acetate into acetone. The CA solution was prepared following the work of [9]. During the electrospinning process, the coagulation of the solution at the emitter tip was observed. Multiple studies have observed coagulation during electrospinning with CA solutions. To mitigate this issue, this study followed the suggestion of increasing the viscosity of the solutions, as found in the literature [5, 9].

2.3 Cementitious Composite

The cement used in this experiment to make a cement-CA electrospun microfiber composite material was an industry-grade binder known as "CEM I 52.5 R" from Heidelberg Material AS (NORCEM). This binder has an early-stage compressive strength of 52.5 MPa and meets NS-EN 197-1 standard.

3 Experimental Apparatus and Methods

3.1 Electrospinning Experiments

Microfibers are created using an electrospinning system manufactured by the company Bioinicia Fluidnatek, model number P 2022623-P1, equipped with an internal power supply. The liquid solution is transferred from a syringe to the electrospinning source, specifically to the needle's tip, through a capillary tube using a pumping device from Kd Scientific, allowing careful flow rate control (Fig. 1).

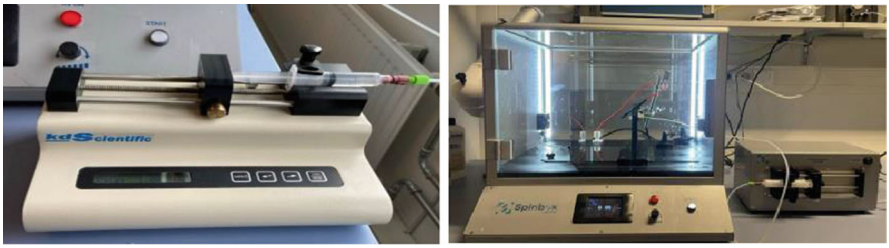

Fig. 1 Electrospinning system: (**a**) syringe pump and (**b**) electrospinning chamber, controlling the flow rate in the experiment

Table 1 The parameters tested with various gauge numbers

Test	List of parameters tested	Gauge number
1	12.5 g CA solution for flow rate effect	G15
2	12.5 g CA solution for flow distance effect	G15
3	12.5 g CA solution for flow voltage effect	G15
4	12.5 g CA solution for flow rate effect	G18
5	12.5 g CA solution for flow distance effect	G18
6	12.5 g CA solution for flow voltage effect	G18
7	12.5 g CA solution for flow rate effect	G21
8	12.5 g CA solution for flow distance effect	G21
9	12.5 g CA solution for flow voltage effect	G21

Standard stainless-steel needles are used as electrospinning emitter tip, with various gauges, including G15, G18, and G21. The solution was prepared by dissolving 12.5 g of CA in 100 ml of acetone. A summary of the tests that were conducted is presented in Table 1.

3.2 Mixing of Fibers and Cement

This study employed two different methods for mixing fibers and cement powder, to check the effect of the mixing approach on the resulting composite. For this purpose, experiments with two distinct collectors for the fiber were conducted.

The first approach entailed the collection of fibers over a flat surface, particularly a flat aluminum foil horizontally located beneath the vertically installed emitter, grounding the foil. Subsequently, a layer of 30 g cement was applied over the aluminum, followed by the spraying of fibers atop the cement layer. Another 30 g layer of cement was then applied over the fibers, which was iteratively repeated. See Fig. 2a.

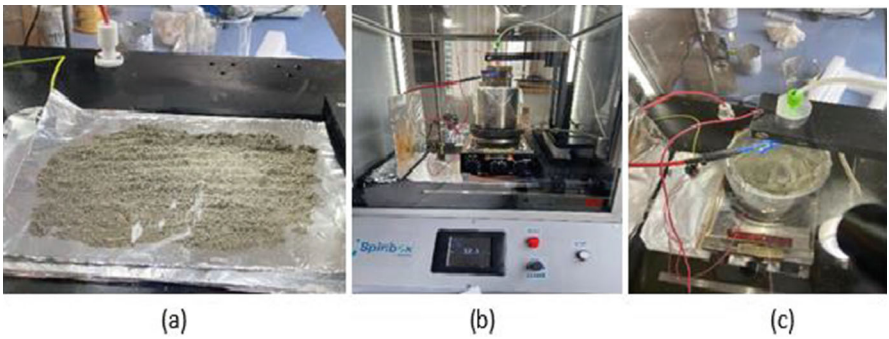

Fig. 2 (**a**) First mixing approach, mixing CEM I and fiber horizontally over aluminum foil; (**b**) and (**c**) second mixing method, involving a metal bowl collector on a magnetic stirrer

Fig. 3 The outcome of combining fiber and cement using a magnetic stirrer

The second fiber collection method involved using a metal bowl collector placed on top of a magnetic stirrer machine. The top of the bowl was covered with plastic to keep the fibers from adhering to its sides. This arrangement allowed for the effective mixing of the fibers with the cement powder. The fibers were collected at the bottom of a negatively charged cylindrical stainless steel bowl, where a 50 mm long magnetic stirrer rotated at 500 rpm [10], as illustrated in Fig. 2b, c.

3.3 Optical Microscope

A compound microscope, specifically the OLYMPUS GX71 model, examines the fibers and measures their diameter following the production process (Fig. 3).

3.4 Mixing and Casting of Fiber–Cement Composite Samples

Mechanical Testing Sample Preparation In compressive testing, specimens are commonly in the form of cubes measuring 50 mm on each side. These size

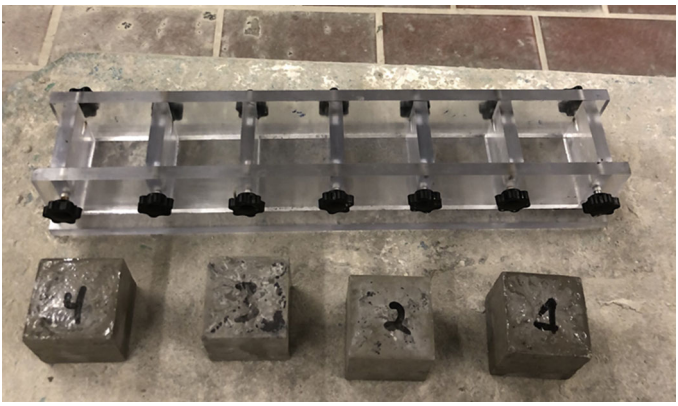

Fig. 4 Sample preparation for compressive test

specifications align with the Norwegian Standard NS-EN 196-1:2016 guidelines for testing cement. The mold and samples used in this experiment are presented in Fig. 4.

As mentioned, this experiment used two methods to mix the fiber with the cement. Three samples were prepared when mixing fiber and cement powder, and the CA fiber content was 0.1 wt% and 0.5 wt%.

Mixture of Cement and Water The casting and curing process of the cement powder/fiber and water mixture involves several steps outlined in the Norwegian standard NS-EN 196-1:2016. The ingredients are mixed according to the specified experimental ratio and method to ensure consistency and quality, with a water-to-binder ratio of 0.5 chosen to maintain consistency with prior research and facilitate comparison with existing literature [1, 2, 6]. Following mixing, the mixture is poured into a mold and left to cure for 24 hours. After this initial curing period, the mold is removed, and the specimen undergoes immersion in water for 7 days for compressive testing in accordance with standard requirements. This curing process is crucial for the cement mixture to achieve its maximum strength and durability, rendering it suitable for various applications, including construction.

3.5 Testing

Compressive Strength Test The compressive strength of cubic samples of fiber–cement composite was tested using a FORM+TEST Prufsysteme machine with a maximum load capacity of 200 kN. The machine determined the compressive strength of the 50 × 50 mm samples by subjecting them to a maximum load across their cross-sectional area.

The work reported in this chapter contains the preliminary results of a larger ongoing project, where additional mechanical testing is planned to be conducted. This will extend testing to bending test, providing a more holistic understanding of the impact of fiber blending in the cement material.

4 Results and Discussion

4.1 Effect of Production Parameters in Electrospun Fibers

Various electrospinning parameters, including polymer solution concentration, emitter voltage, working distance between emitter and collector, and solution flow rate greatly influence polymer fibers' morphology and cross-section diameter. Investigating these parameters is crucial for optimizing the electrospinning process of cellulose acetate and achieving fiber formation without bead defects and with a controlled diameter.

A systematic approach is adopted to assess the thickness of the fibers. Initially, fibers are electrospun directly onto a horizontally positioned aluminum base beneath the emitter (needle). Subsequently, samples are quickly transferred to an optical microscope for immediate evaluation, allowing for observing parameter-induced effects on fiber structure. The graphs below (Figs. 5, 6 and 7) represent the average data collected from each test. We selected ten different locations for each test and measured the fiber diameter. Then, we calculated the average of these measurements to determine the average diameter of the fiber sample.

Furthermore, an aluminum foil is positioned atop an inverted microscope for careful examination. Utilizing a magnification level of 100x, fibers are examined and

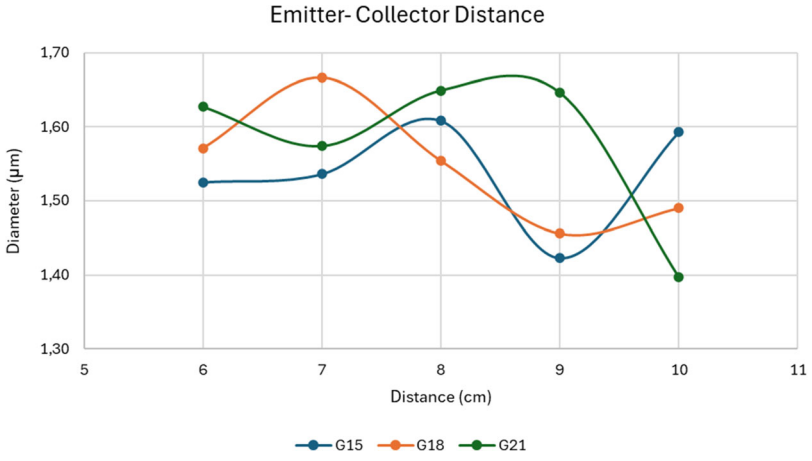

Fig. 5 The effect of the distance between the emitter and the collector on fiber diameter using different gauges

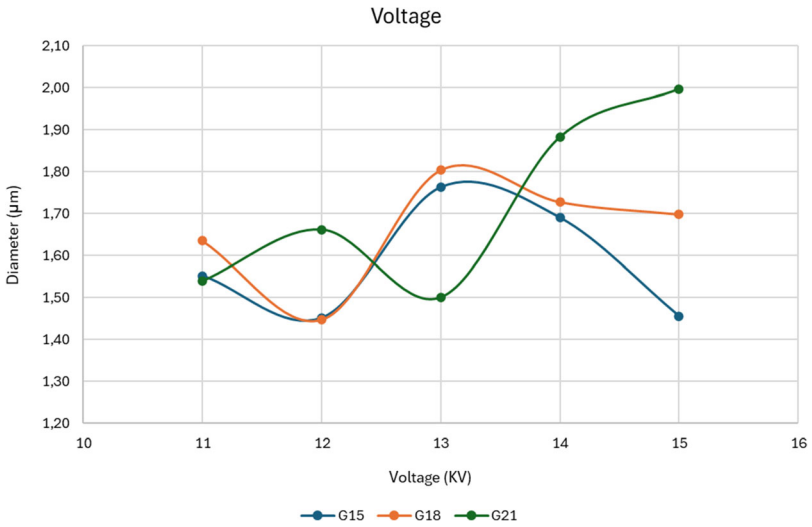

Fig. 6 The effect of the emitter voltage on fiber diameter using different emitter tip gauges

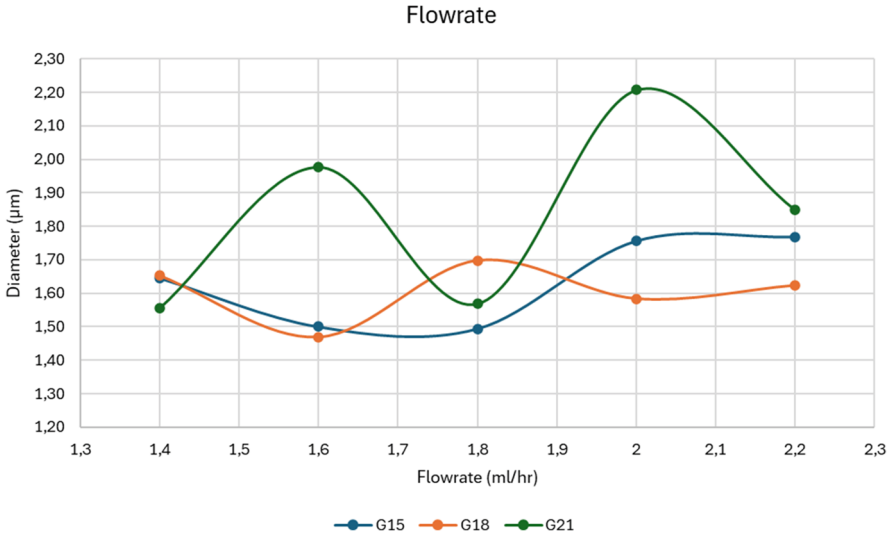

Fig. 7 Flow rate effect on fiber diameter using different gauges

measured with precision. This careful process ensures comprehensive data collection for subsequent analysis, facilitating the identification of optimal electrospinning conditions.

Distance The data analysis reveals insights into the relationship between emitter–collector distance and average fiber diameter across different gauge sizes (G-15, G-18, and G-21). Overall, variations in emitter–collector distance appear to influence

average fiber diameter differently depending on the gauge used. For G-15 and G-18, slight fluctuations in average fiber diameter are observed as the emitter–collector distance decreases from 10 cm to 6 cm. These fluctuations suggest a relatively consistent response to emitter–collector distance changes, with both gauges showing comparable trends. In contrast, G-21 exhibits more pronounced changes in average fiber diameter with decreasing emitter–collector distances. The data indicates that larger emitter–collector distances significantly decrease the average fiber diameter for G-21 compared to G-15 and G-18. This suggests that the effect of emitter–collector distance on fiber diameter may vary depending on the specific properties of the polymer solution and the electrospinning process, highlighting the importance of careful parameter optimization for achieving desired fiber characteristics.

Voltage The data provided represents the average fiber diameter for three different gauge sizes (G-15, G-18, and G-21) at varying emitter voltage levels during microfiber production. Across all gauge sizes, there is a notable variation in average fiber diameter as the voltage changes.

For G-15, there is a fluctuating trend in average fiber diameter as voltage increases from 11 to 15. While there is a general increase in average fiber diameter from 11 to 13 KV, it decreases at 14 KV and then slightly increases again at 15 KV.

For G-18, there is a similar fluctuation in average fiber diameter with changes in voltage. However, the trend is less pronounced than G-15, with more subtle changes observed.

For G-21, there is a more erratic pattern in average fiber diameter as voltage increases. While there is an initial decrease in average fiber diameter from 11 to 12 KV, it then increases sharply at 13 KV before decreasing again at 14 KV and then increasing once more at 15 KV.

Overall, the data suggests that voltage plays a significant role in determining the average fiber diameter during microfiber production, but the relationship is complex and varies depending on the specific gauge size. Further analysis and experimentation may be necessary to fully understand and optimize the relationship between voltage and fiber diameter for each gauge size.

Flow Rate The data suggests that the flow rate influences the fiber diameter during microfiber production and varies across gauge sizes (G-15, G-18, and G-21).

For G-15 and G-18, a flow rate of 1.6 leads to a smaller average fiber diameter compared to adjacent flow rates of 1.4 and 1.8. However, no clear trend was observed for the average fiber diameter at other flow rates for both G-15 and G-18.

In contrast, for G-21, a flow rate of 1.6 results in a significantly larger average fiber diameter compared to adjacent flow rates of 1.4 and 1.8. Similar to G-15 and G-18, there are fluctuations in the average fiber diameter at other flow rates for G-21.

Overall, the effect of flow rate on average fiber diameter varies depending on the gauge size. Further analysis and experimentation are needed to optimize the flow rate and fiber diameter relationship for each gauge size.

The main objective is to create microfibers using CA and explore how they improve hardened cement paste's mechanical properties. The smaller the diameter of the fiber in micrometers, the closer it is to our target microfiber-sized fiber diameter.

The impact of distance, voltage, and flow rate on fiber diameter was investigated using different gauges. Results indicate that a smaller diameter is achieved at a distance of 10 cm, while a better diameter is attained at 12 kV voltage. The optimal flow rate for achieving better fiber diameter is 1.6 ml/h. When all three parameters are applied, gauge G-18 exhibits the best results for fiber diameter (the smallest possible diameter, close to the nanometer range). Consequently, for further investigation in compressive testing, parameters including a flow rate of 1.6 ml/h, an emitter–collector distance of 10 cm, and a voltage of 12 kV are selected. Moreover, G-18 was chosen for production based on its superior fiber diameter performance.

4.2 Compressive Strength

The compressive strength of cement samples was evaluated after a 7-day curing period, with varying percentages of CA fibers. The reference sample, conformed by cement without fiber reinforcement, exhibited a compressive strength of 14.2 MPa. See Fig. 8.

Incorporating 0.5% CA fibers resulted in a notable increase in compressive strength, reaching 16.3 MPa. This represents a percentage increase of approximately 15.5% compared to the reference sample.

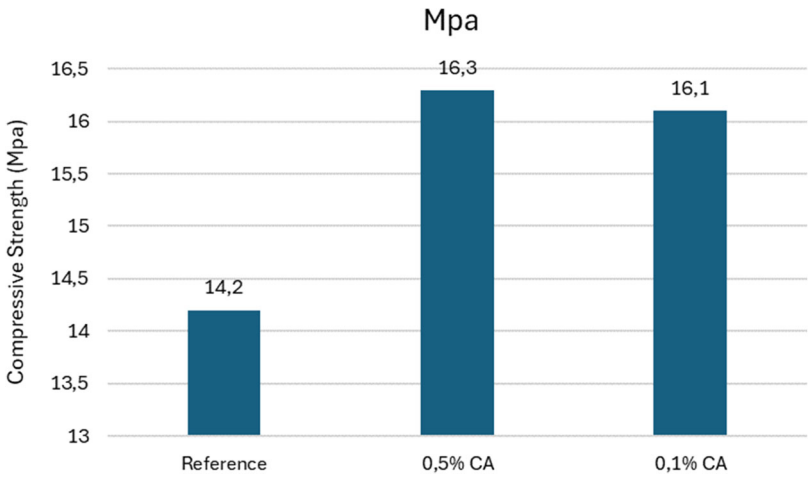

Fig. 8 Compressive strength of specimens after 7 days

Similarly, at a lower fiber concentration of 0.1% CA, the compressive strength remained high at 16.1 MPa. This corresponds to a percentage increase of about 14.6% compared to the reference sample.

These findings show CA fibers' effectiveness in enhancing cementitious materials' compressive strength, even after a relatively short curing period of 7 days. The significant percentage increases in compressive strength indicate the substantial reinforcement CA fibers provide within the cement matrix.

The results suggest that even at lower fiber concentrations, considerable improvements in compressive strength can be achieved within a relatively short time frame. This highlights CA fiber reinforcement's cost-effectiveness and potential applicability in cement-based materials.

5 Conclusion

The addition of CA fibers offers a viable means of enhancing the mechanical properties of cement composites, with notable percentage increases in compressive strength observed at both 0.5% and 0.1% fiber concentrations after 7 days. Further research could explore optimal fiber percentages and their effects on other mechanical properties to fully leverage the benefits of CA fiber reinforcement in cementitious materials.

This study represents an initial exploration, highlighting the need for further research to thoroughly examine the morphological features of CA through scanning electron microscopy (SEM).

1 Introduction

Functional building materials and additives in products like adhesives and paints can significantly improve indoor air quality, lower emissions, and manage water absorption. Porous materials, including lightweight aggregates or rigid polyurethane foams and expanded lightweight clay (LECA), are shown to enhance thermal insulation in concrete, potentially increasing thermal efficiency by up to 50%. Studies point to lightweight concrete with LECA or perlite as effective alternatives for improving thermal performance [1–5].

The rising energy demand and increasing CO_2 emissions highlight the urgent need for sustainable building solutions. Innovations such as phase change materials (PCMs) and hygroscopic materials (HMs), like lightweight concrete—which can absorb and retain more moisture than conventional concrete—are pivotal in wall technologies. These materials enhance thermal storage and regulate humidity,

M. Kioumarsi, B. Shafei (eds.), *The 1st International Conference on Net-Zero Built Environment*, Lecture Notes in Civil Engineering 237,
https://doi.org/10.1007/978-3-031-69626-8_35

resulting in significant energy savings and a reduction in greenhouse gas emissions. By improving the building's ability to maintain stable indoor temperatures and moisture levels, HMs reduce the reliance on heating, cooling, and ventilation systems, thereby lowering energy consumption and the building's overall carbon footprint [5–8].

Integrating PCMs and HMs into buildings provides a unique temperature and humidity control method, enhancing energy efficiency and performance without relying on mechanical systems. This strategy utilizes the thermal storage and phase change capabilities of PCMs, along with the moisture regulation of HMs, supporting sustainable construction and comfort standards. Techniques like shape-stabilized PCM (SSPCM) and microencapsulated PCM (MPCM) have been developed to address PCM leakage, highlighting the growing focus on hygrothermal performance to manage indoor humidity, health, building longevity, and energy use effectively [9–15].

Concrete deformation caused by heat and moisture can lead to cracking, reducing durability and thermal efficiency. Temperature changes lead to thermal stresses and shrinkage, while moisture induces volume changes, creating internal stresses that can cause cracks. These cracks allow external agents to penetrate, accelerating deterioration and reducing concrete's service life. Furthermore, cracks compromise concrete's effectiveness as a thermal mass in buildings, disrupting its heat storage and release capabilities, thereby diminishing building energy efficiency [15–21].

The importance of analyzing hygrothermal performance in building materials has become critical for ensuring indoor comfort. This study aims to enhance lightweight concrete by adding a PCM layer into walls or ceiling, improving heat insulation, water absorption, and storage. While lightweight concrete has benefits like sound insulation and fire resistance, risks include shrinkage, mold growth, and ventilation issues, affecting health and durability. Investigating hygrothermal performance is essential for a moisture-problem-free and comfortable indoor environment.

This research aims to address the gap in studies on hygrothermal performance at normal temperatures by investigating the effects of applying a PCM layer on walls in comparison to uncoated walls, particularly in response to heat and thermal variations over time. Experimental methods are used to evaluate shrinkage, water absorption, and thermal conductivity under humidity-induced stress and hygrothermal deformation in concrete. This approach enhances the understanding of lightweight concrete behavior and encourages the integrated use of construction materials, including PCMs, to optimize building performance.

2 Materials and Setups

This study investigates glycerin's effectiveness as a PCM in improving the energy efficiency of lightweight concrete walls. Using experimental and analytical methods, this study examines the insulation benefits of a glycerin wax layer across temperature variations, guided by Hundt's parameters. Figure 1 shows the experiments that

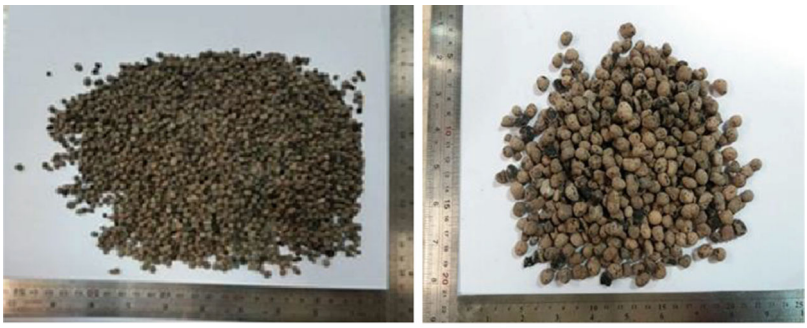

Fig. 1 (**a**) Fine LECA and (**b**) coarse LECA

Table 1 Chemical composition of Portland limestone cement and LECA

Chemical composition (% by mass)	PLC	Expanded clay (LECA)
SiO_2	18.69	63.60
Al_2O_3	3.78	16.70
Fe_2O_3	2.77	6.45

MgO	1.67	3.85
Na_2O	0.17	1.24
K_2O	0.56	2.85
SO_3	2.80	0.18
LOI	6.50	1.40

employ Portland limestone cement Type 1L (ASTM C 595) and lightweight LECA aggregates (Table 1), aiming to capture glycerin's role in energy conservation for residential settings.

In addition to lightweight aggregates, this study uses ordinary aggregates, natural sand, and crushed pea gravel (with grains passing through a 1/2 inch diameter). Table 2 outlines the properties and gradation of these aggregates. A high-range water reducer (HRWR), with a 35% solid content and a density of 1.1 g/cm^3 at 20 °C, was added to enhance mix flowability.

Glycerin, a highly effective phase change material (PCM), significantly enhances the thermal performance of building walls by utilizing its latent heat during phase transitions. It solidifies at about 17 °C and melts just above this, at 18 °C, making it ideal for stabilizing indoor climates—refer to Fig. 2 for two phases of glycerin. With a melting enthalpy of approximately 200 kJ/kg, glycerin can store and release substantial amounts of heat, thereby maintaining stable temperatures. Its properties include a high viscosity that decreases with temperature and a density of about 1260 kg/m^3. Additionally, its non-toxic nature makes glycerin a safe and efficient choice for thermal regulation in construction. The thermal characteristics of glycerin are summarized in Table 3.

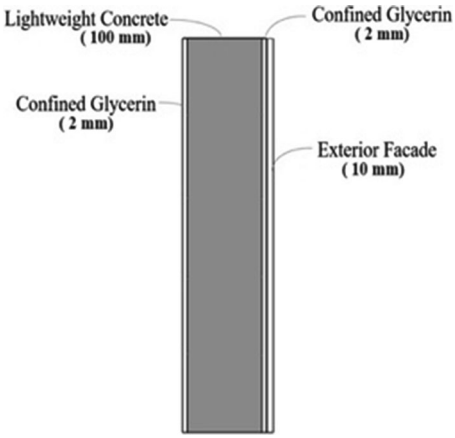

Fig. 3 Cross-section of a lightweight concrete wall with a 2 mm layer of glycerin-based PCM confined on the exterior façade

Glycerin's molecular structure, $C_3H_8O_3$, with three hydroxyl groups, boosts its thermal energy absorption and retention, making it a stable and eco-friendly PCM for enhancing building energy efficiency.

The structural lightweight concrete was produced with a water-to-cement ratio of 0.4, as mix design detailed in Table 4. Samples cured for 28 days at 20 °C demonstrated a compressive strength exceeding 30 MPa, confirming their suitability for both non-structural and structural wall applications. In our experiments, we assessed conductive heat transfer through lightweight concrete, which is influenced by factors such as temperature gradient, material thickness, and thermal conductivity. Additionally, drying shrinkage and water absorption tests were conducted to evaluate moisture loss and the moisture retention capabilities of lightweight walls with and without a PCM layer. Figure 3 illustrates a cross-section of a lightweight concrete wall featuring a 2 mm layer of glycerin-based PCM confined on the exterior façade. The experimental results evaluate the PCM's phase change contribution to both thermal and moisture resistance in the wall. This provides valuable insights for optimizing wall designs to improve thermal efficiency under varying heat loads, ultimately enhancing strategies for better energy efficiency (Fig. 3).

3 Test Methods

In the experimental program, three distinct test methods were employed to evaluate the hygrothermal properties of lightweight concrete samples, which included both samples with and without PCM applied to their surfaces. The hygrothermal properties of the lightweight concrete samples were evaluated using three distinct test methods, examining samples with and without PCM applied to their surfaces. The first method, focusing on drying shrinkage, adhered to the ASTM C596 standard for small prisms measuring 25 × 25 × 285 mm. Comparative readings and calculations were conducted following ASTM C157, with the length change of each specimen determined daily for up to 42 days, using Eq. (1).

$$\varepsilon_{\text{dry}} = \frac{l_{(t)} - l_{(t_o)}}{l_{(t_o)}} \times 10^6 \mu \frac{m}{m} \tag{1}$$

where $l_{(t)}$ is the length of the sample at the measured time t, and $l_{(t_o)}$ is the specimen's initial length at 72 h.

The second method assessed capillary water absorption based on ASTM C1585. Before water contact, the initial weight of the specimen was obtained from Eq. (2):

$$I_c = \frac{m_t - m_o}{A_c} \tag{2}$$

where I_c represents the mean water absorption rate in mm. A_c denotes the water-contact surface area of the specimen in mm^2. ρ_c is the water's density in g/mm^3.

To measure the thermal conductivity of lightweight high-performance concrete (LWHPC), the hot plate method from BS EN 12664 was applied after 35 days. Specimens of 300 × 300 × 50 mm were dried for 24 h at 105 ± 5 °C and then subjected to temperatures of 40 and 18 °C on hot and cold plates, respectively. Temperature was recorded every 10 min daily, and these readings were averaged to calculate thermal conductivity. This method provided detailed insights into LWHPC's thermal efficiency and moisture management.

4 Results and Discussion

4.1 Drying Shrinkage

Applying a 0.5 mm glycerin layer to lightweight concrete specimens significantly reduces drying shrinkage over time, as shown in Fig. 4. This reduction, compared to control samples without glycerin PCM, is due to glycerin's water retention within the concrete, acting as a barrier that decreases evaporation and shrinkage. The

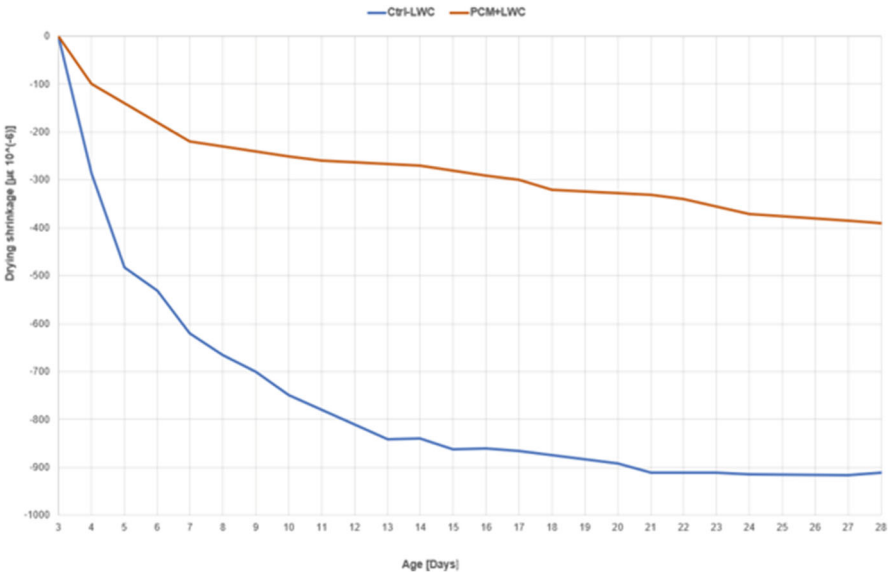

Fig. 4 Comparative drying shrinkage for Ctrl-LWC and PCM+LWC

glycerin layer counters the high porosity of lightweight aggregates, which typically leads to more shrinkage by promoting better moisture retention. This aids the internal curing process, improving hydration and the concrete's overall characteristics. Additionally, glycerin PCM as a curing aid ensures a more even drying rate, essential for maintaining the concrete's durability and preventing defects like cracks.

4.2 Capillary Water Absorption

The data indicate that integrating a PCM into lightweight concrete (LWC) substantially reduces its water absorption at various testing intervals (3, 7, and 28 days) compared to control lightweight concrete without PCM (Ctrl-LWC), as illustrated in Fig. 5. This reduction in water absorption suggests that PCM addition not only impedes water ingress by blocking the pathways within the lightweight aggregate's cavities, but also modifies the concrete's pore structure. These changes enhance the concrete's resistance to water penetration and could potentially improve its durability and thermal properties.

The addition of PCM to lightweight concrete (LWC + PCM) significantly enhances its resistance to moisture by drastically reducing the capillary water absorption rate by approximately 86% compared to control lightweight concrete (Ctrl-LWC), as shown in Table 5. This improvement highlights PCM's effectiveness in minimizing water ingress in porous construction materials.

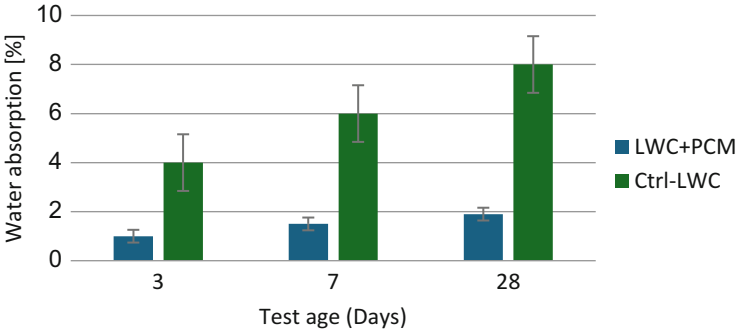

Fig. 5 Comparative percentage of water absorption for Ctrl-LWC and PCM+LWC at different ages

Table 5 Comparative capillary water absorption rates for Ctrl-LWC and PCM+LWC specimens at 28 days

Mix ID	Capillary water absorption rate ($m/s^{1/2}$)
Ctrl-LWC	7.90×10^{-6}
PCM+LWC	1.10×10^{-6}

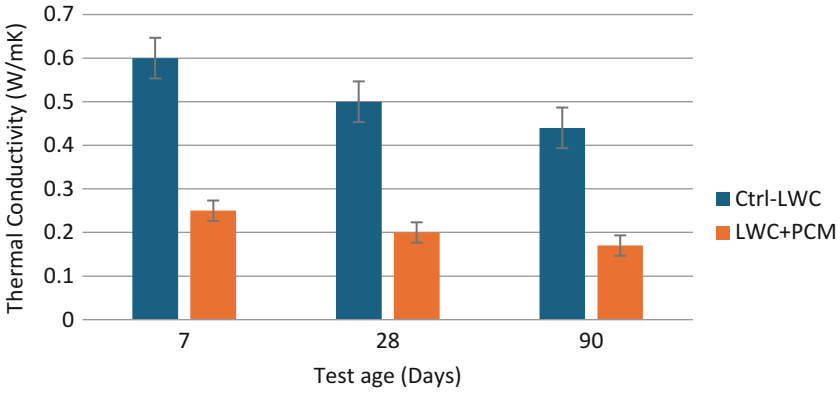

Fig. 6 Comparative thermal conductivity for Ctrl-LWC and PCM+LWC specimens at different ages

4.3 Thermal Conductivity

Figure 6 shows that lightweight concrete with glycerin PCM significantly reduces thermal conductivity, enhancing thermal resistance and insulation, which is especially beneficial in cold climates. Thermal conductivity drops by 71–76% across testing periods, attributed to glycerin's latent heat storage, moderating temperature fluctuations. This improvement supports energy conservation by stabilizing indoor temperatures and minimizing heating and cooling needs.

5 Conclusions

This study has demonstrated that applying a 2 mm layer of glycerin as a phase change material to lightweight concrete significantly enhances its hygrothermal performance and sustainability.

1 Introduction

The construction sector currently represents 43% of the annual energy consumption in France and contributes significantly, accounting for 23% of greenhouse gas emissions [20]. This makes it a major player in climate change within the sector. Globally, the construction industry is the second-largest contributor to CO_2 emissions, trailing only the transportation sector [15]. Given the urgent need for an ecological transition, there is a crucial necessity to innovate and decarbonize the entire construction sector. Experts suggest a promising solution: Transitioning construction systems toward the adoption of biobased materials, which are notably less environmentally impactful than traditional materials and are already transforming our construction practices.

Biobased materials, derived from biomass and animals such as wood, wool, hemp [6], flax [7], seaweed [2], miscanthus [18], sunflower [1], etc., offer distinct advantages over traditional concrete materials. Unlike traditional concrete, which requires significant amounts of carbon-intensive energy for manufacturing (such as grinding and thermal processing), the production of biomaterials involves minimal energy quantities. Moreover, these materials have the unique ability to serve as carbon sinks, as they can store the CO_2 emitted into the air throughout their life cycle. This means that certain buildings constructed with biobased materials can absorb more CO_2 than they emit, contributing positively to carbon neutrality efforts.

One of the key advantages of biobased materials is their potential for regular and infinite recycling [14]. Unlike traditional materials that often end up as waste in landfills, biobased materials can be reused or reintegrated into natural cycles, such as composting. This not only reduces waste but also minimizes the environmental impact associated with the disposal of construction materials [16]. Additionally, the recyclability of biobased materials supports the principles of circular economy, where resources are continuously reused, ultimately leading to a more sustainable and resource-efficient construction industry.

Furthermore, biobased materials offer versatility in design and application, allowing for innovative and environmentally friendly construction solutions. With advancements in material science and technology, biobased materials can now meet the performance requirements of various construction applications while offering environmental benefits. From insulation and structural components to finishing materials and furniture, biobased materials offer a wide range of options for sustainable building design [9].

Overall, the use of biobased materials in construction presents a promising pathway toward reducing carbon emissions, minimizing waste generation, and promoting sustainable practices in the built environment. By harnessing the benefits of biobased materials, the construction industry can play a significant role in mitigating climate change and transitioning toward a more sustainable future.

In order to achieve a low-carbon footprint material, we are incorporating various biobased materials, such as hemp and flax fibers, in combination with different types of hydraulic binders, namely, natural prompt cement and CL 90-S air lime. This study aims to analyze the influence of these two types of binders and two types of biobased aggregates on the material's variability concerning:

Physical and mechanical properties

- Porosity accessible to water (according with the standard NF EN ISO 5017 [23])
- Compressive strength

Thermal properties

- Thermal conductivity (according with the standard ISO 8301 [21])
- Specific heat capacity (according with the standard NF EN ISO 11357-4 [22])

2 Materials and Methods

2.1 Materials

In the context of this research, natural prompt cement and air lime CL 90-S were used for our mixtures. The physical, mechanical, and thermal properties of biobased aggregates play a crucial role in defining the characteristics of insulating concrete. Hemp and flax shives were chosen with a length between 5 and 25 mm, as illustrated in Fig. 1. The data in Table 1 provide detailed information on the physical properties (bulk density measured according to RILEM TC 236-BBM [3]), hydric properties (water absorption measured according to RILEM TC 236-BBM [3]), thermal properties (thermal conductivity measured according to ISO 8301 [21], and mass-specific heat capacity measured according to NF EN ISO 11357.4 [5]) of the biobased aggregates examined in this study. The obtained results are consistent with the literature [3–5, 12]. Additionally, the accompanying Table 2 presents the properties of the binders used in this study.

The objective of this study was to explore the physical, mechanical, and thermal properties through four distinct formulations: cement/hemp, lime/hemp, cement/flax, and lime/flax. Biobased aggregates are widely recognized for their excellent thermal and hydric properties. The aim of this study was to develop a material with insulation properties, both thermal and hydric. With the aim of achieving these objectives, a substantial amount of plant aggregates was deliberately included to enhance these properties. The chosen percentages align with the compositions

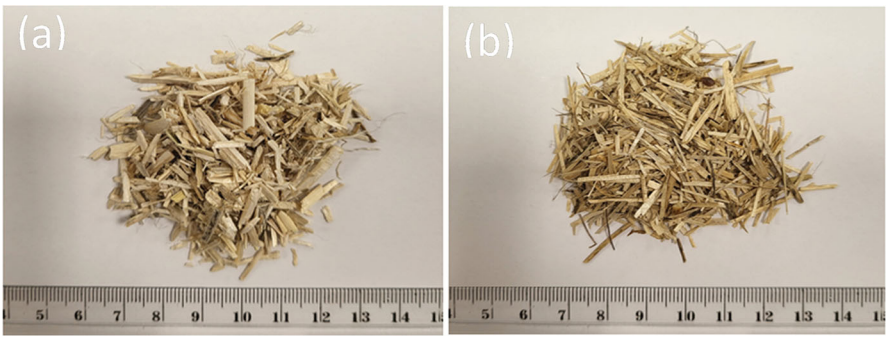

Fig. 1 (**a**) Hemp shives and (**b**) flax shives with a diameter between 5 and 25 mm

Table 1 Mechanical, thermal, and hydric properties of hemp and flax shives

Mixture	Bulk density (kg/m^3)	Water absorption (%)	Thermal conductivity ($W \cdot m^{-1} \cdot K^{-1}$)	Specific heat capacity ($J/(kg \cdot k)$)
Hemp shives	129.57 ± 3.62	363.54 ± 4.86%	0.0529 ± 0.0023	2925.67 ± 111.15
Flax shives	105.52 ± 5.99	334.37 ± 17.83%	0.0472 ± 0.0016	3149 ± 67.26

Table 2 The physical and mechanical properties of low-carbon binders

Low-carbon binder	Bulk density (kg/m^3)	Blaine specific surface (cm^2/g)	Compressive strength at 24 h (MPa)	Compressive strength at 9 months (MPa)	References
Natural prompt cement	2980	7600	7.8	40	[24]
Air lime CL 90-S	450	13,260	–	2.5	[19]

Table 3 Composition of the mixture

Formulations	Prompt natural cement (kg/m^3)	Air lime CL 90-S (kg/m^3)	Hemp shives (kg/m^3)	Flax shives (kg/m^3)	Water (kg/m^3)
C100H	250	–	116	–	271
L100H	–	250	116		271
C100F	250	–	–	116	271
L100F	–	250	–	116	271

derived from the studies of Benmahiddine et al. [4], and they also adhere to the guidelines recommended by Vicat. Consequently, the formulations will include the addition of 46.5% of the binder mass in the form of plant aggregates while keeping the water quantity constant and maintaining a water-to-cement ratio of 1.08. Specific compositions for each mixture are detailed in Table 3.

Physical assessments (open porosity) were conducted using samples ranging from 50 to 200 cm^3 following the NF EN ISO 5017 standard [23]. Additionally, cubes measuring 150 × 150 × 150 mm^3 were used to evaluate compressive strength, and prismatic panels measuring 200 × 200 × 40 mm^3 were employed for thermal tests, assessing thermal conductivity according to ISO 8301 [21] and mass-specific heat capacity according to the NF EN ISO 11357-4 standard [22].

The mixing process begins by first placing the components (2.15-kg binder and 1-kg biobased aggregates). These elements are manually mixed for 30 seconds. Then, half of the water quantity is added, which is 1.161 kg, and the mixture is manually stirred for an additional 30 seconds. Finally, the remaining water (1.161 kg) is introduced, and the mixing process is repeated for 30 seconds before initiating the mold filling.

The fabrication of cubic and prismatic samples follows an identical procedure. Initially, the mold is filled one-third full to form the initial layer. Subsequently, compaction is carried out 30 times using a wooden stick for both this layer and the two subsequent layers. To achieve a smooth surface, horizontal compaction is applied during the final layer of the pouring process.

2.2 Methods

2.2.1 Physical Properties

Porosity accessible to the water test: This method is based on Archimedes' principle [13], as specified in the NF EN ISO 5017 standard [23]. The process involves vacuum saturation for 24 hours of three samples from each formulation. The mass of the samples saturated with water and in the air are then measured for the calculation of porosity, following Eq. (1).

$$\mathrm{Pa}(\%) = \frac{M_{\mathrm{air}} - M_{\mathrm{dry}}}{M_{\mathrm{air}} - M_{\mathrm{water}}} \times 100 \tag{1}$$

The variable "Pa" represents the water-accessible porosity in percentage. Other terms include "M_{air}" for the sample mass after air saturation in kilograms, "M_{water}" for the mass of the sample saturated and immersed in water in kilograms, and finally, "M_{sec}" for the mass of the dry sample, obtained after drying at 60 °C with mass monitoring, also measured in kilograms.

2.2.2 Mechanical Properties

Compressive strength test: In order to study this parameter, three cubic samples measuring 150 × 150 × 150 mm^3 of each formulation were utilized. Compressive strength tests were conducted on three of these samples after a period of 28 days. The tests took place on an IGM press with a constant speed rate of 0.3 mm/minute.

2.2.3 Thermal Properties

Thermal conductivity: The thermal conductivity was investigated using a NETZSCH heat flow meter (model HFM 446 Lambda). The sample, with parallelepiped dimensions of 200 × 200 × 40 mm^3, is positioned between the cooling plate and the heating plate according to the ISO 8301 standard [21].The thermal conductivity value is calculated using the following equation:

$$\lambda = (q\Delta T)/\Delta X \tag{2}$$

where

λ: Thermal conductivity of the sample
q: Heat flux
ΔT: Temperature difference across the sample
ΔX: Thickness of the sample

Specific heat mass: Mass-specific heat capacity (Cp) is a crucial parameter indicating a material's ability to store heat. In this study, the specific heat capacity of the 200 × 200 × 40 mm^3 samples is tested within a temperature range of 15–25 °C according to the NF EN ISO 11357-4 standard [22]. The value of the mass-specific heat capacity Cp is calculated using the following equation:

$$Q = M \times C \times \Delta T \tag{3}$$

where

Q: Heat quantity in kilojoules
M: Processed mass in kilograms
C: Specific heat in [kJ/kg °C]

3 Results and Discussion

3.1 Physical and Mechanical Properties

Porosity accessible to water and compressive strength: Concrete incorporating biobased aggregates is distinguished by its high level of porosity, attributed to the significant absorption of these aggregates. The drying process leads to the formation of voids, resulting in a notable increase in porosity [5, 17]. Figure 2 presents the results of porosity accessible to water measurements for various mix samples examined at the age of 28 days.

The cement/hemp mixture is characterized by particularly high porosity, reaching 70.2%. In contrast, the lime/hemp mixture shows a reduction in this percentage, decreasing to 67%. Mixtures incorporating flax shives with cement exhibit a higher

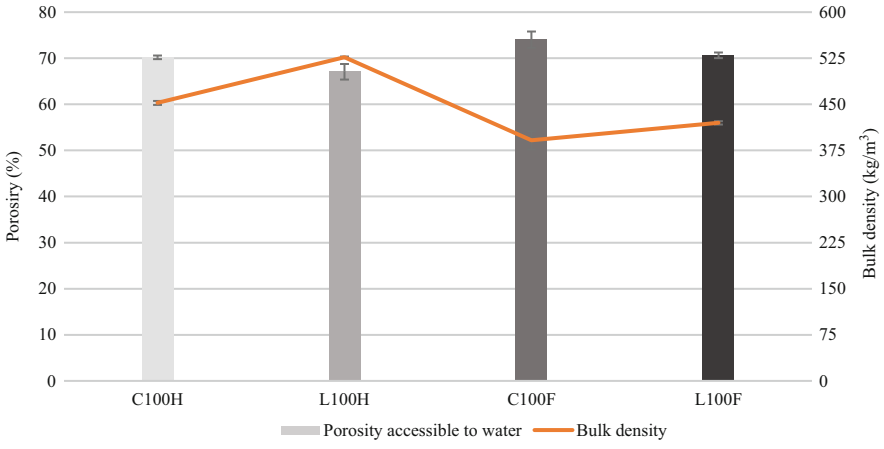

Fig. 2 Porosity accessible to water measured for various formulations at 28 days

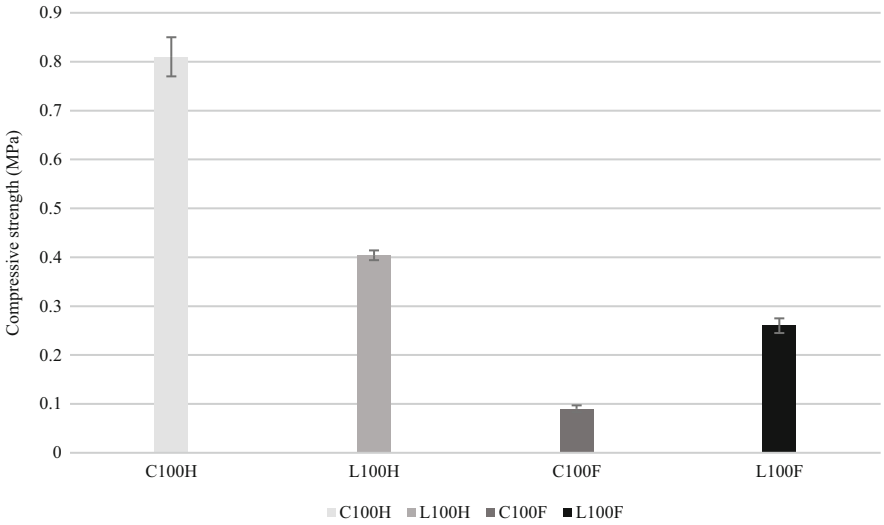

Fig. 3 Compressive strength of various formulations at 28 days

porosity value than those made with lime, with a value of 74%, compared to lime mixtures, which show a value of 70%. The observed variation in porosity between formulations based on cement and those based on lime with both types of biomass can be explained by the significant difference in specific surface area between natural prompt cement (7000 cm^2/g) [24] and air lime CL 90-S (13,260 cm^2/g) [19]. The latter being twice as high means that lime is finer than cement, so its particles fill the voids caused by the biomass. Additionally, this disparity increases the importance of cohesion between the binder and plant aggregates, thus leading to a decrease in the percentage of porosity.

The results from the compressive strength test, depicted in Fig. 3, indicate that the cement/hemp formulation exhibits higher compressive strength compared to the cement/flax formulation. Specifically, the compressive strength value of 0.80 MPa for the C100H formulation aligns with findings in the literature [8, 17], surpassing that of the cement/flax formulation, which measures 0.09 MPa. Similarly, the lime/hemp formulation demonstrates a compressive strength of 0.40 MPa, exceeding that of the lime/flax formulation, which registers at 0.26 MPa. The notable disparities in compressive strength between the cement/hemp and lime/hemp formulations can be attributed to the distinct mechanical behaviors of natural prompt cement and air lime CL 90-S. Notably, technical data reveal a considerably higher compressive strength for cement, reaching 19 MPa at 28 days [24], whereas that of lime is evaluated at 2.5 MPa at 9 months [19]. Similarly, the differences in compressive strength between the cement/hemp and cement/flax formulations may arise from variations in porosity percentage, which are more advantageous for the cement/flax (74.1%) blend than for the cement/hemp (70.2%) one, leading to a lower density in the cement/flax mixture and consequently lower compressive strength.

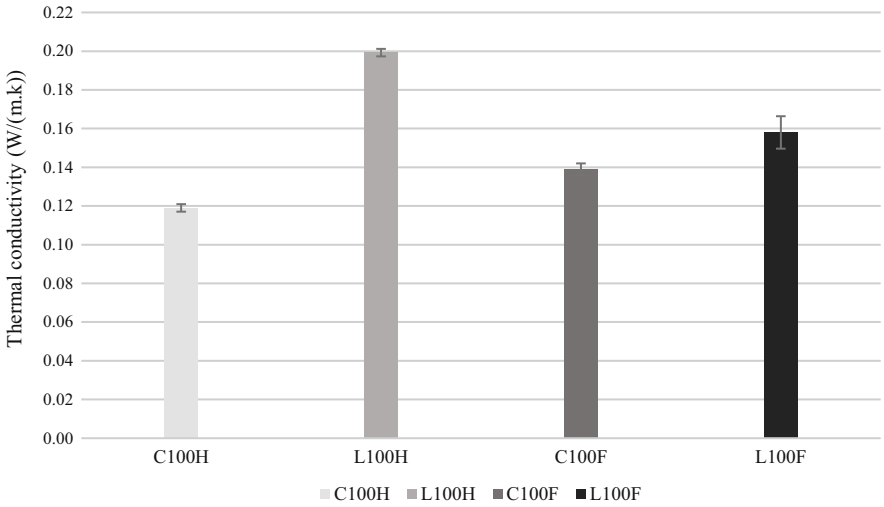

Fig. 4 Thermal conductivity measurement for various formulations at 28 days

3.2 Thermal Properties

Thermal conductivity: Figure 4 illustrates the thermal conductivity results for various mixture samples examined at the age of 28 days. The thermal conductivity increases progressively, going from 0.12 (W/(m·K)) for the cement/hemp mixture to 0.139 for the cement/flax mixture. However, this value shows a significant increase from 0.158 (W/(m·K)) for the lime/flax mixture to 0.20 (W/(m·K)) for the lime/hemp mixture.

The low thermal conductivity of the cement/hemp mixture results from several factors, including the relatively low bulk density and a high porosity percentage reaching 70.2%. In contrast, the high thermal conductivity of the lime/hemp mixture is attributable to the significant bulk density of the mixture [10, 11]. However, the slight disparity between the cement/hemp mixture and the cement/flax mixture can be explained by the differences in thermal conductivity values between hemp and flax shives.

3.2.1 Specific Heat Mass

Figure 5 presents the results of the mass-specific heat capacity for the various mixture samples examined after 28 days. The variation in specific heat capacity follows a gradual progression, starting at 1313 J/(kg·K) for the combination of cement and hemp, reaching 1375 for the lime and hemp mixture. Nevertheless, a significant decrease occurs, dropping to 1155 J/(kg·K) for the cement/flax mixture. More notably, this value increases further, reaching 1274 for the lime/flax formulation.

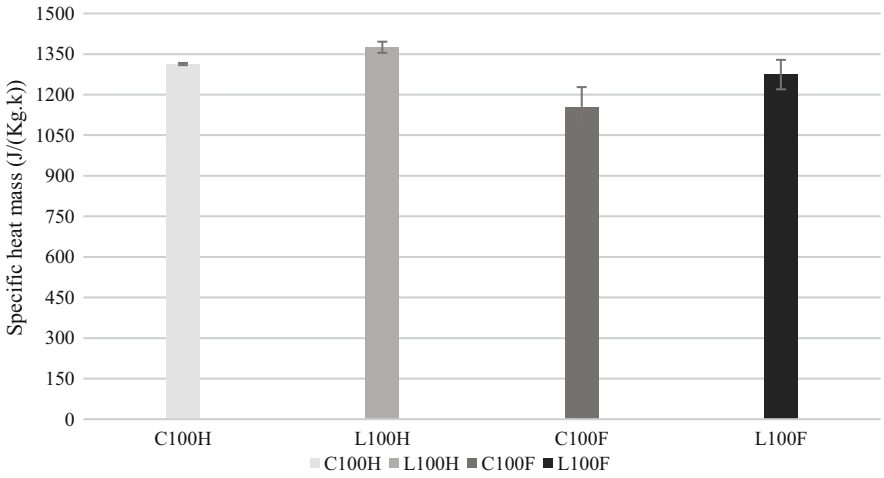

Fig. 5 Specific heat capacity measurement for various formulations at 28 days

The specific heat mass of the mixture is strongly influenced by parameters such as bulk density, porosity, and the heat capacity of the components [11]. The higher specific heat capacity (Cp) observed in the cement/hemp mixture compared to the cement/flax mixture can be attributed to the favorable bulk density of the cement/hemp composite over that of the cement/flax composite. These results are also reflected in the lime/hemp and lime/flax mixtures, where the Cp value for lime/hemp is more favorable than that of lime/flax.

4 Conclusions

Biobased aggregates are recognized for their excellent thermal properties and lightweight nature, imparting exceptional thermal characteristics to vegetable concrete. The main conclusions of this study can be summarized as follows:

- The cement/hemp formulation, characterized by high porosity, imparts excellent thermal properties to the material, resulting in high thermal resistance (thermal conductivity of 0.12 W/(m·K)).
- The mechanical and physical properties of hemp make the cement/hemp formulation a material with good mechanical properties, with a compressive strength of 0.80 MPa.
- The thermal capacity reaches its maximum for the lime/hemp formulation, with a value of 1333 J/(kg·K), attributed to its high bulk density compared to the cement/hemp formulation.

- The cement/hemp formulation exhibits the best mechanical and thermal properties, followed by the lime/hemp formulation from a mechanical perspective, and the cement/flax mixture from a thermal perspective.

Regarding future prospects, the goal is to develop a material with excellent thermal and hydric insulation properties while maintaining robust mechanical characteristics. In this regard, particular attention will be given to evaluating hydric features such as water vapor permeability, sorption, and desorption.

1 Introduction

Cement mortar can be used widely for rendering, masonry bedding, and joint glue in buildings. Producing energy-efficient cement-based materials is desired due to the cost of energy. Phase change materials (PCMs) are the potential materials to reduce energy consumption in buildings due to high thermal energy storage capacity [1]. The heat is absorbed and released during the changing phase from solid to liquid and vice versa [2, 3]. Despite their energy-saving advantages, they have

drawbacks when incorporated into cement-based materials, like leakage and chemical reactions. The current solution is microencapsulating phase change materials (MPCM), consisting of a core as PCM and a polymer shell as a cover [4]. A set of mechanical, physical, and thermal properties should be evaluated to apply the cement mortar in practical projects. Workability, density, compressive strength, water absorption, and thermal conductivity are some of the most critical parameters that should be considered for any new cement mortar and concrete. Previous literature revealed that adding MPCM can affect cement mortar's mechanical and thermal properties [5]. Different studies reported that MPCM reduced the workability, compressive strength, and thermal conductivity of concrete and mortar. The increment in air voids was mentioned as one of the main reasons for the reduction in physical and mechanical properties and thermal conductivity.

X-ray CT scanner has strong advantages for analyzing the internal structure of cementitious materials while providing information about internal defects (i.e., pores) and visualized 3D anatomical images. Image capture and reconstruction are used in a CT scanner to create a 3D image of the pores inside the concrete. In the first step, several 2D projections are acquired, and then the back projection algorithm is used to reconstruct it as a 3D tomographic image. Further analysis of the 3D image provides volumetric information about the solid phase and internal defects based on 3D volumetric elements (voxels). In the tomographic image, a denser phase has a high X-ray attenuation and appears bright, while a low-density phase—consisting of air or gas—will appear quite dark due to low X-ray attenuation [6, 7]. It should be noted that air void content and, consequently, thermophysical properties of mortar can be varied depending on the type of MPCMs, mix proportions, type of cement paste, curing conditions, temperatures, etc.

While numerous researchers have explored various cement-to-sand ratios (C:S) tailored to specific applications, existing literature predominantly focuses on ratios ranging from 1:0.5 to 1:8, with the most common falling between 1:2 and 1:4, as indicated by multiple studies [8–12]. However, an important research gap exists as the impact of incorporating Microencapsulated Phase Change Materials (MPCMs) into cement mortar with different cement content remains largely unexplored.

Therefore, our study's main objective is to address this gap by evaluating the effects of MPCMs on the mechanical and thermophysical properties of cement mortar, specifically focusing on workability, density, compressive strength, water absorption, and thermal conductivity. To achieve our research goals, we have introduced MPCMs into cement mortar with three different grades (C:S ratios of 1:2, 1:3, and 1:4) at 10% and 20% weight of cement. Furthermore, we conducted a microstructural analysis of all mixtures using an X-ray CT scanner and image analysis to visualize potential defects and better understand the material's microstructure.

2 Materials and Methods

2.1 Mix Design

Norcem cement (CEM 152.5R), NorsTone sand (Årdal 0–8 mm), and Micronal-24D were applied as cement, aggregate, and MPCM, respectively. Micronal-24D is a polymer-coated MPCM composite of water (45–65%), acrylic polymer (10–20%), silicon dioxide (10–20%), cellulose derivative (1–5%), and paraffin (1–5%). The appearance is a white powder (mean particle size: 50–300 μm). The heat of fusion and melting point of Micronal-24D are 105 J/g and 24 ± 2 °C, respectively. The lab analysis showed that the Micronal-24D density is 0.4 g/cm^3 and contains 99.5% solid and 0.5% water. All samples were prepared based on NS-EN 196-1. The control mixes (CM2, CM3, and CM4) were prepared with a cement-to-sand ratio of 1:2, 1:3, and 1:4, respectively. Then, MPCM was added to the control mix in 10% (CM210, CM310, and CM410) and 20% (CM220, CM320, and CM420) weight of cement. Adding MPCM reduced the workability of mortar significantly. Gradually, the water was added to the mix to satisfy the required workability (180 ± 10). The fresh workability was measured based on the flow table test conforming EN-EN 1015-3:1999+A1. Table 1 summarizes the mixed proportions of all samples. Samples were demolded after 24 h and cured in water (20 °C) for 28 days.

2.2 Test Procedures

The compressive strength test was carried out on prism samples by the dimension of 40 × 40 × 160 conforming NS-EN 196-1:2016. The dry density of all specimens was measured according to the NS-EN 1015-10. The water absorption was calculated based on the ratio of differences between the sample's weight in dried and saturated conditions and the weight of the wet sample. Thermal conductivity was measured based on the transient plane source (TPS) using TPS 2500-S. Thermal conductivity

Table 1 Mix proportion

ID	Cement (gr)	Sand (gr)	MPCM (gr)	W/C	Flow (mm)
CM2	645	1290.0	0	0.42	190 ± 10
CM210			64.5	0.49	
CM220			129	0.55	
CM3	488.8	1466.6	0	0.50	
CM310			48.4	0.55	
CM320			97.6	0.61	
CM4	389.8	1559.2	0	0.64	
CM410			38.9	0.66	
CM420			77.9	0.68	

was measured when the sample temperature was above 27 °C (solid phase) and below 21 °C (Liquid phase) to evaluate the effect of the PCM phase. It should be noted that all specimens were dried in an oven for 24 h (70 °C for density and 105 °C for compressive strength and thermal conductivity tests). It should be noted three samples were cast for each mixture and the reported results are the average values for each mix proportions. The METROTOM 1500 Scanner was applied to scan the prism samples, with a size of 40 mm × 40 mm × 80 mm (after 28 days of curing and drying in an oven at 105 °C for 24 hours). The VG Studio software was used to analyze the achieved image.

3 Results and Discussion

3.1 Test Results

Table 2 presents the test results for each individual test. The provided values represent the averages of three measurements for each mix proportion. It is observed that the dry density and compressive strength of cement mortar containing Microencapsulated Phase Change Materials (MPCM) were lower compared to the conventional sample. It can be attributed to the less compacted structure, weak interface, and inhomogeneity distribution in the matrix. Conversely, there was a

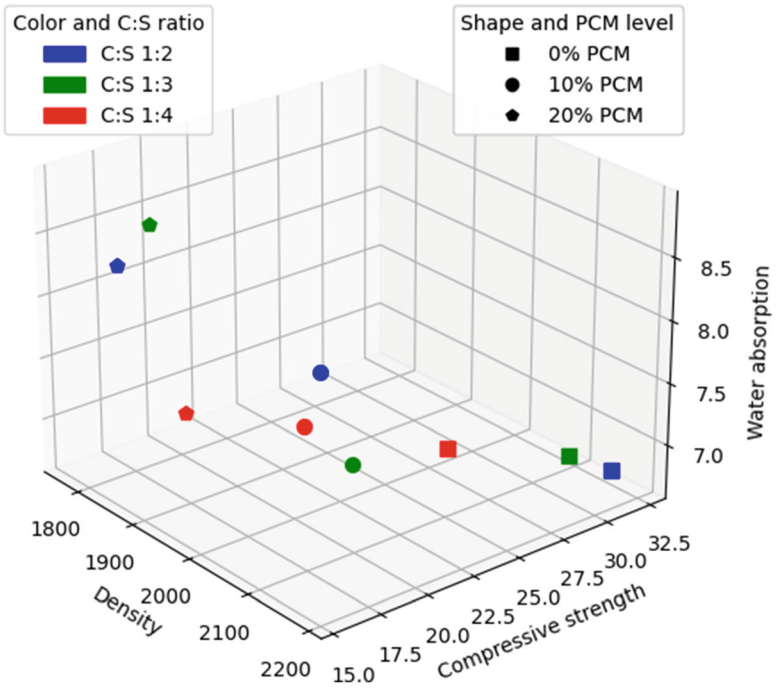

Fig. 1 Dry density, compressive strength, and water absorption

significant increase in water absorption (Fig. 1) due to pore structure, the hydrophilicity of MPCMs, and incomplete bindings. Concerning thermal conductivity, the addition of MPCM to the mortar results in a decrease in its thermal conductivity (Fig. 2). Typically, mortar containing MPCM exhibits reduced thermal conductivity, particularly in the liquid phase. This observation aligns with findings from existing literature [13, 14], suggesting that the decrease can be attributed to the lower conductivity of paraffin in its liquid phase compared to the solid phase.

Figure 3 illustrates the percentage of change in the sample properties due to adding MPCMs. In general, it can be concluded that using MPCMs reduces the workability, density, compressive strength, and thermal conductivity of cement mortar. The potential reasons for reduction are an increment of W/C ratio to the samples with higher amounts of MPCMs, air bubbles increment due to PCM usage, and poor bonding between MPCMs and cement paste [13]. However, different samples exhibit varying changes in properties compared to their reference samples. Some samples show significant changes, while others show minor changes in certain properties. These variations can be crucial for selecting the appropriate material for specific applications based on desired properties. It was noted that the same amount of PCM incorporation in samples with different C:S consequences has different effects. For instance, Density Change: CM220 shows the highest decrease in density (−18.33%), while CM310 exhibits the lowest decrease at (5.84%). Compressive

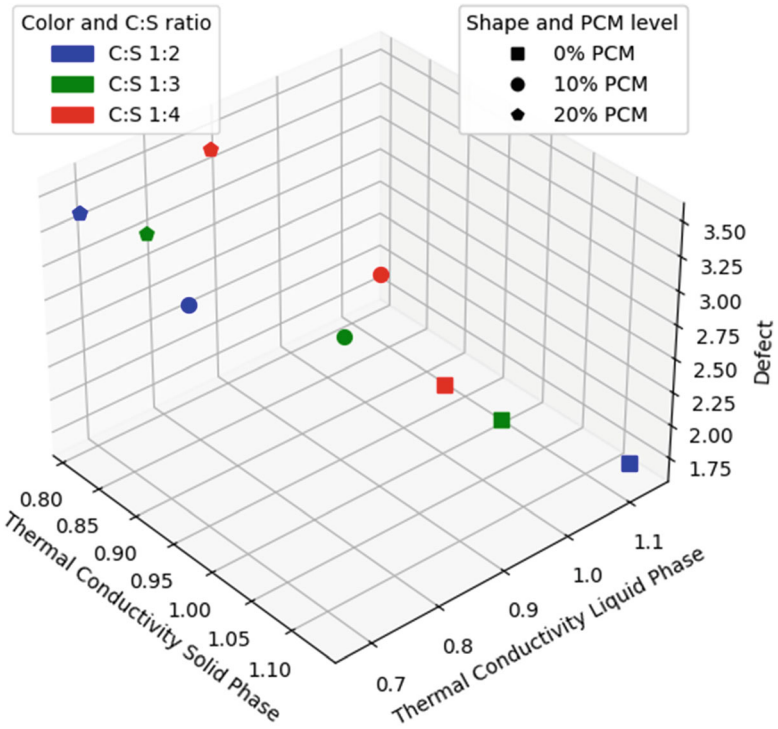

Fig. 2 Thermal conductivity versus defect

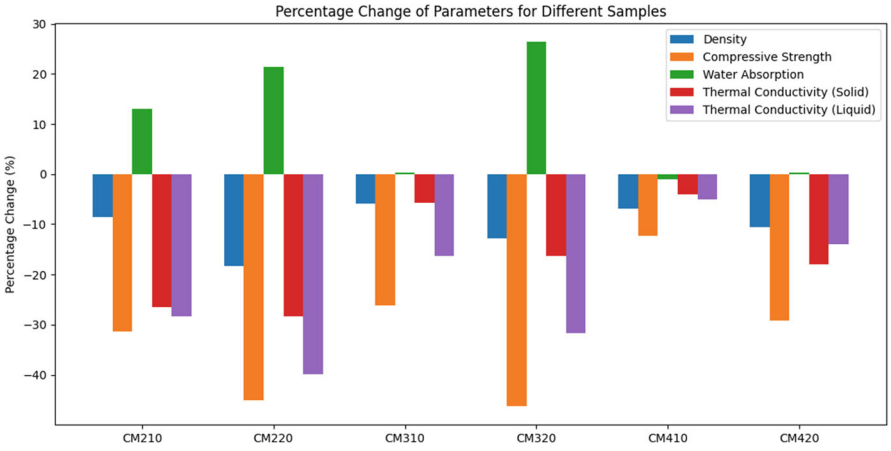

Fig. 3 The effect of MPCMs on the mechanical and thermophysical properties of cement mortar with various grades

Strength Change: CM320 experiences the largest decrease in compressive strength at (46.26%), whereas CM410 shows the least decrease (12.27%). Water Absorption Change: CM320 displays the highest increase in water absorption (26.39%), while CM410 has the smallest increase (−1.06%) (a decrease).Thermal Conductivity (Solid) Change: CM420 demonstrates the most substantial decrease in thermal conductivity (solid) (18.00%), while CM410 shows the least decrease (−4.00%). Thermal Conductivity (Liquid) Change: CM220 exhibits the highest decrease in thermal conductivity (liquid) (−39.82%), while CM410 has the lowest decrease (−5.00%).

A multivariate regression analysis was conducted to establish predictive models for each parameter based on the cement-to-sand ratio of cement mortar and the amount of MPCM, as depicted in Fig. 4. This analytical approach allowed for a comprehensive examination of the interdependencies among the variables, facilitating insights into how changes in cement-to-sand ratio and MPCM content influence the properties of the mortar. Through the regression analysis, equations were derived to estimate the density, compressive strength, water absorption, and thermal conductivity (both solid and liquid phases) of the mortar samples. These equations serve as predictive tools, enabling the assessment of the impact of varying cement-to-sand ratios and MPCM amounts on the performance characteristics of the mortar. The regression models provide valuable insights into the relationships between the independent variables (cement-to-sand ratio and MPCM content) and the dependent variables (density, compressive strength, water absorption, and thermal conductivity). By analyzing the coefficients and significance levels of the regression equations, it is possible to identify the relative importance of each factor and discern their contributions to the observed changes in mortar properties. Furthermore, the predictive capabilities of the regression models offer practical utility in optimizing mortar formulations for specific applications. Engineers and researchers can utilize these equations to tailor mortar compositions to meet desired performance criteria, balancing considerations such as strength, thermal insulation, and moisture resistance.

3.2 X-Ray Tomography

There is a challenge in distinguishing between porosity and MPCM through X-ray scanning. Due to the low density of the air voids and MPCMs, both look like dark colors. Therefore, distinguishing between air voids and MPCM is not possible with a CT scanner. Although some studies used shape and size analysis to visualize the air voids and MPCM in different samples, they can also face a bias. The PCM may not remain in spherical shapes and may be broken during mixing. Also, some small pores are almost spherical. Furthermore, MPCM can be agglomerated and make a much bigger colony than an individual one. Moreover, there are different types of pores in the range of individual MPCM used in this study (50–300 microns). Considering all these, we defined a binary image as follows: 1. Material and

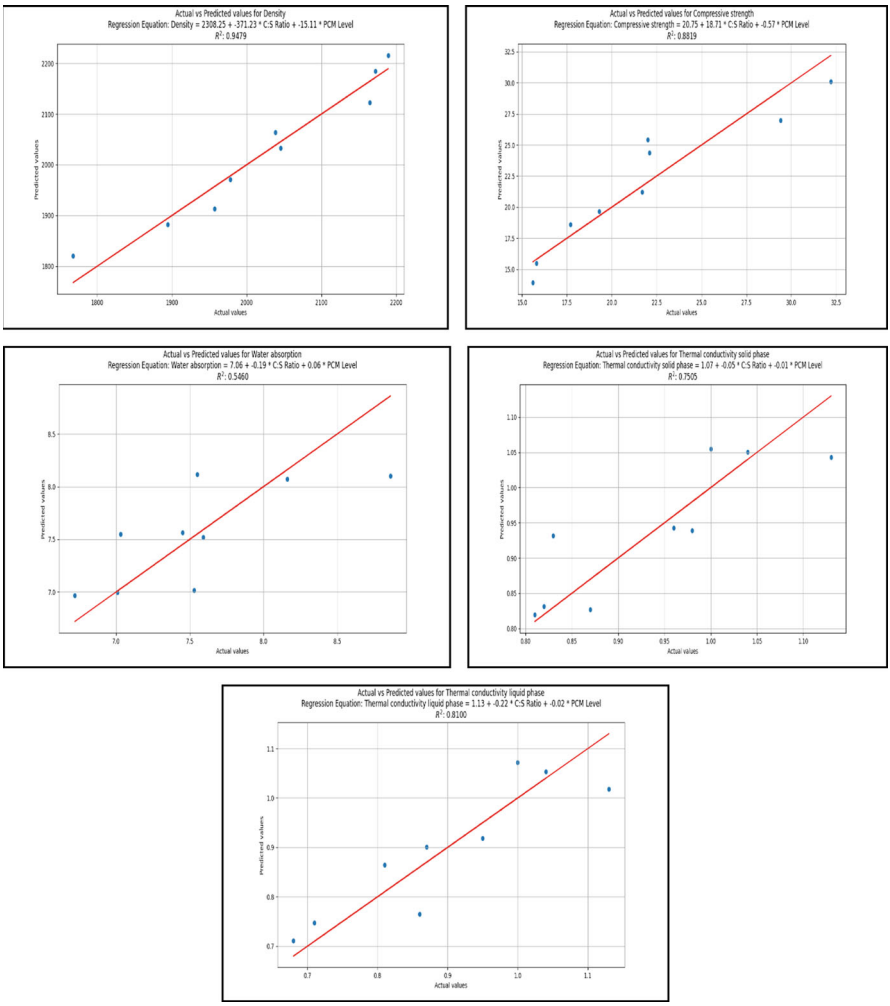

Fig. 4 The relationship between thermomechanical properties with the c:s and MPCM content

2. Defect. Then the defects were analyzed and categorized based on their size and volume (Fig. 5). The material is the white part of the image (sand, hydration products, and unhydrated cement), and the defect is the black part of the image (air voids for CM2, CM3, CM4, and air voids+MPCM for CM210 CM220, CM310, CM320, CM410, CM420). Figure 6 demonstrates the correlation between cement-to-sand ratio, MPCM content, and detected defects.

The equation represents a predictive model for estimating the defect level in a cement mortar based on two key factors: the cement-to-sand ratio and the content of MPCM. The coefficient associated with the cement-to-sand ratio indicates that an

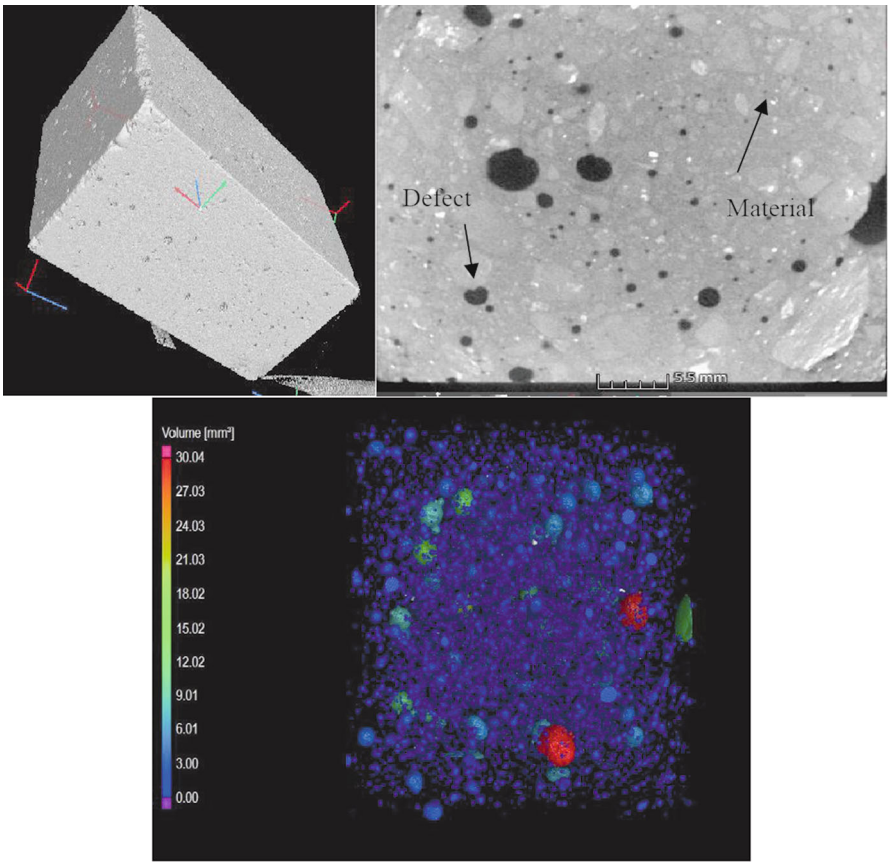

Fig. 5 The defect detection by SC Scanner

increase in this ratio is expected to lead to a decrease in the defect level, with a magnitude of 1.14 units per unit increase in the ratio. Conversely, a decrease in the ratio is anticipated to result in an increase in the defect level by the same magnitude. On the other hand, the coefficient linked to the MPCM content suggests that an increase in the MPCM content would lead to a higher defect level, with each unit increase in MPCM content corresponding to an increase of 0.080.08 units in the defect level. Conversely, a decrease in MPCM content is expected to reduce the defect level by the same amount. This equation provides valuable insights into how changes in these two factors can influence the defect level of the material, aiding in the optimization of material composition and defect mitigation strategies.

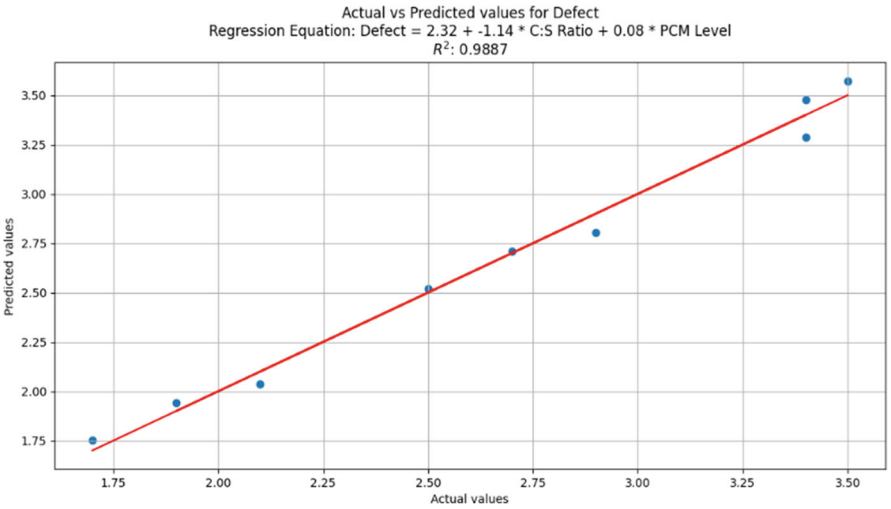

Fig. 6 The relationship between defects with the c:s and MPCM content

4 Conclusion

In conclusion, the experimental findings and further analysis throughout this study shed light on the multifaceted effects of incorporating MPCMs into cement mortar with different grades. The results indicate a notable reduction in dry density and compressive strength of the mortar containing MPCMs compared to conventional samples. This decrease can be attributed to factors such as less compacted structure, weak interface, and heterogeneous distribution within the matrix. Conversely, there is a significant increase in water absorption, attributed to alterations in pore structure, the hydrophilicity of MPCMs, and incomplete bindings. However, the addition of MPCMs leads to a decrease in thermal conductivity, particularly in the liquid phase, aligning with existing literature. The variations observed among samples underscore the importance of considering specific material compositions for tailored applications. Multivariate regression analysis provided predictive models for estimating various properties of mortar based on cement-to-sand ratio and MPCM content. These models offer valuable insights into the interdependencies among variables and facilitate the optimization of mortar formulations for desired performance criteria. Overall, this comprehensive investigation offers insights into the complex interactions between MPCMs and cement mortar properties. By understanding these relationships, researchers can make informed decisions to develop mortar compositions fitted to specific research studies based on their intended applications within the field of mortar technology.

1 Introduction

The EU generates 12.6 million tons of textile waste per year. Clothing and footwear alone accounts for 5.2 million tons of waste, equivalent to 12 kg of waste per person every year. Currently, only 22% of post-consumer textile waste is collected separately for re-use or recycling, while the remainder is often incinerated or landfilled. Today, the Commission is proposing rules to accelerate the development of the separate collection, sorting, reuse and recycling sector for textiles in the EU, in line with the EU Strategy for Sustainable and Circular Textiles [1]. Common EU Extended Producer Responsibility (EPR) rules will also make it easier for Member States to implement the requirement to collect textiles separately from 2025, in line with current legislation. Therefore a large amount of separated textile waste is

expected to be available soon and there is a great interest in the possibility to recycle what is not suitable for reuse in the clothing sector, as raw material for other sectors, such as in building applications.

In the last decade, many researches have been carried out with the purpose of exploring solutions and potentialities of recycling waste materials for making insulating panels, and some of them have specifically considered textile waste. Zach et al. [2] tested thermal insulation panels made from sheep wool, with different bulk densities and at different temperatures. The results showed thermal insulation performances comparable with mineral/rock wool. Patnaik et al. [3] studied thermal and sound insulation samples developed from waste wool and recycled polyester fibers (RPET) for building industry applications. Waste wool fibers were mixed with RPET fibers in 50/50 proportions in the form of a two-layer mat. The behavior of the samples was evaluated also under high humidity conditions, but in such case the waste wool components were sprayed with silicon, concluding that an adequate moisture resistance may be achieved preserving insulation and acoustic performances. Drochytka et al. [4] tested samples produced in laboratory from polyester fibers and bi-component fibers, made by combining hot air and pressure, in order to simulate the real producing technology named "Airlay" [5]. Different percentage of binding bi-component, different bulk densities and operating temperatures were considered. The results show thermal insulation performances comparable with mineral/rock wool. In [6], Diassanayake et al., by facing the recycling complexity associated to the increasing use of multi-materials in textile production, and the environmental impact of synthetic textiles, developed, tested and modeled the performances of a novel insulating material made of postindustrial cutting waste, Nylon/Spandex and Polyurethane. Rubino et al. [7] modeled and experimentally investigated the effective thermal conductivity in highly porous fibrous materials like Merino wool panels, realized with a natural binder made by a chitosan solution. Different samples were obtained and studied, by combining the same percentages of binder and fibrous matrix (60% and 40% respectively), with different bulk density values (ranging between 80 and 197 kg/m^3), in order to characterize and compare their thermal behavior. Finally, a recent review on the factors influencing the thermal conductivity of insulating materials was given in [8]. The review considers both conventional and alternative materials, including natural and fibrous ones, and summarizes results obtained from different experimental investigations. One major conclusion is that the moisture content strongly affects the thermal conductivity of both organic and inorganic materials.

In this context originated MATE.RIA (Methods and Actions for the Ecological Treatment of Post-Consumer Textiles and their Innovative Recycling in Architecture), a collaborative and interdisciplinary research project funded by MASE (Italian Ministry of Environment and Energy Security), spanning the years 2022–2024. This study was carried within MATE.RIA with the objective to investigate and optimize the thermal performances of semifinished panel obtained by recycled textile materials.

The experimental analysis concerning the heat transfer properties was carried out on mats obtained from the post-consume textile waste selected and processed with "Airlay" technique by the industrial partners. The analyzed prototypal panels have been produced from three kind of textile fabric selection (mostly polyester, mostly cotton or mixed) and with different density (low, medium and high) and percentage of binding component (10% or 20%).

The heat transfer properties were measured through the dynamic methodology of the hot disc, both in laboratory conditions and in a climatic chamber (where temperature and humidity are controlled). The aim of the study is to assess the thermal insulation performance of the panels, considering the influence of density, temperature and humidity, and to investigate to what extent such performance is influenced by the kind of waste fabric material.

Although in literature different kinds of waste fabric materials are used to create building insulation, they are rarely processed in the same way and tested with the same methodology. In turn, in this work the performances of different combination of materials can actually be compared, as the same production process and the same experimental technique are adopted.

2 Case Study

The prototypes of products for building applications, based on recycled textile materials, were developed in collaboration between University and industrial partners. The production process of the mats for these semi-finished panels includes: selection of the post-consume textile materials, granulation of the fabric, addiction of a binding component and a thermal mechanical process called "Airlay technique" for the mixing and cohesion of the granulates. Different fabric materials and percentage of binding component (10% or 20%) were used for the productions of the mats, resulting in different density and rigidity. Three family of compositions were considered for the recycled material selection, mainly cotton (>90%), mainly polyester (>90%) and a mix (34% polyester, 30% wool, 23% viscous and 13% cotton). For each composition, three levels of mat density were investigated, in a range from 50 to 150 kg/m^3. Table 1 reports the main features of tested panels.

3 Methods

3.1 Hot Disc Method for Thermal Conductivity and Diffusivity Measurements

The heat transfer properties by conduction (thermal conductivity λ, thermal diffusivity α) of the semi-finished panels were obtained through the dynamic measurement technique called Transient Plane Source (TPS) or hot disk method, also

described in the ISO technical standard 22007-2:2022 [9]. The measurement methodology is based on the application of a step pulse heat source at a sample surface and the simultaneous measurement of its temperature increase over time. The sensor (hot disk), which is sandwiched between two samples of the same material (Fig. 1), acts both as a heat source and a temperature probe, and is powered by an electric current. It consists of a thin double spiral resistor enclosed in an electrical insulating material (Kapton in the case of the apparatus in use). Moreover, great care has been taken to ensure good thermal contact between the sensor and the two samples, while keeping the surfaces as planar as possible. The variation over time of the sensor's electrical resistance is measured, it is proportional to the temperature increase. The measuring apparatus therefore includes, in addition to the measuring disc, a power supply, a resistor bridge which allows the variation in resistance of the sensor to be measured in terms of an unbalancing potential of the bridge, a digital voltmeter and a control system. The temperature variation over time is then interpreted via a model, thus allowing the thermal conductivity and diffusivity of the material to be derived.

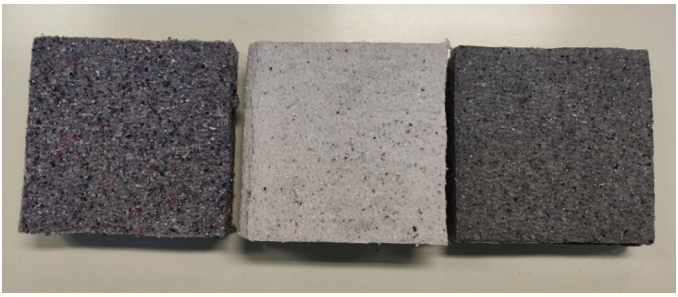

Fig. 2 Samples of semi-finished panels tested with the hot disc method, from left to right: blend, cotton and polyester

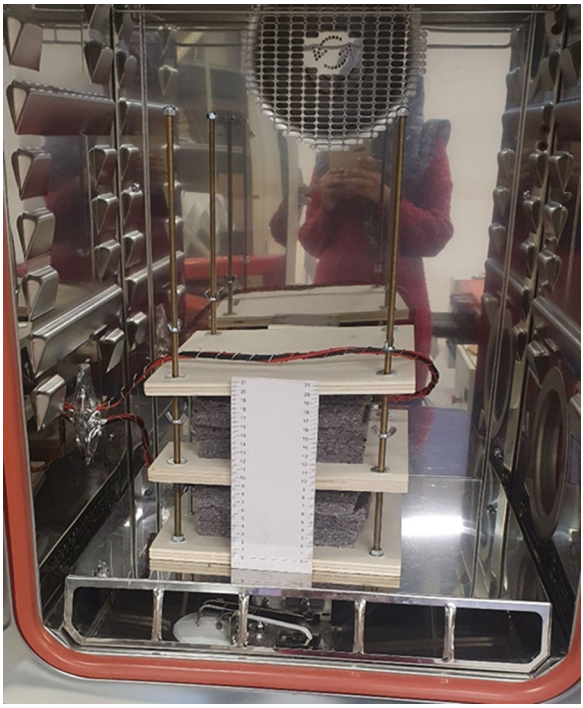

Fig. 3 The sample fixing system inside the climatic chamber of the Textile Hub

In the case of the samples of semi-finished panels in recycled textile (Fig. 2), in order to guarantee good thermal contact between the hot disk and the faces of the samples, a panel fixing system was realized, consisting of two wooden panels 25 cm × 25 cm and a screw system (Fig. 3). At the same time, a graduated scale allows to measure the reduction in thickness of the samples caused by the (modest) pressure applied. It was thus possible to record and limit the thickness reduction in the order of 10% and evaluate the effective density of the samples in the measurement condition.

3.2 TPS Measurements in Climatic Chamber

The thermal transport parameters of the material can generally be influenced by the temperature and, if the material is porous, by the water content, which in turn depends on the degree of humidity in the environment. Therefore, after having carried out a first series of measurements at the Building Physics Laboratory of the Department of Energy, with temperature varying between 18 °C and 24 °C and the ambient relative humidity between 35% and 65%, a second series of measurements was performed, where temperature and humidity conditions were controlled via the climatic chamber available at the Interdepartmental Textile Hub Laboratory.

The operating range of the Votsch VC 7018 climatic chamber (Fig. 3) is equal to 10–95 °C for the air temperature, and 10–100% for the relative humidity, but depending on the temperature the minimum attainable relative humidity changes (being the 10% for temperatures higher than 40 °C and rising up to 65% for temperatures of 10 °C).

In the case of the MATE.RIA project, the TPS measurements in climatic chamber were performed on a small number of samples, i.e., those with the lowest densities, at a temperature of 20 °C and for three relative humidity, i.e., 20%, 50% and 80%. Low density samples were chosen, as from the first characterization in laboratory conditions they were found to have the best insulating performance.

For this second series of measurements, the samples were pre-conditioned in the controlled climatic chamber at the same temperature and relative conditions of the measurement for at least 3, 6 or 12 h before, depending on the starting and target condition. Larger preconditioning times, up to 72 h, were also tested without evidence of significant differences in the measurements results.

4 Results

4.1 Thermal Conductivity and Diffusivity Measurements Versus Density

The results of the first group of TPS measurements are reported in Table 2 and represented in Fig. 4 as a function of the effective density under measurement condition.

As it can be seen in Fig. 4, thermal conductivity has an increasing trend with density. This trend is consistent with the literature relating to cellular materials [10] which predicts that thermal conductivity decreases with density until transmission is dominated by radiative exchange, reaches a minimum and then begins to increase linearly with density again when conduction through the solid matrix and the air becomes prevalent. It is therefore deduced that in the density range analyzed the heat transmission through the semi-finished panels is dominated by the conduction mechanism and it is possible to expect a minimum at even lower densities.

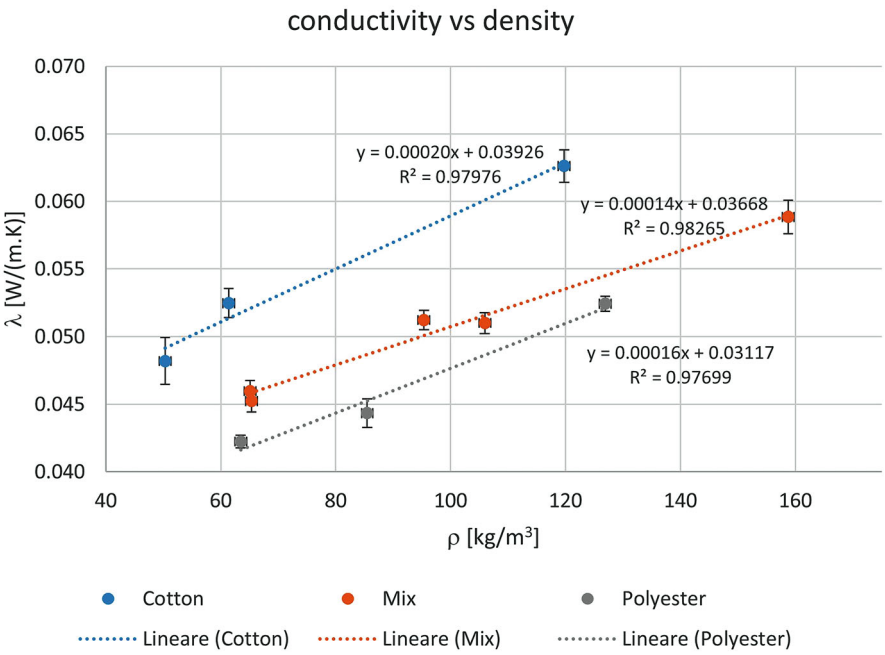

Fig. 4 Thermal conductivity as function of probing density, TPS measurements in laboratory without samples pre-conditioning

The linear trend of conductivity with density is distinct for the three types of materials used. The interpolation lines shown in Fig. 4 allow to compare different materials with the same density: it can thus be observed that polyester-based panels show the lowest conductivities. Specifically, in the density range studied, the cotton-based panels appear to have a higher conductivity than polyester by an average of 26%, while the mixed material panels appear to have a conductivity higher than that of the polyester-based panels by 5–9%. Therefore, it is observed that the insulating performance of mixed material-based panels is intermediate between polyester-based panels and cotton-based panels, at a short distance from the former.

Moreover, Tables 1 and 3 allow to evaluate the possible role of the fraction of the bi-component used as binder. The Run 7 and Run 8 samples, both obtained from mixed textile waste, have a very similar effective density and differ substantially in the percentage of the binding component used, equal to 20% and 10%, respectively. Since the resulting heat transfer properties are the same within the measurement uncertainty, it can be deduced that the different amount of binder does not significantly affect the conductivity.

4.2 *Thermal Conductivity and Diffusivity Versus Relative Humidity*

The results of the second group of TPS measurements are reported in Table 3 and Fig. 5. The latter shows for each of the five low density samples, belonging to the three family of recycled textile (A: Polyester, B: Mix and C: Cotton), the trend of the thermal conductivity measured in the climatic chamber as a function of the relative humidity. The same graph also shows for each sample the comparison with the average thermal conductivity previously obtained in the laboratory (first group), at the average relative humidity present in free running conditions and without preconditioning.

A good consistency can be observed between the measurements performed in laboratory conditions and those performed with fully controlled hygrothermal conditions in the climatic chamber.

As it is evident from the angular coefficient of the interpolation lines in Fig. 5, the thermal conductivity for the cotton-based samples (Run 3 and 4) is more sensitive to ambient relative humidity than the polyester-based sample (Run 13). The mixed-based samples (Run 7 and 8) also appear to have an intermediate behavior between cotton and polyester. These results suggest that cotton-based samples may have a greater hygroscopicity compared to polyester, as also found for similar panels by [11].

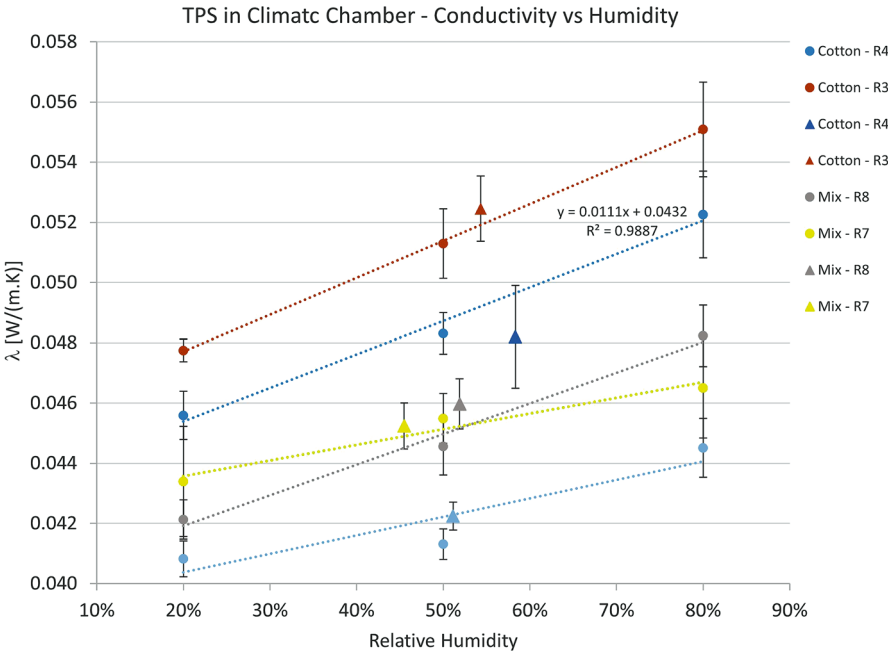

Fig. 5 TPS measurements in climatic chamber (CC). Thermal conductivity as function of effective density (A: Polyester, B: Mix, C: Cotton). Linear trends and comparisons with measurements performed in laboratory without sample preconditioning

5 Conclusions

A good thermal insulation performance was observed for all the panels, so that the general conclusion is that all the panels can be used in building envelope solutions. For a given kind of waste textile, the thermal conductivity was found to increase with density, leading to identify the low-density panels as the most ones. Moreover, thermal conductivity was found to increase with relative humidity, in line with the expected hygroscopic behavior of the porous matrix. For the same density and relative humidity, the thermal conductivity of the cotton-based panels is higher by 26% on average compared to the polyester-based panels. The question then arises whether it is worth the effort of sorting the textile waste into the different fibers. Indeed the thermal conductivity of the mixed waste based panels was found to be only slightly higher than that of the polyester based ones. If this outcome could be confirmed for any kind of mixed textile waste deriving from post-consume clothing, namely collected in other regions and periods of the year, it could be concluded that fibers sorting can be avoided for this kind of building application.

The development of this work will further investigate the hygroscopic properties of the sample panels, their relation with the environmental conditions and their influence on the thermal performances.

Acknowledgments This research has been carried out within the project "MATE.RIA: Methods and actions for ecological treatment of post-consume textiles and innovative recycling in architecture," funded by the Italian Ministry of Ecological Transition (MITE), call D.D. n. 72/2020, project code D33B22000030004.

1 Introduction

The application of energy tunnels has garnered attention from engineers and researchers in recent years due to its alignment with carbon reduction initiatives [1, 2]. High geothermal tunnels, characterized by a geothermal environment, represent a promising energy underground structure owing to substantial heat energy reservoirs within surrounding rock formations [3]. However, the heat energy stored in these tunnels presents challenges when following traditional construction methods [4, 5]. Limited research has explored the harnessing of geothermal energy from high geothermal tunnels. High-temperature water within these tunnels can be extracted directly to heat surrounding buildings [6]. Previous studies by Li et al. [7] and Xu et al. [8] have examined energy tunnel applications in tropical zones and proposed hazard mitigation systems for utilizing heat energy in mining tunnels.

Phase-change materials (PCMs) offer significant advantages in heat energy storage due to their high latent heat capacities, prompting their exploration for use in energy tunnels [9]. Zhang et al. [10] proposed a solution for heat transportation in geothermal tunnels utilizing PCM energy storage units, while Cao et al. [11] integrated PCM plates with lining ground heat exchangers to extract geothermal energy. Wang et al. [12] proposed PCM-modified support structures to serve as insulation layers in high geothermal tunnels. However, there is limited research addressing the operational modes of PCM-modified energy tunnels.

This study introduces a temperature-dependent dual-operation mode for energy tunnels with PCMs, capitalizing on the advantageous properties of PCMs. The performance of heat reduction and energy extraction are evaluated, taking factors such as PCM mass fraction and thermal properties of PCMs into account.

2 Concept of Temperature-Dependent Dual-Operation Mode

The schematic depiction of the establishment procedure for an energy tunnel incorporating PCMs is presented in Fig. 1. The foundational material for constructing the tunnel structure comprises cement mixed with PCMs, constituting the base material for concrete formulation. The PCMs are homogeneously blended with cement in a small-scale mixer to achieve uniformity, resulting in the formation of cement with PCMs. Subsequently, meticulous mixing of this composite material with water and aggregates yields concrete integrated with PCMs, serving as the lining material installed within the geothermal sections of the tunnels. Thermal sensors are strategically embedded within these distinct linings to facilitate real-time monitoring of the temperature dynamics within the linings. Concurrently, absorber pipes are embedded within the linings, facilitating fluid circulation within them to facilitate

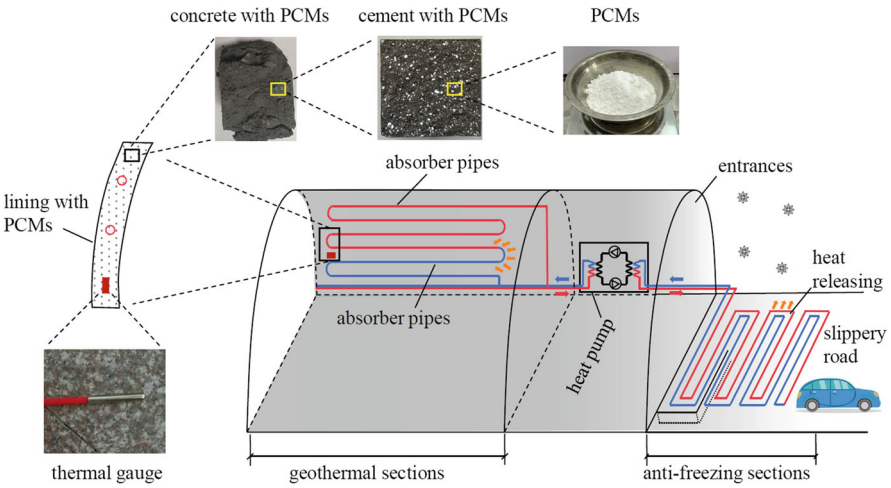

Fig. 1 Establishment procedure of energy tunnel integrated with PCMs

efficient heat exchange processes. A heat pump system is integrated into the infrastructure to provide the necessary power for fluid circulation, enabling the transportation of energy-laden fluid to mitigate against freezing conditions, such as the tunnel entrances susceptible to frost heave, as well as on road surfaces prone to snow-induced slippery conditions.

Based on the system of energy tunnel with PCMs, we develop a temperature-dependent dual-operation mode, consisting of storing mode and cooling mode, see Fig. 2. The temperature of the lining is the indicator of the operation status of the system. The cooling mode is required when the lining temperature T_{lin} increases the temperature at the end of the solid-liquid phase transition T_o. The Ground Source Heat Pump (GSHP) is opened at this time, where the fluid with low temperature enters the absorber pipes and extracts the heat stored in concrete and PCMs, see the blue area in Fig. 2a and b. Both the temperatures of lining and air decrease, when huge heat is extracted out of tunnels for anti-freezing. Meanwhile, the liquid PCMs are converted into solid PCMs with the release of heat. The system enters the storing mode, when the lining temperature T_{lin} decreases the temperature at the start of the solid-liquid phase transition T_c, see the pink area in Fig. 2a and b. The GSHP is closed at this time, no heat exchange between pipes and linings. The heat from high temperature surrounding rock is stored in linings, where the latent heat of PCMs augments the heat-storing capacity of concrete to a large extent through the solid-liquid phase transition. The lining temperature increases until the T_o, where the GSHP is reopened, starting the next cooling-storing cycle.

(**b**) Temperature evolution of lining switching between storing mode (in pink area) and cooling mode (in blue area)

3 Model Setup

3.1 Governing Equations

The thermal behavior within the energy tunnel incorporating PCMs is governed by the combined effects of heat conduction and non-isothermal flow fields. In order to achieve reasonable simulation accuracy while minimizing computational efforts, several fundamental assumptions are employed: (1) Homogeneity and isotropy of materials throughout the tunnel structure are assumed. (2) Thermal resistances at

interfaces are neglected. (3) The heat exchange process between the fluid and pipes is approximated as quasi-steady heat conduction, considering the relatively short time required to reach a steady state. (4) Temperature gradients along the thickness direction of pipes and ventilation ducts are disregarded due to their small thicknesses. (5) The effects of stress within linings on the thermal properties of PCMs are not accounted for.

The heat conduction for objectives in simulating follow [13, 14].

$$\rho_i c_{p,i} \frac{\partial T_i}{\partial t} = \nabla(\lambda_i \nabla T_i) + \dot{\Phi}_i (i = 1, 2, 3, 4), \tag{1}$$

where $T_i$and t denote the temperature (°C) and time (s), respectively. ρ_i, $c_{p,\ i}$, and $\lambda_i$represent the density (kg/m^3), specific heat (J/(kg · ° C)), and thermal conductivity, respectively. $\dot{\Phi}_i$ is the internal heat source (W/m^3). i = 1, 2, 3, 4 denote the surrounding rock, linings, pipes, and air, respectively. Meanwhile, quasi-steady heat conduction is imported to describe the convective heat transfer between pipes and fluid [15–18], following

$$\rho_f c_{p,f} u \frac{\mathrm{d}T_f}{\mathrm{d}z}(z) = h_{pf}\left(T_p - T_f(z)\right), \tag{2}$$

driving

$$T_f(z) = T_p + \left(T_{in} - T_p\right) e^{-\frac{h_{pf}}{\rho_f c_{p,f} u} z} \tag{3}$$

for

$$h_{pf} = \frac{0.023\, Re^{0.8} Pr^{0.3} \lambda_f}{d_p}, \tag{4}$$

$$Re = \frac{u d_p}{\nu_f}, \tag{5}$$

$$Pr = \frac{\nu_f \rho_f c_{p,f}}{\lambda_f}. \tag{6}$$

Among them, $T_f(z)$ denotes the fluid temperature at the z position of absorber pipes. u, ν_f, λ_f, and $c_{p,\ f}$ represent the flow velocity, viscosity coefficient, thermal conductivity, and specific heat of fluid, respectively. T_p and d_p represent the temperature and internal diameter of pipes, and h_{pf} is the convective heat transfer coefficient between pipes and fluid.

3.2 *Establishment of Finite Element Model*

Based on the principles of heat conduction, a two-dimensional finite element model (FEM) is constructed utilizing the COMSOL software. The model exhibits a square geometry with sides measuring 60 m, encompassing a horseshoe-shaped lining at its center with dimensions of 8.26 m in width and 10.43 m in height. This configuration mirrors the linings of the Sangzhuling tunnel, a representative tunnel with geotherm in the southwestern region of China, as illustrated in Fig. 3. The lining itself is 0.25 m wide, accommodating heat exchanger pipes with internal diameters of 4 cm and a thickness of 3 mm, strategically embedded within. To facilitate a temperature-dependent dual-operation mode, the Implicit Event Component in COMSOL, functioning as a temperature sensors, is introduced into the linings. This component monitors the temperature evolution within the linings and effectively controls the on-and-off status of the GSHP, as depicted in Fig. 3d. This integrated approach ensures a comprehensive simulation of the dynamic thermal behavior of the system.

The basic values of materials used in the simulations refer to Table 1. The description of the phase-change process of PCMs is based on the apparent heat capacity [19], following

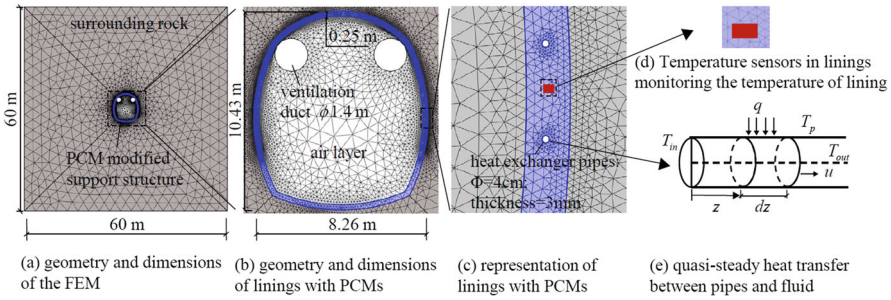

Fig. 3 Establishment of the finite element model of energy tunnel with PCMs

Table 1 Values of materials used in simulations

Materials	Thermal conductivity [W/(m · K)]	Specific heat [J/(kg · K)]	Density [kg/m^3]	Latent heat [kJ/kg]
Surrounding rock	2.9	850	2600	–
Concrete	1.65	837	2300	–
Air layer	3	1005	1.128	–
Heat exchanger pipes	0.6	400	936	
Circulating fluid	0.599	4183	998.2	
PCM (solid)	0.136	1800	856	325.57
PCM (liquid)	0.127	1762.8	779	325.57

$$k_c = \theta(T)k_s + (1-\theta(T))k_l, \tag{7}$$

$$\rho_c = \theta(T)\rho_s + (1-\theta(T))\rho_l. \tag{8}$$

$\theta(T)$ is the mass fraction of solid phase at temperature, taken as a linear function. k and ρ denote the thermal conductivity and density, respectively. The subscript c, s, and l represent the PCMs, solid phase of PCMs, and liquid phase of PCMs, respectively. The calculation of heat capacity c_p of PCMs follows

$$c_{p,c} = \frac{1}{\rho_c}\left(\theta(T)\rho_s c_{p,s} + (1-\theta(T))\rho_l c_{p,l}\right) + L\frac{\partial\alpha(T)}{\partial T}, \tag{9}$$

where the $\alpha(T)$ is a transition equation, following

$$\alpha(T) = \frac{(1-\theta(T))\rho_l - \theta(T)\rho_s}{2(\theta(T)\rho_s + (1-\theta(T))\rho_l)}. \tag{10}$$

The estimation of properties of concrete mixed with PCMs, including density, thermal conductivity, and heat capacity, follow

$$P_{\text{eff}} = (1-\phi_c)P_{\text{con}} + \phi_c P_c, \tag{11}$$

where the ϕ_c is the mass fraction of PCMs. The subscript eff and con denote the concrete mixed with PCMs and the concrete, respectively.

Based on the on-site experiment conducted at Sangzhuling tunnel, initial temperature values for the surrounding rock, lining, and air layer are determined to be 62 ° C, 32 ° C, and 30 ° C, respectively. The boundary condition for the surrounding rock is set as a constant temperature of 62 ° C to simulate the geothermal environment accurately. Additionally, the temperature of the ventilation ducts is specified as 28 ° C. Moreover, parameters including the inlet temperature T_{in}, flow velocity of circulating fluid u, and the total length of heat exchanger pipes Z are defined as 20 ° C, 0.6m/s, and 400 m, respectively.

3.3 Performance Merits

In the present study, a comprehensive assessment is conducted to appraise the efficacy of energy tunnels with PCMs under the temperature-dependent dual-operation mode. The average air temperature T_a and the average lining temperature T_{lin}, derived from the simulation results of a 2D numerical model, serve as indicators for assessing thermal load reduction effectiveness. Additionally, we analyze the heat exchange rate of the heat exchanger pipes q and the increment in energy extraction E_{inc} to evaluate the efficiency of energy extraction. The heat exchange rate is estimated by

$$q = c_{p,w}\rho_w \pi \left(\frac{d_{\text{inn}}}{2}\right)^2 u(T_{\text{out}} - T_{\text{in}}), \tag{12}$$

where the temperature of circulating fluid at the outlet is quantified through Eq. (3). The energy extraction increment E_{inc} is defined as the relative difference between the annual energy extraction through the energy tunnel with PCMs Q_L and through the ordinary tunnel $Q_{L,\,o}$ expressed as,

$$E_{\text{inc}} = \frac{Q_L - Q_{L,o}}{Q_{L,o}},, \tag{13}$$

where the energy extraction Q_L and $Q_{L,\,o}$ are respectively defined as:

$$Q_L = \pi \left(\frac{d_{\text{inn}}}{2}\right)^2 \rho_w u c_{p,w} \int_0^{1a} (T_{\text{out}} - T_{\text{in}}) dt \tag{14}$$

and

$$Q_{L,o} = \pi \left(\frac{d_{\text{inn}}}{2}\right)^2 \rho_w u c_{p,w} \int_0^{1a} (T_{\text{out},o} - T_{\text{in}}) dt. \tag{15}$$

4 Results and Discussions

Based on the temperature-dependent dual-operation mode, the performances of thermal load reduction and energy extraction of energy tunnel integrated with PCMs through one year are investigated, considering the mass fraction of PCMs and thermal properties of PCMs.

4.1 Influence of Mass Fraction of PCMs

The mass fraction of PCMs considered in this simulation group varies from 0% to 20%. The phase-change temperature window is defined within the range of 35 ° C to 40 ° C. Additionally, the specified temperatures for the closure and opening of the GSHP are 35 ° C and 40 ° C, respectively. The simulation condition corresponding to an ordinary lining, denoted as $\phi_c = 0$, serves as the reference state for calculating $Q_{L,\,o}$ in Eq. (15). The predicted temperature evolution of air T_a, the lining T_{lin}, the heat exchange rate q, and the increment in energy extraction E_{inc} are shown in Fig. 4.

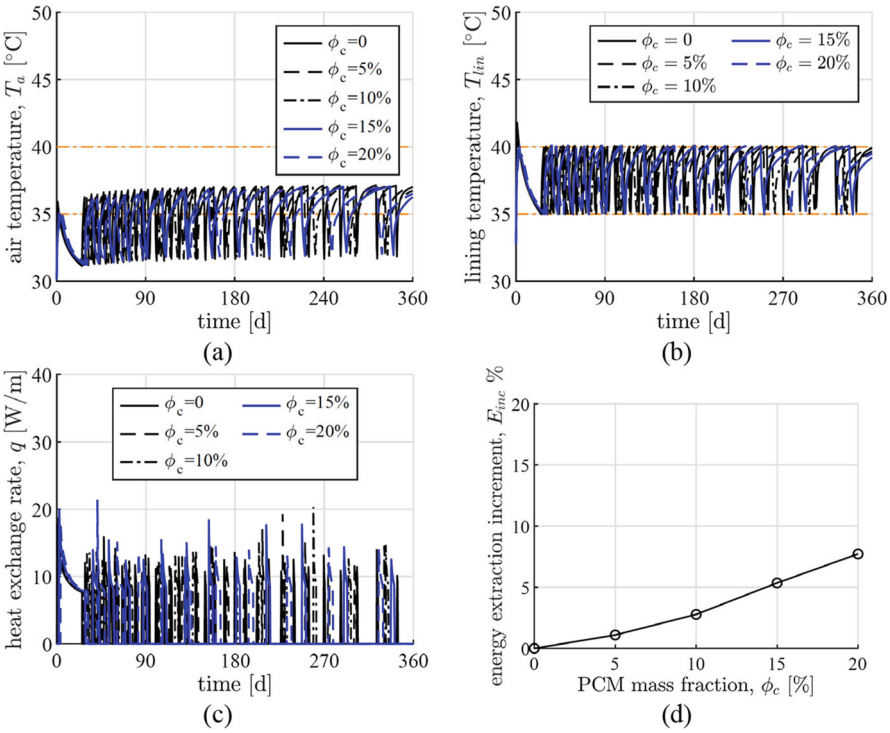

Fig. 4 Performances of energy tunnel with different mass fractions of PCMs based on the temperature-dependent dual-operation mode: (**a**) the air temperature as a function of time; (**b**) the lining temperature as a function of time; (**c**) the heat exchange rate as a function of time; (**d**) energy extraction increment as a function of mass fraction of PCMs

The air temperature changes with the opening and closure of GSHP, mainly ranging from 31.2 ° C to 36.9 ° C, see Fig. 4a. The mass fraction of PCMs exhibits negligible influence on the magnitude of air temperature variations. However, an increase in the mass fraction of PCMs results in a reduction in the frequency of air temperature fluctuations over the course of one year. The temperature of the lining can be controlled in the defined opening-closure temperature, i.e. from 35 ° C to 40 ° C, see Fig. 4b. The evolution of the lining temperature demonstrates reduced fluctuations over the course of one year with increasing mass fraction of PCMs, attributable to the latent heat characteristics of PCMs. The energy tunnel with PCMs extracts the thermal energy stored in the lining integrated with PCMs when the GSHP is opened, see Fig. 4c. The higher the PCM mass fraction, the longer the lasting time of each opening-closure cycle, characterized by the number of opening-closure cycles in one year decreasing from 33 to 11 as the escalating from 5% to 20%. The PCMs mass fraction has less effect on the total opening time of GSHP in one year, ranging from 75.6 d to 79.1 d. Although the number of opening-closure cycles decreases with the increase of PCMs mass fraction, the heat exchanger rate

increases. The amount of energy extraction of lining with PCMs is higher than that of ordinary lining, where the energy extraction increment under the five simulating conditions are calculated, see Fig. 4d The energy extraction increment increases from 0% to 7.73% throughout the year as the mass fraction ranging from 0% to 20%.

4.2 *Influence of Phase-Change Temperature Window*

The performances of energy tunnels with $\phi_c = 15\%$ for ΔT_{pc} ranging from 1 ° C to 5 ° C are investigated. The closure and opening temperatures of GSHP keep consistency with the phase-change temperature window. The efficacy in heat reduction and energy extraction is depicted in Fig. 5.

The evolution of the air temperature shows a drop and rise with the opening and closure of GSHP, see Fig. 5a. The amplitude of air temperature exhibits an escalation as the phase-change temperature window widens. Conversely, the frequency of air

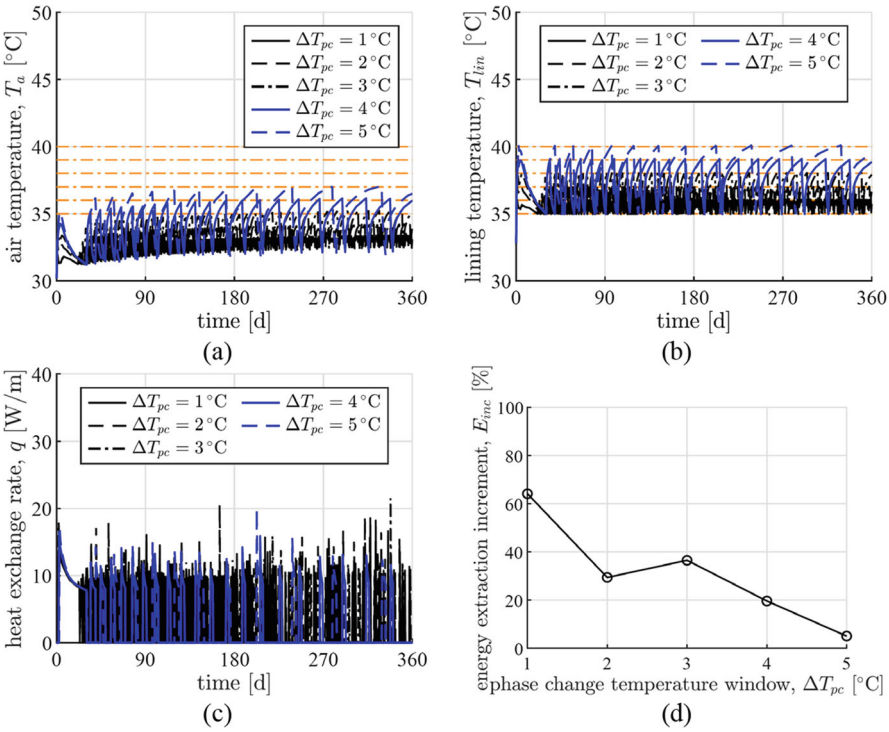

Fig. 5 Performances of energy tunnels with 15% PCM mass fraction for ΔT_{pc} ranging from 1 to 5 ° C based on the temperature-dependent dual-operation mode: (**a**) illustrates the air temperature as a function of time; (**b**) illustrates the lining temperature as a function of time; (**c**) illustrates the heat exchange rate as a function of time; (**d**) illustrates energy extraction increment as a function of phase-change temperature window

temperature fluctuations over the span of one year diminishes concomitantly. The lining temperature can be controlled in the corresponding phase-change temperature window effectively under the temperature control operation mode, see Fig. 5b. The maximum heat exchanger rate shows a significant difference as the phase-change temperature window widens, see Fig. 5c. As the phase-change temperature window expands, there is a reduction in the frequency of opening-closure cycles and an extension in the duration of each individual cycle. The total opening time of GSHP in one year shows a decreasing trend with the increase of phase-change temperature window, where the working days are 121.8 d, 99.9 d, 107.3 d, 94.7 d, and 76.9 d for ΔT_{pc} ranging from 1 ° C to 5 ° C. Compared with the amount of extracted energy from the ordinary lining (the $\phi_c = 0$ simulation condition in Sect. 4.1), the energy extraction increment is calculated, see Fig. 5d. The energy extraction increment decreases from 64.13% to 5.01% as the phase-change temperature window ΔT_{pc} increases from 1 ° C to 5 ° C. When the phase-change temperature window is 3 ° C, a larger energy extraction increment is obtained due to the longer lasting time of opening of GSHP in one year. These indicate that the improvement of the phase-change temperature window of PCMs will be accompanied by less opening-closure cycle and longer lasting time of each opening-closure cycle. Therefore, a suitable phase-change temperature window of PCM should be determined based on the application.

4.3 Influence of Latent Heat

The effects of latent heat L ranging from 100 to 500kJ/kg on the performances of energy tunnel with PCMs are discussed. The mass fraction of PCMs ϕ_c, phase-change temperature T_{pc}, and phase-change temperature window ΔT_{pc} are taken as 15%, 35 ° C, and 3 ° C, respectively. The performances of thermal load reduction and energy extraction are summed up in Fig. 6.

The evolution of the air temperature shows fluctuations with the working status of GSHP, where the opening of GSHP results in a drop in air temperature, see Fig. 6a. Higher latent heat narrows the frequency of fluctuations of air temperature in one year but does not affect the amplitude of air temperature after the first cycle. The temperature of the lining can be limited in the phase-change temperature window (i.e. from 35 ° C to 38 ° C) after the first opening-closure cycle of GSHP, see Fig. 6b. The latent heat has more effects on the lasting time of the opening-closure cycle rather than the maximum heat exchanger rate, see Fig. 6c, where the larger the latent heat, the less of the number of opining-closure cycles and the longer lasting time of each opening-closure cycle. The total opening time of GSHP in one year decreases with the increase of latent heat, whereas the opening time of GSHP in one year decreases from 115.7 d to 71.9 d as the latent heat escalates from 100 to 500kJ/kg. Compared with the amount of extracted energy from the ordinary lining $Q_{L,\ o}$, the energy extraction increment is calculated, see Fig. 6d. The energy extraction increment decreases from 44.50% to 17.17% as the latent heat Lincreases from

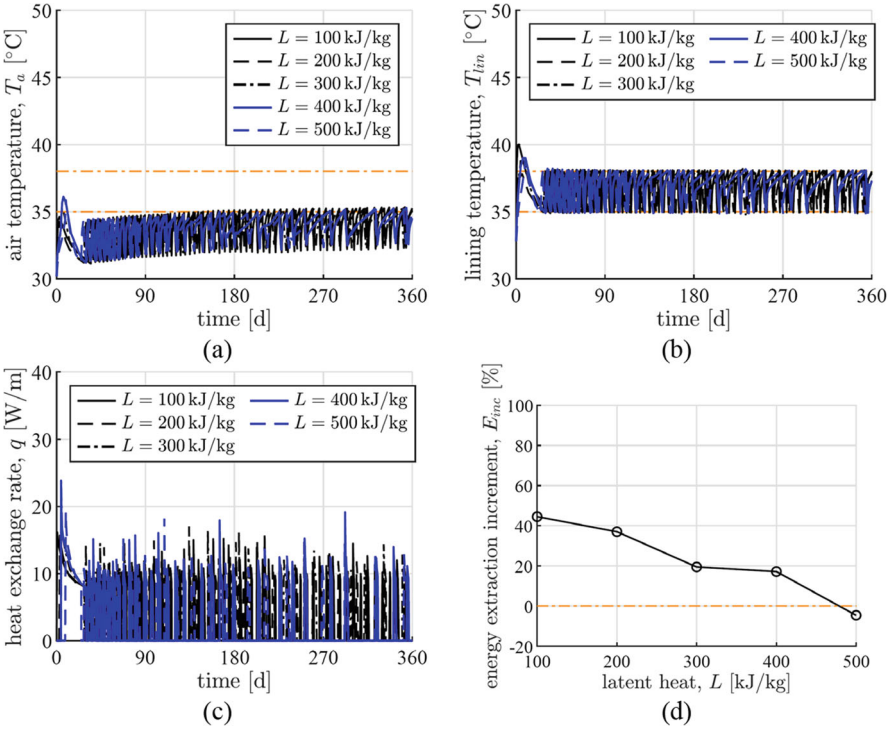

Fig. 6 Performances of energy tunnels with 15% PCM mass fraction for latent heat L ranging from 100 to 500kJ/kg based on the temperature-dependent dual-operation mode: (**a**) illustrates the air temperature as a function of time; (**b**) illustrates the lining temperature as a function of time; (**c**) illustrates the heat exchange rate as a function of time; (**d**) illustrates energy extraction increment as a function of phase-change temperature window

100 to 400kJ/kg. When the latent heat is 500kJ/kg, less heat energy is extracted compared with the reference ordinary energy tunnel. Thus, under this operation mode, the PCMs with low latent heat can also show advantages in energy extraction.

5 Conclusions

In this study, we introduce a temperature-dependent dual-operation mode for energy tunnels with PCMs. Using a finite element model, we assess the feasibility of implementing this mode in a geothermal environment. The performances incorporating heat reduction and energy extraction are evaluated, considering the mass fraction, phase-change temperature window, and latent heat of PCMs. The conclusions are delineated as following

1. The temperature-dependent dual-operation mode maximizes the energy storage potential of PCMs. Compared to conventional energy tunnels, the increment in energy extraction ranges from 0% to 7.73% annually with increasing PCM mass fraction from 0% to 20%.
2. Under this mode, the air temperature can be effectively controlled within the desired range. Energy tunnels with PCMs demonstrate superior heat reduction performance, particularly with smaller phase-change temperature windows and higher latent heat capacities of PCMs.
3. Larger phase-change temperature windows and higher latent heat lead to reduced energy extraction due to less operation time GSHP under this mode. The PCMs with low latent heat show advantages in energy extraction under this operation mode.

Overall, the proposed operation mode for energy tunnels with PCMs in geothermal environments offers notable advantages. However, further investigations regarding the safety of linings incorporating PCMs are warranted. Additionally, the influence of stress within linings on the thermal properties of PCMs remains unidentified, potentially impacting system performance and operational efficacy. Furthermore, future design considerations should entail a comprehensive multi-factor and multi-level analysis to optimize the operation mode and the overall energy tunnel system.

1 Introduction

The current era demands sustainability in the built environment to address the escalating concern of greenhouse gas (GHG) emissions and their adverse environmental impacts. GHG emissions from the construction sector contribute significantly, accounting for one-third of total emissions and 40% of global energy consumption [1]. Mitigating the environmental effects requires a reduction in carbon emissions from construction activities. Considering the significant natural resource utilization in the construction sector, it is imperative to assess the environmental footprint of emerging building materials. This assessment should consider both GHG emissions and natural resource conservation before recommending their use in construction. Green materials like glass-fiber reinforced gypsum (GFRG), fly-ash-based building materials (cement, bricks, etc.), and vegetal concrete are recognized as environmentally friendly options in the construction industry [1, 2], promoting sustainable development.

Bricks, cement, and steel reinforcement are the three key elements that considerably subsidize the embodied energy of a building [1, 3, 4]. Conventional bricks, which constitute a predominant building material, are manufactured predominantly in Asia, accounting for approximately 87% of global brick production [5]. The production of conventional fired clay bricks depletes the natural agricultural soil along with the emission of significant CO_2 by burning fossil fuels, making it a non-environmentally friendly material. In India, the brick sector is the third largest consumer of coal [5]. Given this context, the construction industry offers various sustainable alternatives to conventional clay brick, including fly ash bricks, GFRG panels, lightweight cellular and aerated blocks, and others that have the potential to reduce the carbon footprint and embodied energy of building construction.

Over the past two decades, there has been a notable surge in the utilization of lightweight infill materials such as autoclaved aerated concrete (AAC) and cellular lightweight concrete (CLC) in urban construction projects, particularly for load-bearing and framed structures. This trend can be attributed to their numerous advantages over conventional fired clay bricks, including reduced weight, superior thermal and acoustic insulation, heightened fire resistance, and consistent geometrical properties. Despite these benefits, the adoption of these infill blocks remains limited in rural areas of developing nations. Factors contributing to this disparity include the scarcity of production facilities, the high initial investment required for establishing such plants, elevated transportation expenses, inadequate public awareness, and the perceived lower structural strength of these materials [6, 7].

The carbon content of AAC blocks and fired clay bricks is approximately 0.23–0.24 kg CO_2/kg, as per the published literature [8]. However, AAC blocks are recognized as environmentally friendly, and certified by several environmental agencies. This may be due to the lightweight nature of AAC blocks, resulting in significantly lower consumption by weight compared to fired clay bricks in identical buildings. However, there is insufficient detailed research available in the area of the comparative advantages of replacing traditional masonry with AAC block masonry concerning embodied energy.

The primary goal of the present study is to quantitatively evaluate the life cycle energy (*LCE*) of a chosen AAC-infilled residential building. Additionally, this study also compared the material flow and initial embodied energy of a selected building infilled with AAC to a comparable hypothetical building infilled with conventional fired clay bricks. The findings of this investigation add to the rising body of information surrounding sustainable construction practices, emphasizing the advantages of AAC as a green material. The research aims to guide decision-makers, architects, and builders in making informed choices that align with environmentally conscious building practices. Ultimately, this work seeks to foster a more sustainable future in the construction industry by promoting the adoption of materials that reduce embodied energy and environmental impact.

2 Methodology

The present research centers on assessing the embodied energy of residential buildings constructed with AAC block masonry infill, utilizing the life cycle assessment (LCA) methodology. The method employed to calculate embodied energy and *LCE* adheres to recognized standards and existing literature [8, 9].

2.1 Embodied Energy and Life Cycle Assessment

LCA is a comprehensive examination of the environmental impacts related to a product, device, or process from its creation to its disposal [9]. In the present study, the LCA was carried out for the chosen residential building infilled with AAC, evaluating its *LCE* from cradle to grave, covering the manufacturing, construction, operation, and demolition phases. Figure 1 illustrates a schematic presentation of the methodology followed in the present study.

Embodied energy in the building sector refers to the overall energy consumed per unit weight or volume of a building, typically quantified in MJ/kg or MJ/m^3. The cumulative energy requirement encompassing the production of raw materials, their transportation to the construction site, the construction process itself, ongoing operation and maintenance throughout the building's lifespan, and eventual

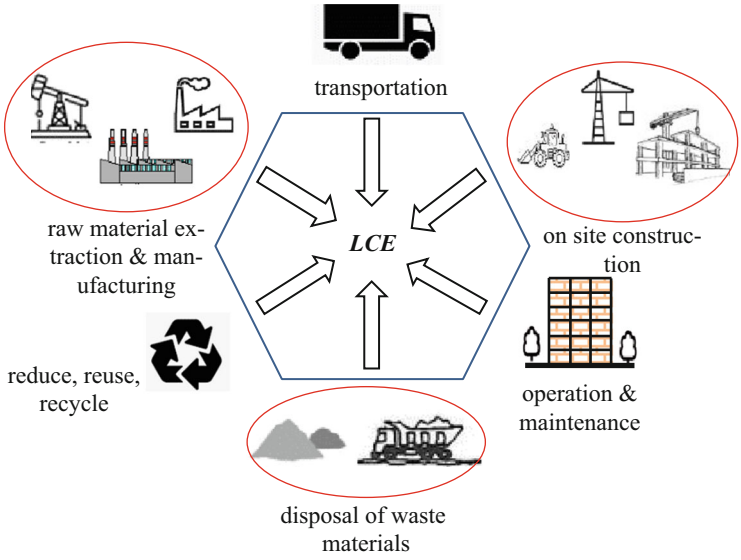

Fig. 1 Schematic presentation of *LCE* of building

demolition is referred to as the Life Cycle Energy (*LCE*) of a building [10], as illustrated in Eq. 1.

$$\text{LCE} = \text{IEE} + (\text{REE} + \text{OE}) \times \text{Lifespan} + \text{DE} \tag{1}$$

where IEE is the initial embodied energy, the total energy used in the production of raw material and building construction phase, REE is the recurring embodied energy, the energy used for the maintenance and renovation of a structure over its lifetime, OE is the operational energy, the energy used on a daily basis for tasks such as ventilation, lighting, air conditioning, space heating, and cooking, and DE is the demolition energy, the energy consumed during the demolition process, including dismantling the building and transporting the resulting waste to landfills.

The embodied energy linked with the manufacturing of raw materials used for building construction is approximated by considering the quantity of material (θ_m) utilized during construction and the material energy content (EE_m) [1, 3], as depicted in Eq. (2). The energy consumption during building construction (E_c) constitutes the cumulative energy expenditure for material transportation (E_{tm}), equipment transportation (E_{te}), labor transportation (E_{tmp}), and on-site construction activities requiring construction equipment (E_{ce}), as outlined in Eq. (3). The IEE denotes the aggregate energy consumed in both raw material production (E_m) and construction activity (E_c), as presented in Eq. (4).

$$E_m = \sum \theta_m \times \text{EE}_m \tag{2}$$

$$E_c = E_{\text{tm}} + E_{\text{tmp}} + E_{\text{ce}} \tag{3}$$

$$\text{EII} = E_m + E_c \tag{4}$$

2.2 Selected Building Details

The present study focuses on conducting an LCA of a seven-storey RC building situated at the National Institute of Technology in Rourkela, India. This building features an open ground floor designated for parking. Rourkela is situated at latitude 22.12 N and longitude 84.54E, positioned in the extreme northwest of Odisha state within Sundergarh district. The climate in this region is characterized by intense heat during the summer months, with the rainy season spanning from June to September. The average annual rainfall ranges from 750 to 1000 mm, while summer temperatures typically fluctuate between 30 °C and 42 °C.

The selected residential building consists of two identical towers joined by a connecting block, separated by a 50 mm expansion joint. Each tower accommodates six residential units per floor, resulting in a total of 72 units across the entire building. All units are uniform, with each offering a carpet area of 122 m^2. The overall floor

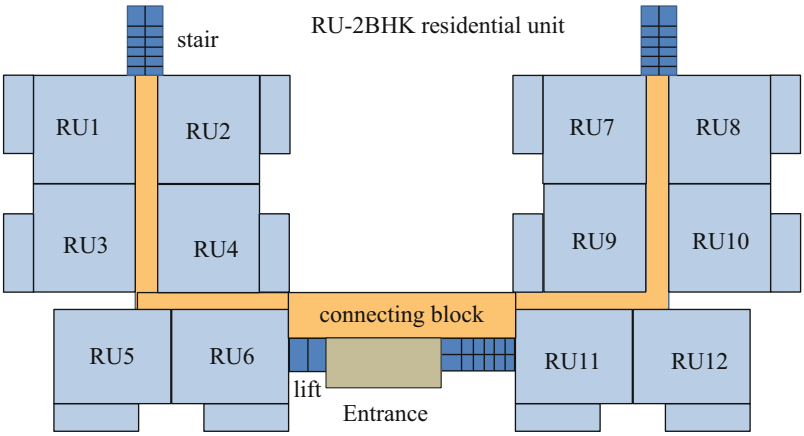

Fig. 2 Schematic presentation of the selected building

Fig. 3 Photograph of the actual structure

area, inclusive of residential units, common spaces like corridors and stairs, the connecting block, and the stilt floor, spans 11,810 m^2. Vertical access across different floors is facilitated by two elevators and three staircases. Figure 2 provides a schematic representation of the typical layout of the selected building, while Fig. 3 offers a visual depiction of the actual structure. The chosen framed building incorporates nonintegral AAC block masonry as infill, with structural design tailored accordingly. The selected building underwent analysis and redesign to conduct a comparative evaluation of embodied energy resulting from the substitution of AAC infill (Case 1) with conventional clay infill (Case 2).

In both scenarios, the dimensions of the partition and main walls stay unchanged, with a thickness of 115 mm for the partitions and 230 mm for the main walls. Analysis of various building elements' contributions to the combined dead and live load of the building superstructure reveals that approximately 35% of the total weight is attributed to brick masonry infill when conventional clay brick is utilized. However, this proportion reduces to 16% when AAC block masonry is employed. Because of the restricted bearing capacity (125 kN/m^2) of the underlying soil, a raft foundation was implemented for the initial building design. However, in Case 2, where the superstructure is assumed to be infilled with conventional clay brick, the raft foundation underwent a redesign.

3 Results and Discussion

As stated earlier, the *LCE* encompasses initial, recurring, operational, and demolition energy components. In this section, each aspect of the *LCE* is calculated and presented for the Case 1 building. However, the *IEE* is obtained for both cases (Case 1 and Case 2), which includes the energy linked with the construction activity and construction materials.

3.1 Initial Embodied Energy and Material Flow

The quantity of materials used in the construction of the building (Case 1) was determined through an analysis of the inventory of materials and structural plans. This data was cross-referenced with the materials utilized in construction, and necessary adjustments were made to ensure accuracy. Comparable estimates for the hypothetical building (Case 2) were derived based on its design specifications. These estimates were then adjusted to accommodate anticipated variations observed during the construction of the Case 1 building.

3.1.1 Embodied Energy for Building Construction

Table 1 offers a comprehensive overview of the material utilized for both selected buildings. The greater RC sections in the Case 2 building, resulting from the increased self-weight of the superstructure, necessitated a greater usage of rebar, cement, fine and coarse aggregate, and water for both the foundations and superstructure. As indicated in Table 1, it is evident that the building in Case 2 requires an additional 6386.8 tons of material compared to the building in Case 1.

The estimation of embodied energy in building materials involves assessing the quantity of material used during construction and its energy content, as outlined in Eq. (2). When specific embodied energy data for construction materials are not

Table 1 Selected building's material flow

Building elements	Constitutive material	Weight (t)	
		Case 1	Case 2
Substructure up to plinth level (RCC, PCC, Filling)	Cement, Sand, Coarse aggregate, Clay brick, Rebar, Quarry dust fill, murum, boulders, Water	26,757.8	27,338.6
Superstructure (RC frame elements, wall, slab, flooring)	Cement, Sand, Coarse aggregate, Water, Rebar' Clay brick, AAC block, Granite, Ceramic/Mosaic tiles, Stone flooring (marble/kota)	14,889.7	20,254.9
Finishing work (plastering, waterproofing, and painting)	Cement, Sand, Aggregate, Water, Primer, Waterproofing, Wall putty, Paint, Turpentine, Lime, Aluminium	1783.0	2223.7
Doors, Windows, Railings, and welding's Miscellaneous	Wood, PVC, Mild Steel, Welding, Stainless steel, Aluminium, Zink' Anti-termite treatment, Glass	98.6	98.6
	Cement, Sand, Aggregate, Water, Porcelain, Primer, Paint, PVC, PTMT, CPVC, MS, Stainless steel, Brass, Iron (CI + GI)	93.6	93.6
Firefighting equipment (heavy-duty pipes, fire hydrant, CO_2 extinguisher, etc.)	Mild steel, Stainless steel, Brass, CI+GI (Iron), EPDM rubber	15.4	15.4
Total weight of the materials used (t)	–	43,638.2	50,025.0

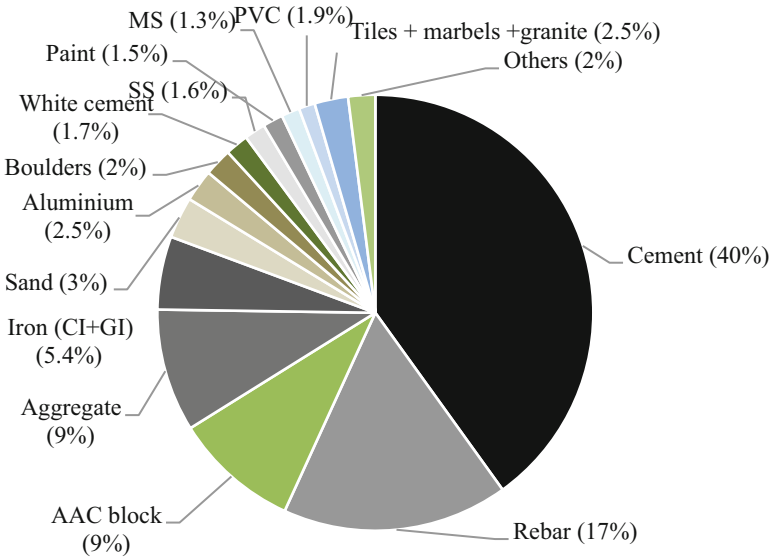
Table 2 The energy content of the selected building materials

Material	Embodied energy coeff. (GJ/t)
Cement	6.85
Sand	0.15
Aggregate	0.4
Water	0.01
Rebar	35.1
Clay brick	1.2–4.05
AAC block	3.54
Boulders/Dust fill	0.15
Mild steel	20.1
Stainless steel	56.7

Note: The embodied energy of materials for various building materials can be found in elsewhere [1, 3, 10–14].

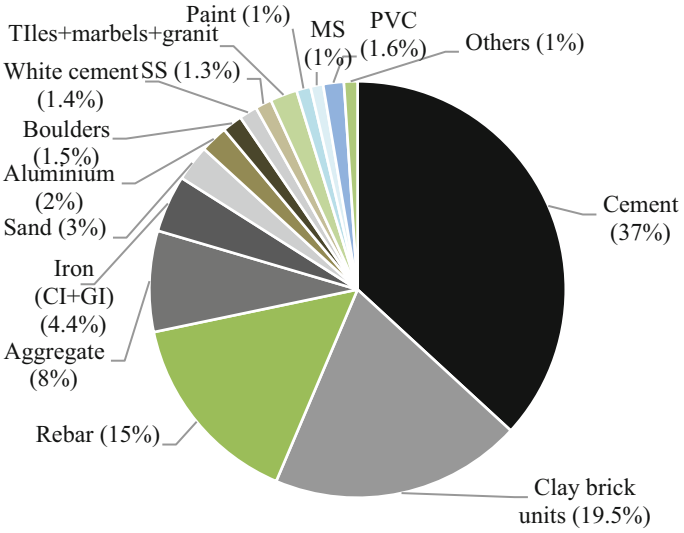
available in the Indian region, the 'carbon and energy inventory database' developed by Hammond and Jones [11] is utilized. Table 2 presents the energy content of various commonly used building materials as obtained from published sources. Given the notable deviation in the embodied energy of the conventional clay bricks in India [12], the mean of the highest and lowest values range is employed to compute the embodied energy associated with the bricks used in the present study.

In cases where embodied energy coefficients for sanitary and hardware items are lacking, such as mild steel (MS) grills, door and window fittings, cast iron and galvanized iron (CI + GI) pipes, MS pipes, china pedestals, kitchen sinks, washbasins, and faucets, energy consumption is estimated based on the embodied energy coefficients of their parent materials.



For buildings in Case 1 and Case 2, the flow material per unit built-up area is calculated to be 3.71 t/m^2 and 4.25 t/m^2, respectively. These values align with existing literature on RC-framed building construction in India [3, 4]. This suggests that the weight of buildings with AAC block masonry infill is reduced by approximately 13% related to assumed clay brick-infilled buildings. Several factors contribute to this weight reduction, including the lightweight nature of AAC blocks, smaller RC section sizes, fewer masonry joints due to larger AAC block sizes, and thinner plaster due to AAC block smooth surfaces. Figure 4 illustrates the comparative embodied energy contribution of different building materials for the chosen buildings.

The embodied energy for Case 1 and Case 2 buildings is calculated at 5.19 GJ/m^2 and 6.32 GJ/m^2, respectively. Published literature [1, 4] reported an embodied energy range of 4.21–10.8 GJ/m^2 for the Indian region. The energy associated with building materials per unit built-up area is observed to be 18% lower for the chosen building infilled with AAC (Case 1) compared to the assumed building (Case 2) infilled with clay brick. Cement, rebar, and clay bricks/AAC blocks emerge as the major contributors to the embodied energy, collectively constituting approximately 66% (Case 1) and 70% (Case 2) of the overall embodied energy of construction materials. The replacement of conventional clay bricks with AAC block is observed to reduce the embodied energy of infill material by approximately 40%.



3.1.2 Construction Embodied Energy

During construction, various activities were carried out, including material and labor transportation, manufacturing of formwork and materials onsite, and the utilization of construction equipment. This study takes into account the energy linked with the equipment employed for tasks such as excavation, material transport, and concreting only. Field data concerning the construction phase were gathered from the project manager and site engineer, enabling the determination of the corresponding embodied energy of this phase.

Table 3 presents an assessment of the *IEE* for the chosen AAC block-infilled building and a theoretical building infilled with clay brick masonry, showing a 17% lower *IEE* per unit area for the AAC-infilled structure. Additionally, the AAC-infilled building shows a 6% transportation energy savings, attributed to the absence of AAC block manufacturing plants nearby, unlike locally available clay bricks. The wide variation in onsite construction energy for residential buildings, ranging from 0.14 to 0.88 GJ/m^2 in the published literature [15, 16], aligns with the obtained value.

(a) Case 1

(b) Case 2

Fig. 4 Relative contribution of materials embodied energy

Table 3 *IEE* of the selected buildings

Infill type	Material EE, E_m (GJ/m^2)	Construction EE, E_c		Total *IEE* (GJ/m^2)
		Transportation EE, E_{tm} (GJ/m^2)	Onsite construction EE, E_{eq} (GJ/m^2)	
Case 1 (AAC)	5.19	0.249	0.133	5.57
Case 2 (Clay)	6.32	0.264	0.155	6.74
% saving	17.9	5.7	14.2	17.4

3.2 Operational Energy

The energy required to operate a building is determined by monitoring both the electricity consumption of the residential units and the usage of liquefied petroleum gas (LPG) for cooking purposes. Electricity data were gathered from the electricity meters of all 72 residential units over 12 months. Additionally, records of LPG consumption were obtained through direct communication with residents from 12 selected residential units.

The combined electricity usage of all residential units amounted to 157,515 kWh during the typical year (2020–2021). It was noted that, on average, each residential unit changed its cylinder once every two months. The overall operational energy consumption of the chosen building amounts to 2241.6 GJ/year, encompassing both electricity and LPG usage, equating to 0.19 GJ/m^2/year. Comparative analysis reveals that operational energy ranges from 0.01 to 0.22 GJ/m^2/year for urban housing across different climatic zones in India [17], aligning with the obtained value. However, the observed operational energy is slightly lower than findings from other published literature [18], possibly due to variations in environmental conditions and architectural characteristics. Notably, improved thermal insulation of AAC results in a reduction of approximately 20–25% in energy usage for cooling during summer and heating in winter, as compared to conventional infilled structures [19, 20].

3.3 Life Cycle Energy

The life cycle energy of a building encompasses the initial embodied, recurrent embodied, operational, and demolition energy over its anticipated lifespan [16]. However, due to the relatively low significance of *REE* in *LCE* [1, 21] and a lack of requisite data, *REE* could not be considered in this study. Although the energy required for demolition is not explicitly calculated in this study, it is estimated to be around 3% of the *IEE* based on existing literature [15].

Table 4 *LCE* of the chosen residential building infilled with AAC over a service span of 50 years

Different phase	Energy (GJ)	Relative contribution (%)
Construction (material + construction activity)	65789.9	36.6
Operation	112,079.9	62.3
Demolition	1973.7	1.1
LCE	179,843.5	100.0

The *LCE* of the chosen residential building, which is infilled with AAC block masonry, is detailed in Table 4, for a service period of 50 years. Unfortunately, due to insufficient data, a comparable analysis could not be conducted for the assumed clay-infilled building (Case 2). The relative contributions of *IEE* (material and construction) and *OE* are determined to be 36.6% and 62.3% of the *LCE* calculated for a service period of 50 years, respectively. The derived *LCE* of 15.2 GJ/m^2, which equates to 0.30 GJ/m^2/year, aligns with the range of values (0.12–0.66 GJ/m^2/year) documented in the published literature [22, 23].

4 Conclusions

The sustainability of building materials is crucial for construction decisions. Despite their non-eco-friendly characteristics, conventional fired clay bricks remain popular in developing countries like India due to limited awareness and convenience. This study evaluates the environmental impact of AAC block masonry compared to traditional clay brick masonry, focusing on initial embodied energy. Additionally, a detailed life cycle energy assessment of an AAC masonry-infilled building is conducted. The primary findings are outlined as follows:

i) Replacing traditional clay bricks with AAC blocks can result in a 13% reduction in material usage attributed to several factors, including the lower density of AAC blocks, smaller section sizes of RC elements, reduced number of mortar joints, and decreased plaster thickness.
ii) For clay-infilled buildings (Case 1), the sequence of building materials in terms of increasing embodied energy is observed to be cement > masonry unit > rebar. However, this sequence shifts to cement > rebar > masonry unit when AAC blocks are employed as infill. This alteration results in savings of approximately 17% in overall initial embodied energy for an infilled RC frame.
iii) The life cycle energy estimation for a service span of 50 years of selected AAC-infilled buildings is determined to be 0.30 GJ/m^2/year.

1 Introduction

In Finland, most urban areas are heated with district heating systems. The heat is mostly generated by combustion of local biomass or fossil fuels like peat, coal and natural gas. Thanks to the low carbon electricity generation, electrification of heating by switching to heat pumps has been found to be a very effective solution for decarbonizing heating [1]. In large heat pump systems, ground-source heating is a

common option. However, in urban areas, geothermal systems with high energy coverage may not be feasible due to the space requirement of the borehole field. The boreholes need to be spaced far enough apart to prevent the ground in the borehole field from cooling too much. Otherwise, this might cause premature freezing of the water-grouting in the boreholes and malfunctioning of the heat pump system.

A borehole thermal energy storage system (BTES) is a borehole field that is used not only to extract energy but also to store it [2]. BTES has been considered for seasonal energy storage with solar energy systems in Canadian [3] and Finnish conditions [4]. Industrial waste heat is another potential heat source to store in borehole fields [5]. While industrial sources are not widely available, ambient air is another promising alternative. In [6], a dry-cooler was connected to a two-part BTES system for heat and cold storage. Sewage heat also shows some potential for energy storage. Sewage heat recovery was compared to a solar energy solution and was found to be economical when electricity prices are low and the heat source is plentiful [7].

Ventilation heat recovery (HR) is required in new buildings in Finland, but the standard method only preheats incoming supply air with air-to-air heat exchangers. In warm weather, the potential heat is lost as there is no way to store the heat. The building regulations do not require sewage heat recovery, which is why it generally is not implemented. Using these additional heat sources for borehole regeneration and direct load reduction, a tightly spaced borehole field in a space-limited urban area might be feasible.

This study examines the effect of tight borehole spacing on borehole field ground temperature and heat transfer fluid temperature in the case of an up-to-code apartment building in Finland. The potential of ventilation and sewage heat recovery for borehole field regeneration is shown. The research questions are How is the long-term ground temperature of ground-source heat pump systems impacted by borehole field spacing and size? What is the benefit of thermal regeneration of borehole fields by residential waste heat?

2 Methodology

2.1 Simulation Tools

To estimate the impact of various borehole field and heating configurations, a heating demand profile was generated using the building energy simulation tool IDA-ICE [8]. The borehole field seasonal storage, heat recovery and heat pump systems were modeled in TRNSYS [9], which used the generated demand profile as input data. The TRNSYS model was used to estimate the temperature of the borehole field and the heat transfer fluid.

2.2 Building Description

The simulation study is based on a cold climate case study in Finland, where space heating is needed for 8 months of the year. The examined building was an apartment building that meets the requirements of the current Finnish building code. U-values of the envelope were 0.17, 0.09, 0.16 and 1.0 W/(m^2K) for the external walls, roof, floor and windows, respectively. Ventilation was handled by a balanced mechanical ventilation system with a heat recovery efficiency of 65%. The annual space and ventilation heating demand was 110 MWh (22.1 kWh/m^2), while the annual domestic hot water (DHW) heating demand was 128 MWh (25.7 kWh/m^2). The heated floor area of the building was 4994 m^2, with 88 occupants. Heating demand was calculated using the Helsinki TRY2020 weather file [10].

The ventilation system was operated constantly, with a total exhaust air flow of 7200 kg/h. The minimum temperature of the exhaust air was 21 °C, according to the indoor temperature setpoint. The air-to-air heat recovery system was allowed to reduce the waste air temperature down to 2 °C. Total water consumption in the building was assumed to be 120 L/occupant/day, of which 35% was hot water (42 L/occupant/day) [11]. The average sewage temperature was assumed to be 26 °C [12]. This is for the total water flow, as even cold water gets heated up while standing in pipes and toilets.

2.3 Waste Heat Recovery System

In the reference system, waste heat was only recovered from ventilation exhaust air to preheat incoming fresh air. The studied heat recovery scheme is shown in Fig. 1. In this system, two additional heat recovery methods were added. An air-to-liquid HR system was included to recover any heat remaining after the reference HR system. This is used to take advantage of energy contained in the air outside the heating season. The air-to-liquid heat exchanger was assumed to operate at a constant 60% efficiency. Sewage heat was recovered using a HR tank with an indirect heat exchanger of 74% efficiency [12]. The tank was filled with brine, allowing direct flow of the heat pump fluid through it.

The same fluid was circulated from system to system. First, cold heat transfer fluid from the heat pump was fed into the borehole field. After initial heating, it was further heated by the ventilation excess heat and then by the recovered sewage heat. After the three stages, the fluid was sent to the heat pumps, which produced heat to the hot water storage tank for DHW and space heating. For simplicity of control, the heat pump was divided into two parts which heat different sections of the same hot water storage tank. The low-temperature heat pump keeps the lower section of the hot water tank at 45 °C, while the high-temperature heat pump keeps the top part of the tank at above 55 °C to ensure adequate DHW temperature level. If the heat transfer fluid temperature remained high after the heat pumps, any excess heat would

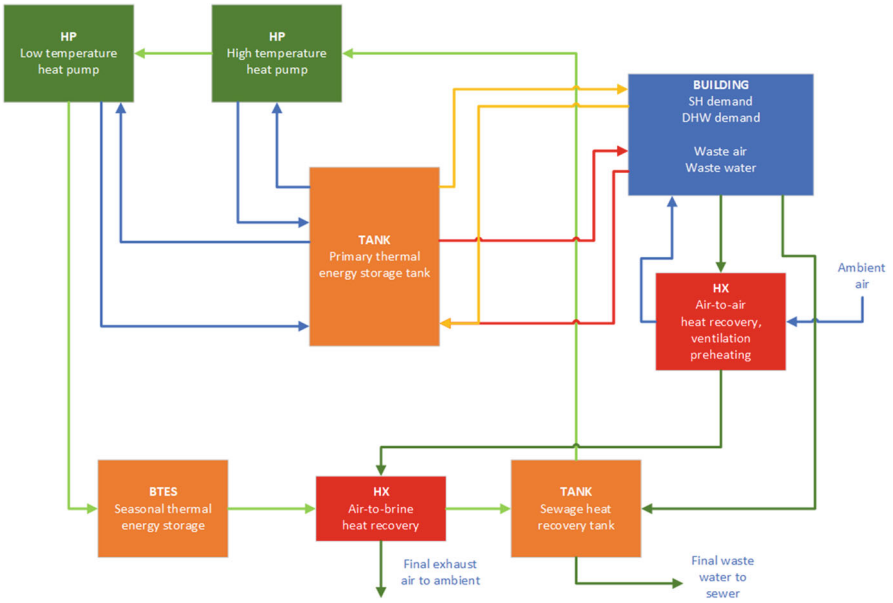

Fig. 1 Heating system schematic

be stored into the borehole field. Thus, the borehole field works in two directions and can be considered to be a borehole thermal energy storage system (BTES). The heat conductivity of the ground was assumed to be 3.5 W/(mK), the heat capacity was 2200 kJ/(m^{3}K), and the starting temperature of the ground was 5.6 °C. The heat collector was a U-pipe of 40 mm diameter, filled with a glycol-water mixture of 3.67 J/(kgK) specific heat capacity. The grout around the borehole was water.

2.4 Studied Scenarios

The reference borehole field was sized according to a simple rule of thumb, where a typical borehole will provide 80–100 kWh/m of annual heating. The various system configurations are shown in Table 1. The 'exhaust air heat recovery' column indicates whether the air-to-liquid HR was utilized in addition to the default air-to-air HR system, which was always included. In cases where seasonal storage charging was active, the heat transfer fluid was kept in constant circulation, even when the heat pumps weren't running. This way, the BTES was injected with additional heat recovered from ventilation and sewage during period of low energy consumption.

Scenario 1 describes the default situation with the heat pumps dimensioned to 80% of peak heating load, using typical borehole spacing. The total borehole length was estimated to cover all of the annual heating needs of the building. Scenario 2 was otherwise the same, but the boreholes were closer together. Scenario 3 included

Table 1 Scenario descriptions

Scenario	# of boreholes	Borehole depth (m)	Borehole spacing (m)	Exhaust air heat recovery	Sewage heat recovery	Seasonal storage charging	BH field horizontal surface area (m^2)
1A	10	300	12	No	No	No	1250
2A	10	300	5	No	No	No	216
3A	10	300	5	Yes	No	No	216
4A	10	300	5	Yes	Yes	No	216
5A	10	300	5	Yes	Yes	Yes	216
1B	100	300	12	No	No	No	12,500
2B	100	300	5	No	No	No	2160
3B	100	300	5	Yes	No	No	2160
4B	100	300	5	Yes	Yes	No	2160
5B	100	300	5	Yes	Yes	Yes	2160

additional heat recovery from ventilation, thus reducing somewhat the energy drain on the borehole field. Scenario 4 added the sewage heat recovery as the third heat source. In Scenario 5, the borehole field was really used as a BTES, with constant charging whenever heat was available.

The A scenarios describe a case with a single apartment building, while the B scenarios show the same cases for a block of ten identical buildings. Instead of ten separate small borehole fields, there was a single large borehole field evenly shared by all the buildings. In both groups, reducing the borehole spacing reduced the surface area requirement of the borehole field by 83% compared to the reference case (Scenario 1).

3 Results

3.1 Ground Temperature

The purpose of the seasonal waste heat storage was to maintain borehole temperatures while reducing the surface area requirement of the borehole field through tighter spacing. To estimate the feasibility of the recovery system, the average ground temperature in the borehole field is presented in Fig. 2. Scenario 1A shows the reference system with heat pumps receiving all heat from the ground in a conventional setup. Over five years of operation, the average ground temperature gradually decreased from 5.6 °C down to 4.2 °C but remained at reasonable levels for continued use. In Scenario 2A, the borehole spacing was switched from 12 m to 5 m, significantly reducing the total energy storage capacity around each borehole. Now, the final ground temperature was reduced to 2.0 °C. In both cases, a decreasing temperature trend was in effect at the end of the simulation, indicating further 0.2–0.3 °C/year temperature reduction with continued operation. In Scenario 3A,

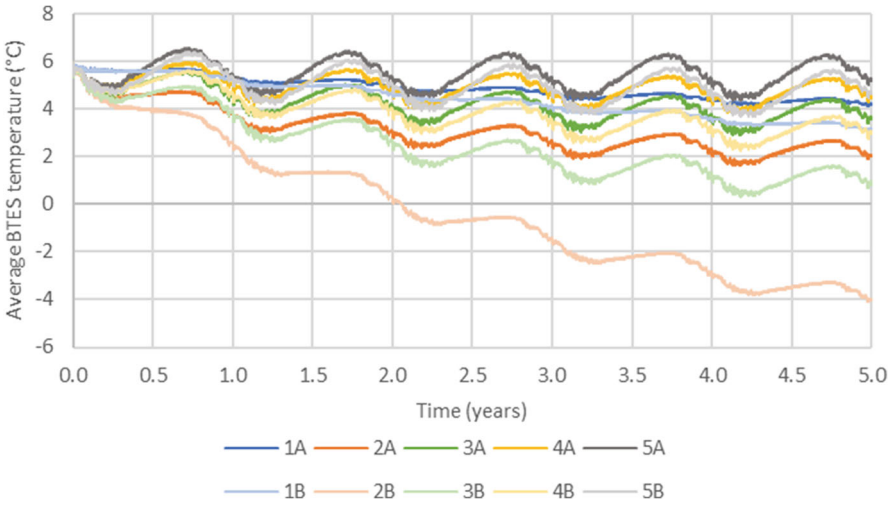

Fig. 2 Development of the average borehole field temperature in different scenarios

however, the additional energy provided by the utilization of ventilation waste heat slowed the cooling of the ground, ending up at 3.6 °C at the end of the fifth year. A clear seasonal variance was now observed compared to the pure GSHP cases, as the ground was allowed to rest during summer and some heat was even charged into the ground. In Scenario 4A, sewage waste heat was also utilized, which shifted the whole temperature curve upwards, ending with 4.5 °C at the end of the fifth year. In both Scenarios 3A and 4A, the BTES temperature was still reducing by 0.1 °C/year at the end of the simulation. However, in Scenario 5A, the heat supply flow into the BTES was increased by constantly injecting recovered heat, even if the heat pumps weren't running. This further raised the temperature levels in the ground and resulted in the final temperature remaining at 5.2 °C in years 3, 4 and 5. This means that the borehole field temperature could be maintained indefinitely without fear of excessive cooling, despite much tighter borehole spacing.

The B scenarios represent cases with larger borehole fields. In these cases, the surface-to-volume ratio of the BTES went down by 76–82% compared to the A scenarios, which means that there was less contact with the surrounding ground. This resulted in lower natural regeneration of the borehole field from the heat contained in the environment. Thus, Scenario 1B resulted in a similar, but faster temperature reduction trend as 1A. The final temperature after the fifth year was only 3.1 °C, with an expected further reduction of 0.5 °C/year. In the tightly spaced system of Scenario 2B, this effect was even more drastic. The final average borehole field temperature was −4.0 °C, which would mean total freezing of the water-filled boreholes. While further reduction would still be expected, in practice the system would stop functioning long before this, preventing the temperatures from actually reaching such levels. In a large GSHP system without additional heat sources, such a tight spacing is clearly infeasible and would drastically reduce the energy coverage. However,

with the addition of the waste heat sources in Scenarios 3C and 3D, despite the tight spacing, there was a notable rise in the average ground temperature. The ventilation heat alone was not enough, as further temperature drop of 0.5 °C/year was still to be expected. With sewage heat, the expected reduction at the end of simulation was 0.2 °C/year. Finally, when active charging of the ground was included, the final temperature after the fifth year of operation was 4.6 °C, with an expected drop of only 0.1 °C/year.

3.2 Heat Transfer Fluid Temperature

It was seen that regenerating the boreholes with residential waste heat can sustain the average temperature in the BTES indefinitely, at least in the case of the smaller field. However, low temperatures within the water-filled boreholes themselves may cause local freezing, which may cause malfunctions in the heating system. Freezing may occur if the heat transfer fluid temperature remains below zero for extended periods (e.g. a whole day). Figure 3 shows the temperature of the heat transfer fluid exiting the BTES during the fifth year of operation in each scenario. The local temperature in the borehole may be assumed high enough if the exiting fluid temperature is above 0 °C.

Scenario 2A is the only one of the single building scenarios where the exit temperature is below zero for extended periods of times. However, the reducing trends in average borehole temperatures show this risk remains during long-term operation of the system. Scenario 3A shows elevated temperature levels during the summer, but in winter there is little energy left from the conventional ventilation heat

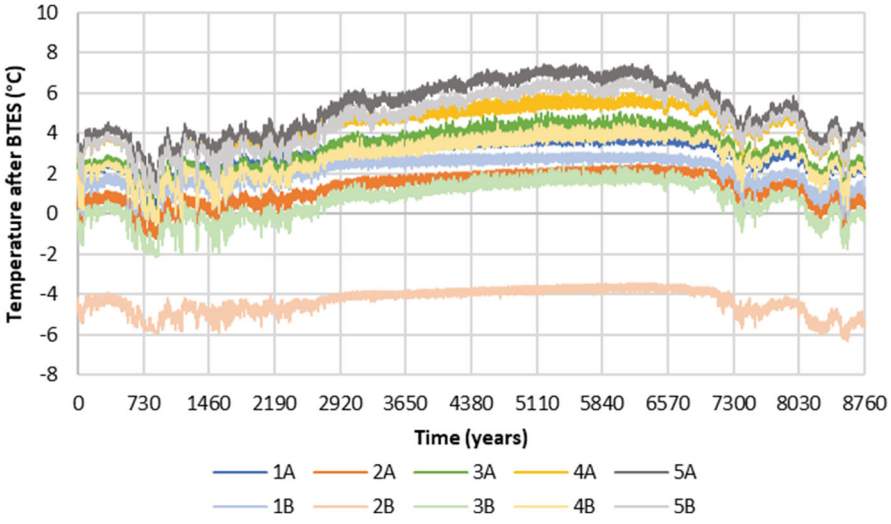

Fig. 3 Temperature of the fluid exiting the BTES during the fifth year of operation

Table 2 Temperature statistics

Scenario	1A	2A	3A	4A	5A	1B	2B	3B	4B	5B
Final BTES temperature (°C)	4.2	2.0	3.6	4.5	5.2	3.1	−4.0	0.8	3.0	4.6
Total time output below 0 °C (h)	0	537	11	0	0	162	8760	2202	63	0
Longest period output below 0 °C (h)	0	197	5	0	0	58	8760	404	9	0

recovery to provide further benefits to the ground heat collection loop. The addition of sewage heat recovery (4A) notably raises the temperature level of the heat collection loop and seasonal storage further increases the temperature (5A).

Seasonal trends are identified in all of the scenarios. During the coldest parts of the year, the risk of low temperatures in the boreholes was increased. The heat transfer fluid temperature correlated with the BTES temperature. Thus, the fluid temperature was lower in the larger borehole fields in the B scenarios. Tight borehole spacing exacerbated the situation as shown in the extreme case of 2B. Higher temperatures compared to the reference case (1B) were realized in the large BTES with sewage recovery (4B) and regeneration (5B), despite the tighter borehole spacing.

The temperature levels may be better illustrated by duration data, shown in Table 2. It shows the total hours the BTES output is below 0 °C and the longest consecutive period of subzero hours. In the reference Scenario 1A, the heat transfer fluid temperature exiting the BTES remained quite stable and always stayed above 0. However, with the tighter spacing in Scenario 2A, there was several week's worth of subzero hours in the borehole output temperature. Scenarios 1B, 2B and 3B are identified as other problematic cases.

4 Discussion

This study examined borehole field regeneration under a limited amount of scenarios. No optimization of the connections was done, and the reference scenario was designed in a simplified way. A more complete study with a wider range of examined parameters could reveal further information about the potential of regeneration.

Electricity consumption in circulation pumps was ignored, but according to [4, 13], it is negligible compared to the electricity consumption of heat pumps. Heat losses in piping were not included in the calculation model, and the practicalities of connecting the various heat sources were not considered. Horizontal piping from the borehole field to the buildings was similarly ignored. According to [13], heat losses in a low temperature heating grid could be 3–5% of delivered heat. These things should be accounted for in more detailed life cycle calculations, but here the idea was to demonstrate the basic idea and potential of the residential waste heat recovery.

The block of several buildings was modeled by simply multiplying the flow rates from a single building. In a more practical case, there could be individual variations between load profiles of buildings within the same location, which might reduce peak heating loads compared to simple multiplication. This would make it easier to keep the system temperatures within acceptable limits.

5 Conclusions

This simulation study examined the seasonal storage of residential waste heat to reduce the ground space requirements of boreholes in a heat pump-based heating system in a cold climate. Reducing the distance between boreholes can reduce the surface are requirement of a borehole field by over 80%. This improves the feasibility of borehole systems designed in urban areas with very little usable space around buildings. Borehole fields of 10 and 100 boreholes were examined.

The simulation results showed that if borehole spacing was reduced without the addition of borehole regeneration, after five years of operation the borehole temperatures were reduced enough to cause significant risk of freezing and system malfunction due to low heat transfer fluid temperatures for long periods of time. This was especially the case in larger borehole fields, with a very low surface-to-volume ratio and resulting low natural regeneration rate. Keeping the final borehole field temperature above 4 °C improved the chance of keeping outlet temperatures high enough.

Utilizing the waste heat from the building's ventilation and sewage flows helped mitigate the long-term cooling of the boreholes when tight borehole spacing was used. However, to fully stabilize the temperature levels in the long term required active borehole regeneration with the excess heat whenever there was no immediate need for heating. With larger borehole fields, the stabilization process may need more time, alternative control strategies, or additional energy input.

The seasonal storage of residential waste heat shows great potential for reducing the space need of urban ground-source heat pump systems. This is especially true of larger energy systems, where a block of buildings could share the same borehole field or thermal energy storage system. Further studies could examine optimal borehole configurations and heat source connection methods and how to reduce the total borehole field length and cost.

1 Introduction

Hunton Fiber AS (hereafter; Hunton) is a manufacturer of building materials, founded in Gjøvik, Norway, in 1889. They are the only producer of porous wood fiber-based building materials in the Nordic region. Hunton started producing wood fiber-based insulation in 2019. They produce both insulation boards and blown-in insulation based on wood-fibre with a production capacity of 32,000 tons/600000 m^3 of insulation boards. Hunton aims to contribute achieving UN's Sustainable Development Goals, especially SDG9 (Industry, Innovation, and Infrastructure), SDG12 (Responsible Consumption and Production and SDG13 (Climate Action), and for this reason it is active in performing LCA studies and Environmental Product Declarations (EPDs) to its products. Hunton conducted an LCA study [1] on the

https://doi.org/10.1007/978-3-031-69626-8_42

insulation products shortly after they started manufacturing. The study was based on 6 months of production from the first 6 months after initializing manufacturing. This, in addition to marginal internal involvement in the LCA process has led to some uncertainty regarding the data produced and the resulting EPD. There are certain themes included in the existing LCA which contain larger uncertainties than others. The bulk of uncertainties are related to allocation of impacts stemming from the phase of extraction and production of raw materials (A1), impacts from the transportation of raw materials (A2) and impacts of different scenarios of waste processing (C3).

The study at hand has focused on the environmental impacts, in terms of greenhouse gas emissions, from the product life of Huntons Nativo® wood fiber insulation boards.

2 Methodology

A Life Cycle Assessment (LCA) is a comprehensive method for evaluating the environmental impact of a product or system throughout its entire lifecycle. The method is standardized by the ISO14040-44:2006 standards [2, 3]. A LCA consists of the four following phases: 1. Goal & Scope, 2. Life cycle inventory (LCI), 3. Life cycle impact assessment (LCIA) 4. Interpretation of results. In the present paper, the software Simapro 9.3 and the Ecoinvent v3 database were used.

2.1 Goal and Scope

The goal of this study is to address the uncertainties mentioned in the introduction. Several different aspects will be analysed, namely: (i) different scenarios for allocation of impacts from raw materials (wood chips), (ii) the impact of different modes of transportation of raw materials and (iii) few different waste treatment scenarios. This will be studied by a comparative analysis of several different LCA scenarios. The focus of the study will be on the product's impact on climate change indicators.

The product is manufactured for the purpose to provide insulation for residential and professional buildings. The functional unit associated with these types of products is dictated by the Product Category Rules [4]. This document specifies that the functional unit is to be calculated to an R-value of 1 per m^2. In this case, the functional unit will be identical to the one stated in the existing EPD for the product: 1 m^2 wood fibre insulation installed in a thickness of 38 mm and a thermal resistance of $R = 1$ m^2K/W from cradle-to-grave with a reference lifecycle of 60 years.

In pertinence to system boundaries, the compared LCA scenarios will focus on different life-cycle stages. For the themes related to raw materials, the study will focus on the cradle-to-gate part of the life cycle (A1–A3). For the part of the study investigating waste treatment scenarios, the focus is limited to the waste processing

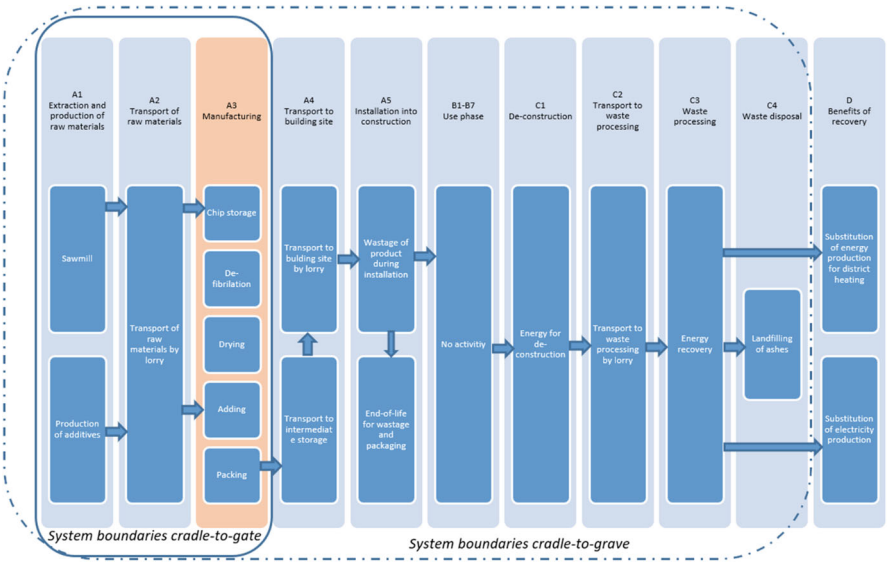

Fig. 1 Flowchart cradle-to-grave for Hunton Nativo insulation boards

stage (C3) (Fig. 1). To present an overview of the complete process, a simple LCA is conducted for the entire process for A1–C4, but with some crude approximations made, in stages not particularly relevant for the main focus themes.

2.2 The Life Cycle Inventory (LCI) Analysis

The LCI is an obligatory part that describes what data and prerequisites have been applied in the LCA performed. In general, it can be viewed as a recipe of sorts for the product at hand.

2.2.1 Data Collection Procedure

Most of the data were collected from the life cycle inventory of product phase (A1–A3) from the existing LCA-report for the insulation [1]. We were not able to find all the known inputs from technosphere (materials/fuels/electricity/heat) based on Ecoinvent, which made us rely on multiple proxies.

Raw Materials A short description of the actual components that go into the production of Hunton Nativo insulation boards.

Woodchips The inventory inputs for woodchips are based on processes found in ecoinvent.

Fire-Retardant The inventory inputs for the fire-retardant are split into two materials. We couldn't find the materials that were used in the existing LCA-report [1] which made us use proxies. This results in a difference in GWP-values for this LCA-report compared to the existing LCA-report. The closeness of the values indicates that the proxies were not far off, and we judge the proxies to be usable for this report. This is in part due to the close correlation to the results from the existing LCA-report and due to the fact that the fire-retardant is not a focus in this report.

Polyolefin Fibre (Bico) Hunton uses a polyolefin fibre to aid in making the structure of the wood fibre insulation boards. These are bicomponent fibres of a mix of polypropylene (PP) and polyethylene (PE) granulates. We couldn't find a similar material in ecoinvent, which also made us rely on a proxy material. We know from the existing LCA-report [1] that the data for the *bico* were labelled as confidential, from the supplier. The data used in the existing LCA-report are therefore not readily available. The proxy used likely underestimates the contribution of *bico* somewhat.

Production Process (A1–A3) The main component in producing the insulation boards is wood fibre, stemming from wood chips originating from local Norwegian sawmills in the vicinity of the production site in Gjøvik. The wood chips are transported by lorry, an average of approximately 50 km from the sawmills. The lumber entering the product at the sawmill is sourced from sustainably managed forestry. The actual wood chips, used by Hunton, to produce insulation is a by-product from a process in which the final product is sawn construction timber.

The wood chips are processed using heat and mechanical manipulation to break it down to wood fibre. The fire-retardant is added to the fibre prior to a drying stage. After drying, the *bico* is added to aid with the structuring of the board. The insulation boards are then formed before a heating process is applied to partly melt the *bico*, solidifying the structure of the final product. After this, the insulation boards are trimmed and cut to the desired measurements before packaging.

The production process is summarized in the illustration in Fig. 2.

Data entering the LCA stems from a data survey conducted by the manufacturer when creating the existing LCA-report.

To investigate the impact of different allocations of impacts from wood chips, separate processes were created for the input of wood chips in the process. Processes were created for allocation based on three different scenarios, in addition to 100% allocation: volume based, market price based (economic) and allocation of all impacts to sawn timber (0% allocation). The estimates for allocation were obtained from Jungmeier et al. [5]. To investigate the impact of transportation of raw materials, we created an alternative scenario where all transportation based on fossil fuel-driven lorries were conducted using lorries conforming to the EURO6 standards instead of EURO4/EURO5 which is the case in the existing documentation. In addition, a scenario was created where the transportation of raw materials inside of Norway was conducted using lorries driven on biodiesel. The scenario for

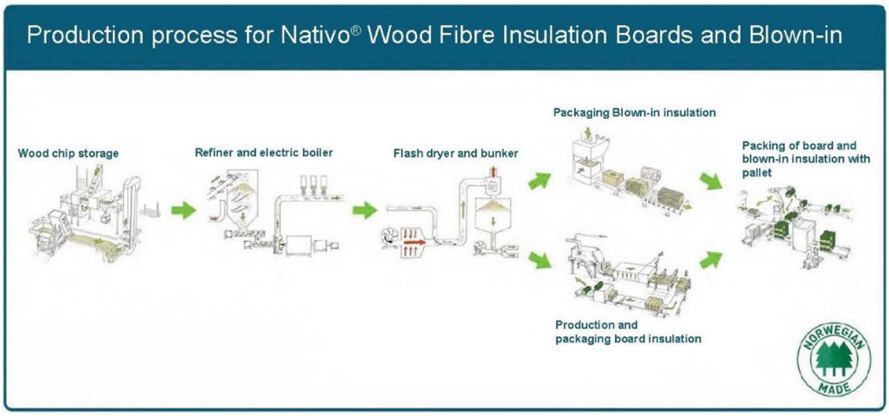

Fig. 2 Flowchart of the production process for Nativo Wood Fibre Insulation

transportation using lorries powered by electricity for the transportation within Norway was not included as there no process for electrically powered lorries in the Ecoinvent database. The possible benefits of such a substitution are discussed in the latter parts of the report.

Transport to Building Site (A4) The transportation from the production site to the building site occurs by lorry. In general, the product is transported by large lorries to warehouses, from which transportation to the actual building site is conducted by medium-sized lorries. In accordance with national product category rules [2], the total transport distance is set to 300 km. This is split into 250 km of transportation by means of large lorries and 50 km of transportation by means of medium lorries. The product has a high volume compared to weight. Therefore, the capacity utilization of the vehicles has been adjusted to volume limitations, in the LCA conducted.

Installation of the Product (A5) The impacts, related to the LCA in the installation phase, is constituted by the use of electricity and waste treatment for 2% scrap and the packaging, which is discarded during this stage.

Use Phase (B1–B7) During the use phase, wood has natural emissions, but no emissions have been found relevant to the LCA.

De-construction (C1) It is assumed that it is necessary to expend a certain amount of electric energy during the de-construction of the structure into which the product is installed. A small part of this is allocated to the product under investigation. The allocated amount is sourced from the existing EPD, which cites Wærp et al. [6] as its source for information.

Transport to Waste Processing (C2) The transport distance is set to 85 km, in accordance with Raadal et al. [7]. The weight of the transported waste corresponds with the weight of the product without packaging, due to the assumption made, that the packaging is discarded during the installation phase (A5).

Waste Processing (C3) The waste processing applied is based on assumptions made in the existing LCA report [1] using scenarios available in Ecoinvent. The practice for waste processing of mixed wood waste in Norway is dominated by incineration with energy recovery, so the scenarios that are applied are based on municipal incineration. Some scenarios are proxies, due to the lacking existence of specific scenarios for all the relevant product components. There were no data available for ammonium polyphosphate, but it is inorganic and therefore ash was used as a proxy. There are no specific for *bico* either, but these are fossil-based organic materials, so plastic packaging was used as a proxy.

To investigate into the potential effect of substituting parts of the existing waste processes with composting, we created waste treatment scenarios where 25, 50 and 75% of the waste processing was handled through composting. The remaining proportion of waste treatment was maintained as incineration with energy recovery in each scenario.

Waste Disposal (C4) Following incineration, there is an amount of residual ash that needs to be deposited in a landfill. In the data entering the LCA for the existing LCA report [7], Ecoinvent processes for municipal incineration, where all flows except landfilling related have been removed, are used in C4. We have not found a way to conduct this in SimaPro software [8]. Therefore, the proxy process for *bico* has been omitted. This is a very crude approximation, but for our purposes, it is considered adequate since C4 is not a stage in which we are conducting detailed analysis.

2.3 The Life Cycle Impact Assessment (LCIA)

In the LCIA, we will introduce the methods used, and the results of our LCA relevant to analyse the selected topics highlighted in goal and scope.

Methods To evaluate the impact on climate change relevant to our selected focus areas, we have analysed the data using the method IPCC 2021 GWP100. The method is based on the final government distribution version of the IPCC report "AR6 Climate Change 2021: The Physical Science Basis". This is a mid-point method developed to yield insight into climate change impact, using relevant units used for comparisons within the building manufacturing industry [9]. It also excludes CO2 uptake and biogenic CO2 emissions, which is in line with current practice for climate calculations after Norwegian building regulations.

Results An overview of the analysis, presented as a network flowchart can be seen in Fig. 3. The visualization shows climate change impact represented as GWP-values in the unit kg CO2-equivalents. From the flowchart, it is apparent that the largest contribution stems from the A1 stage (extraction and production of raw materials). This includes the fire-retardant compound made of inorganic nitrogen fertilizer. Interestingly, it is also the largest contributor to GWP when looking at absolute numbers for amounts, even though it only constitutes approximately 8% of the total

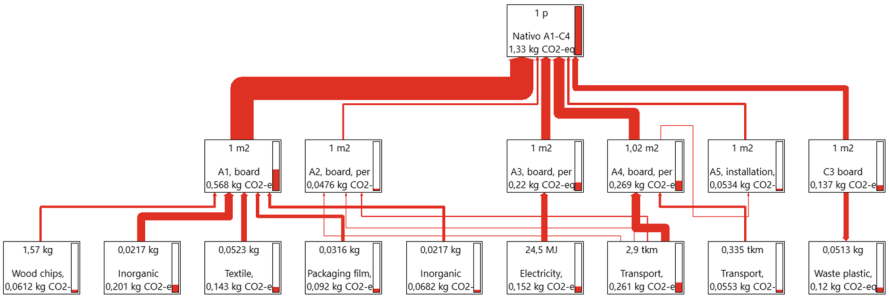

Fig. 3 Network flowchart showing GWP-contributions for the largest contributing processes for Nativo insulation boards

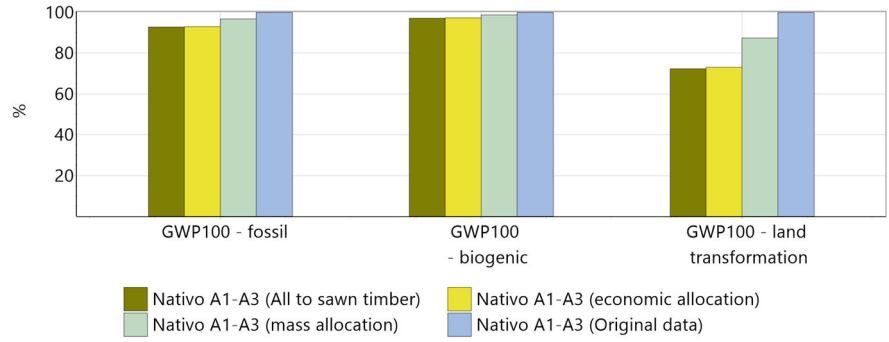

Fig. 4 Illustration showing results of a sensitivity analysis comparing four scenarios for allocation of impacts from wood chips. Method IPCC 2021 GWP100

product mass. Second largest contribution is from the A4 stage (transport to building site). This is interesting to us considering that two of our focus themes concern these two stages. The last focus theme concerns C3 (waste processing) which also has a quite substantial contribution.

3 Allocation and Sensitivity Analysis

3.1 Allocation of Impacts from Wood Chips

In Fig. 4, we can see the results of a sensitivity analysis comparing the four different allocation scenarios for impacts imparted by the raw material wood chips. The analysis is conducted on the processes A1–A3 as this is the value that is routinely compared, when selecting building materials based on climate change impact, in Norway.

Table 1 GWP numbers for the A1 stage for four different allocation scenarios for climate change impact from wood chips

		Allocation scenario			
Damage category	Unit	All to sawn timber	Economic allocation	Mass allocation	Original data
GWP100	Kg CO_2-eq	0.508	0.510	0.541	0.568

Table 2 GWP numbers for the A1–A3 stages for three different scenarios for climate change impact from raw material transport

		Transportation scenario		
Damage category	Unit	EURO6	EURO6 + Biodiesel	Original data
GWP100	Kg CO_2-eq	0.834	0.840	0.836

Compared to the data used in the existing LCA-report, there is a relatively large impact from using alternative allocation models. If considering the A1 stage separately, there is a reduction of GWP of 10.6% if all impacts from the wood chips are allocated to the final product in the sawmill. Corresponding values are 4.8 and 10.3% for mass allocation and economic allocation, respectively. The actual numbers for GWP in A1 for the different scenarios are shown in Table 1. According to Jungmeier et al. [5], the following percentages of CO2 emissions from a sawmill contributed to wood chips in different scenarios: 35.4% for mass allocation, 1.6% for economic allocation and 0% when all emissions are allocated to sawn timber. These percentages are included as a basis for our analysis.

3.2 Different Transportation Modes

The differences between the scenarios are minuscule. The scenario with the highest number for climate impact is the scenario with EURO6 and Biodiesel. The original scenario has a 0.5% smaller impact, while the scenario where all transport is based on EURO6 has a 0.7% smaller impact than the scenario including biodiesel (Table 2).

3.3 Analysis of Waste Treatment Scenarios

When looking at the C3 stage, composting appears to have a large effect on the GWP-numbers (Fig. 5). Compared to no composting, composting of all the waste after use infers a climate change impact reduction of 80.3%. The reduction is linear; therefore, the scenarios of 25% and 75% composting are intermediate at a reduction of 20.1% and 40.2%, respectively.

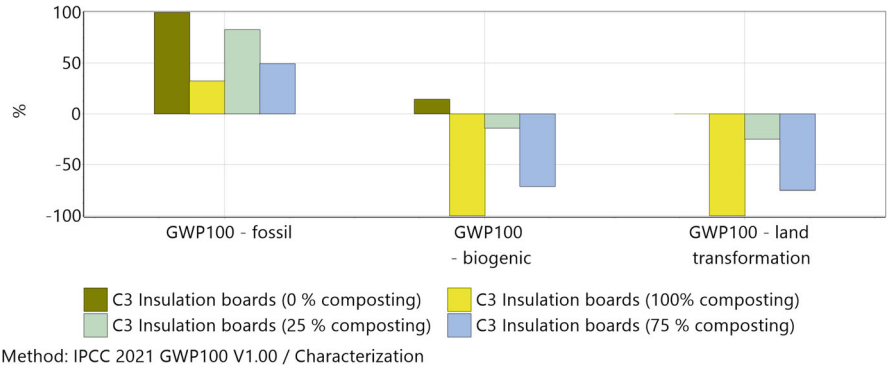

Fig. 5 Illustration showing results of a sensitivity analysis comparing four scenarios for different quantities of waste treated by means of composting

4 Results and Discussion

4.1 Life Cycle Interpretation

From the LCA conducted, it is apparent that the stage mainly contributing to the climate change impact imparted by the Hunton Nativo insulation boards is A1 (extraction and production of raw materials. Other important stages in this respect are A4 (transportation to building site), A3 (manufacturing) and C3 (waste processing).

The analysis of the impact of allocation of the wood chips, which is the largest raw material source in terms of volume, yielded some interesting results. Choosing one of the described allocation scenarios massively alters the climate change indicator GWP for the wood chips in isolation. However, the relative contribution to the impact from A1 to A3 as a whole is quite modest. Considering the distribution of the total climate change impact indicator illustrated in the flowchart in Fig. 3, this is not that surprising. Even though the wood chips make up approximately 77% of the finished product (including packaging), its contribution to the GWP for A1–A3 is less than 11%. Even though other raw materials do have much higher impact on the GWP, it could be worth looking into whether the allocation used in the existing LCA-report is correct and fair.

The results from the analysis of different transportation scenarios for the raw materials were meager. The change in GWP resulting from a scenario consisting of upgrading the lorries used for transportation from EURO4/5 to EURO6 yielded next to no effect on the climate change impact indicator. Introducing biodiesel for the transportation conducted in Norway resulted in a somewhat higher GWP-number for A4. Even though biofuels do have certain characteristics making them a good alternative in some fossil fuel-driven processes, there are large uncertainties considering their negative impacts. These arise from a wide array of sources, such as land use, use of fertilizers and pesticides, refining with coal or natural gas. The result is

that biofuels are oftentimes considered to have a greater impact on climate change than fossil fuels, for example, UN Energy (2007) [10]. We also wanted to investigate the effect of substitution some of the fossil fuel-driven transportation with electrically powered lorries. We were, however, unable to locate a process for electrically powered lorries in the Ecoinvent database, so we were not able to carry out such an analysis. Considering the electrical mix in the Norwegian market, we are confident that such an analysis would have yielded positive results.

Introducing composting as a waste treatment substituting incineration with energy recovery appears to have a significant effect on GWP. After A1, A3 and A4, C3 (waste processing) is the largest contributor to the total climate change impact of the complete product. It is uncertain how large a percentage of the waste processing it is realistic to convert to composting, but this appears to be a potentially fruitful issue to explore.

4.2 Conclusions

One conclusion of the study is that the most imperative material input for climate change impact is the fire-retardant compound made of inorganic nitrogen fertilizer (Fig. 3). Therefore, it is highly recommended that a search for an alternative fire-retardant is conducted for further development. If this is not seen as feasible, it is recommended to conduct a critical review of the amount of fire retardant added to the product. Could one obtain the desired fire-retarding properties of the end product with a smaller addition of fire-retardant.

About the different allocation scenarios, it could be useful to investigate whether the allocation applied in the existing LCA-report is correct and fair. Should one uncover that other allocation models are more accurate and fairer, one might get a more accurate and more beneficial GWP value for the insulation boards through a modest effort.

The analysed scenarios for transportation of raw materials yielded such miniscule changes to the GWP value for the product that it is considered not worthy of any effort to employ them. In our view, it might, however, be interesting to investigate how other transportation modes might affect the climate change potential of the product, if it could be beneficial to redirect some of the transport in the Norwegian market to electrically powered lorries. The production of electricity in Norway is based on renewable sources, to such an extent that we believe this will offset other, potentially negative, impacts from other processes concerning electrically powered lorries, to be deemed interesting to investigate.

About waste management, the analysis results suggest that composting produces avoided impact concerning climate change, and it would be worthwhile to exert some effort into applying the process. Hunton is currently involved in a process to obtain an approval from authorities concerning the feasibility of composting these products. Should such approval be granted, we recommend that Hunton work together with Norwegian municipal recycling companies in this issue. Even greater

effect could be obtained through employing a take back-system where used products can be reused in Hunton's manufacturing, to make new isolation boards. This would both yield avoidance of impact from waste treatment processes and reduce impact from today's practice of using virgin raw materials. Although this would be a win–win scenario, it is unlikely to be able to take back 100% of the used products. Could a significant amount of the used products, not taken back, be treated through composting, rather than incineration, this appears to result in a decent reduction of the climate impact at the end-of-life stage.

1 Introduction

Ash is the by-product obtained after combustion of pulverized coal in thermal power plants. In general, two kinds of ashes are produced in a thermal power plant, namely, bottom ash and fly ash. Bottom ash is comparatively heavier and coarser, and collected from the bottom furnace after burning of coal, whereas the fly ash is the comparatively lighter and finer counterpart, which is collected from the electrostatic precipitators. After combining a significant amount of water to the bottom ash and fly ash, and transforming the mixture to a slurry form, it is generally transported to nearby storage ponds. It is evident that a large amount of space is required for this disposal. Not only the material poses a huge space issue, it can also cause environmental consequence by being airborne due to its weightlessness. Utilization of pond ash as a fill material in various infrastructure projects can control the above-mentioned disposal problem in addition to reducing the cost of the project.

https://doi.org/10.1007/978-3-031-69626-8_43

Numerous studies carried out in the past few decades focused on behaviour of pond ash material and assessing its potential as a fill material. Martin et al. [1] investigated the geotechnical properties of ashes from coal-burning utilities in different cities of USA and found that fly ash can be rapidly compacted with methods similar to those used for granular soils, whereas construction is less sensitive to compaction-moisture content than the fine-grained soils. Gandhi et al. [2] carried out extensive field trials to evaluate the effectiveness of deep blasting for densification of deposited fly ash. Das and Yudhbir [3] performed a series of laboratory experiments to characterize some Indian fly ashes in terms of their geotechnical properties such as grain size, specific gravity, compaction characteristics, and unconfined compression strength in order to evaluate their suitability as embankment material. Jakka et al. [4] performed a detailed experimental study on the strength and other geotechnical characteristics of pond ash samples collected from inflow and outflow points of two ash ponds in India. Mohanty et al. [5] studied the strength and deformation behaviour of Rae-Bareli pond ash under cyclic loading by conducting a series of stress controlled one-way cyclic compressive triaxial tests on reconstituted samples of pond ash. Mohanty and Patra [6] performed strain-controlled cyclic triaxial tests on pond ash samples collected from plants from different seismic zones of India. Vijayasri et al. [7] performed a series of cyclic triaxial tests on pond ash samples obtained from Renusagar pond ash embankment of Northern India and evaluated the effect of inclusion of geotextiles in improving the shear modulus, strength, and liquefaction potential of the material.

Although several studies had focused on evaluating the properties of Indian pond ash through element level triaxial tests, dynamic characterization of the material using cyclic simple shear tests are very limited. As we know that a soil sample in a direct shear test setup resemblance better with an in situ soil deposit subjected to an earthquake induced vibration, compared to other element level tests such as triaxial test. In this context, the present study ventures to present some experimental observations on a pond ash sample collected from Parichha power plant in North-Central India through a series of cyclic simple shear tests.

2 Geotechnical Characterization of the Pond Ash Sample

The pond ash material was collected from the **inflow points of the** ash ponds at Parichha thermal power station near Jhansi town of Uttar Pradesh state in India. Prior to determination of the dynamic properties of the material, basic characteristic tests including specific gravity, gradation, and particle mineralogical tests were performed. Further, standard proctor test and direct shear tests were also conducted to estimate the maximum dry density, optimum moisture content, and the static shear strength properties of the material. The observations from these static tests are described in the following subsections.

2.1 X-Ray Fluorescence (XRF) Test

XRF test was performed on the pond ash sample to determine the chemical composition of the pond ash sample by measuring the fluorescent (or secondary) X-ray emitted from the sample when it is excited by a primary X-ray source. In this case, an amount of 4.5 g of pond ash sample was placed in a beaker and then was mixed with 0.5 g of boric acid to bind the pond ash particles. After that, the pressed powder pellets were prepared at Advanced Centre for Material Sciences (ACMS), Indian Institute of Technology Kanpur (IITK) with the help of stainless steel dye-cast having a diameter of 30 mm. Then the samples were pressed on a hydraulic pre-machine with a pressure of 12–13 ton to make 30 mm diameter pressed powder pellets and heated in oven for about 20 minutes at 80 °C to remove any moisture absorbed by the pellets. Afterwards, the sample was placed in Rigaku ZSX Primus II wavelength dispersive X-ray fluorescence spectrometer to determine the major oxides and some of the trace elements (in parts per million, ppm) present in the pond ash sample. The chemical composition of pond ash from XRF tests are shown in Table 1. It may be observed that Oxides of silica, alumina and iron together constitute the major proportion (of about 95%). According to the American Society for Testing Materials standard (ASTM C618), ashes containing more than 70% of SiO_2 + Al_2O_3 + Fe_2O_3 (by weight) are defined as Class F, while those with a SiO_2 + Al_2O_3 + Fe_2O_3 content between 50% and 70% (by weight) are defined as Class C. The free lime content in the Pond ash samples is low, indicating that the ashes belong to class F category. It is to be noted that Class F category ashes are suitable for use a geotechnical fill material, whereas the chemically active Class C category ashes are not. Hence, it is concluded that the sample used in the present study is in the suitable category.

Table 1 Chemical composition (%) of Parichha thermal power station pond ash

Chemical composition	%
Silica (SiO2)	61.6
Alumina (Al2O3)	22.6
Iron oxide (Fe2O3)	6.84
Titanium (TiO2)	1.81
Potash (K2O)	1.23
Lime (CaO)	0.68
Phosphorus pentoxide (P2O5)	0.29
Magnesia (MgO)	0.11
Soda (Na2O)	0.11
Manganese (MnO)	0.09
Nickel (NiO)	0.006

2.2 Morphological Characteristics

Particle morphology indicating the shape and surface of the particle of the sample was analysed using scanning electron micrographs (SEM) facility available at Indian Institute of Technology, Kanpur. Figure 1 shows the obtained SEM graphs for the collected pond ash sample. It may be observed that the shapes of the ash particles are angular and irregular in shape and has complex pore structure. When a higher magnification has been used, some agglomerations of smaller ash particles are observed. Further, i**ntra-particle voids were observed in the sample. It was observed to be a more porous material than initially thought, making the particles more crushable.**

2.3 Specific Gravity

The specific gravity of the sample was obtained using a standard Pycnometer test as per IS: 2720: Part-3 [8]. The specific gravity was obtained to be 2.22. This lies in the range of standard Indian pond ashes, which is reported to be 1.64–2.66 by several previous studies including Das and Yudhbir [3].

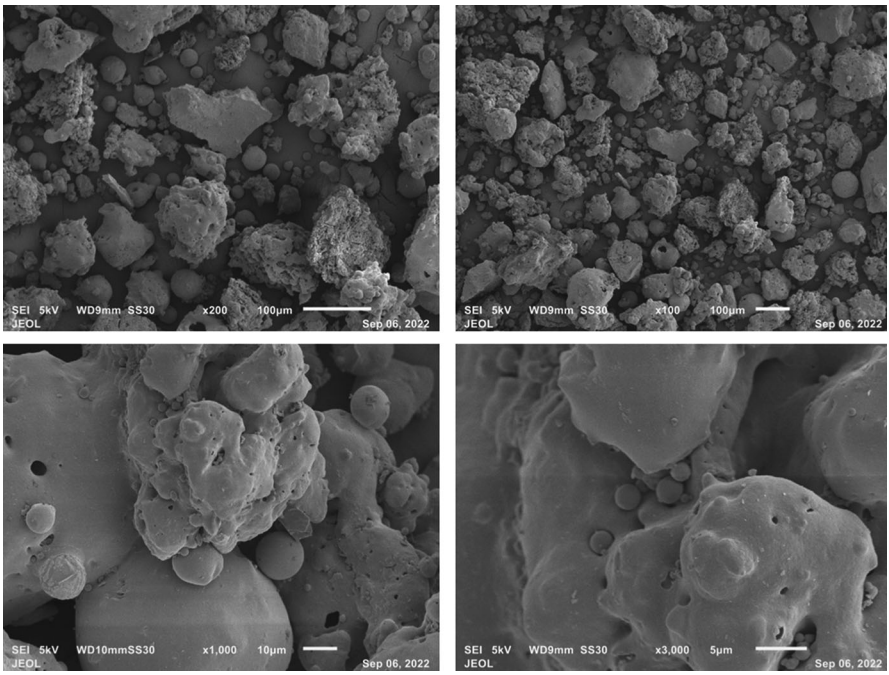

Fig. 1 Scanning electron micrographs of Parichha pond ash

2.4 Grain Size Distribution

The grain size distribution of the pond ash was obtained following IS: 2720-Part 4. First, the sieve analysis was carried out, followed by a hydrometer analysis for the remaining sample passing through the 75 μm. The grain-size distribution indicated the fraction of gravel, sand, silt, and clay to be 0%, 79.2%, 20.8%, and 0%, respectively, by weight. As per unified soil classification system, thee pond ash considered in this study can be classified as silty sand with the symbol SM. Table 2 provides the fractions of different components in the sample, whereas Fig. 2 shows the grain-size distribution plot obtained from the test. In this plot, apart from the grain-size distribution of the chosen pond ash sample, the ranges for liquefiable soils as proposed by Tsuchida [9] have also been shown. It can be seen that Parichha pond ash definitely fall in the liquefiable range confirming potential for liquefaction.

Table 2 Grain size characteristics of Parichha pond ash

Physical properties	Values
Gravel (> 4.75 mm)	0
Sand (4.75–0.075 mm)	79.2% (by weight)
Silt (0.075–0.002 mm)	20.8% (by weight)
Clay % (<0.002 mm)	0
Coefficient of uniformity *Cu*	2.57
Coefficient of Curvature *Cc*	0.681
D_{10}	0.068 mm
D_{30}	0.09 mm
D_{60}	0.175 mm
USCS Group symbol	SM
USCS Group name	Silty Sand

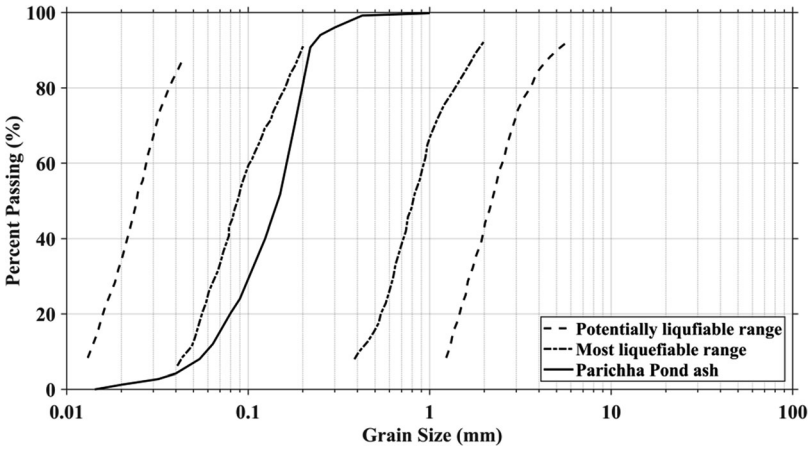

Fig. 2 Grain size distribution curves for Parichha pond ash sample overlaid with a range of liquefiable soil as given in Tsuchida [9]

2.5 Compaction Characteristics

To obtain the compaction characteristics of the pond ash, standard Proctor test was done. The compaction curve obtained from the test is shown in Fig. 3. The maximum dry unit weight and optimum moisture content of the material were estimated as 1090 kg/m3 and 38.5%, respectively.

2.6 Direct Shear Test

In order to estimate the shear strength properties of the pond ash sample, a series of direct shear tests had been carried out as per the guidelines of IS:2720 (Part-13), [10]. The sample was prepared at a density of 65%. Normal stresses of 50 kPa, 100 kPa, and 150 kPa were applied on the specimen. The deformation applied at a rate of 0.6 mm/min. Figure 4 shows the shear stress versus shear strain plots at different normal stress levels. It can be observed from the plot that the sample shows dilative behaviour corresponding to 150 kPa normal stress case. The angle of internal friction was estimated as 33°.

3 Cyclic Simple Shear Test Setup and Sample Preparation

A series of strain-controlled cyclic tests was performed on the Parichha pond ash using the cyclic simple shear test at the Indian Institute of Technology Kanpur. The primary components of equipment include: a loading unit, a pneumatic control panel, an electronic control and a display unit. The photograph of the testing facility is given in Fig. 5.

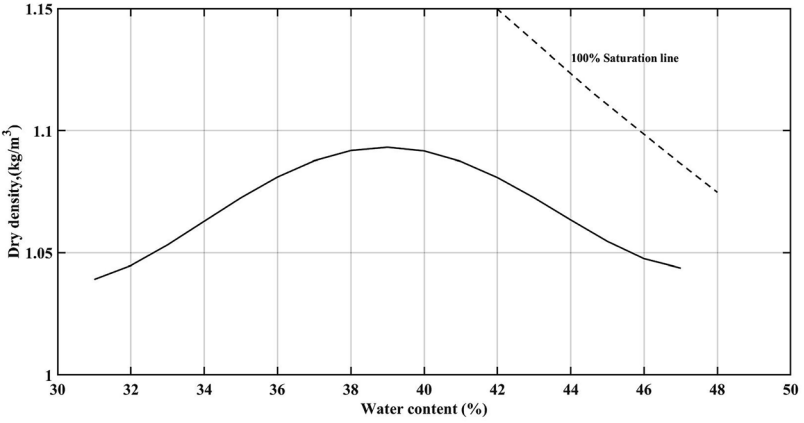

Fig. 3 Compaction curve of Parichha pond ash

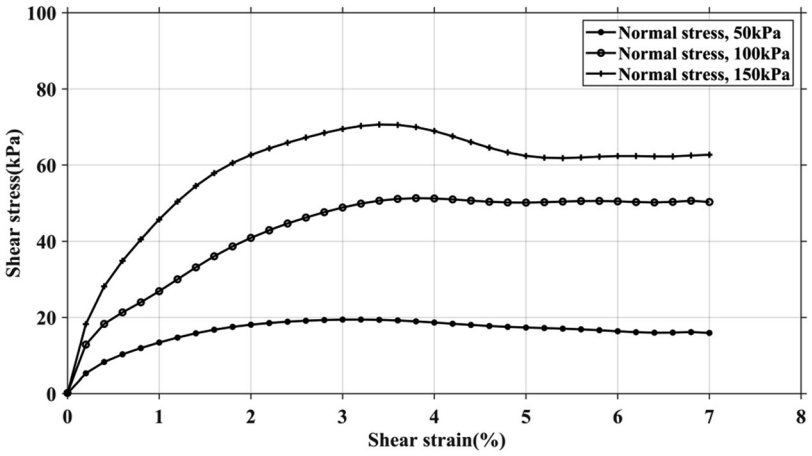

Fig. 4 Shear deformations vs. shear stress curve of Parichha pond ash

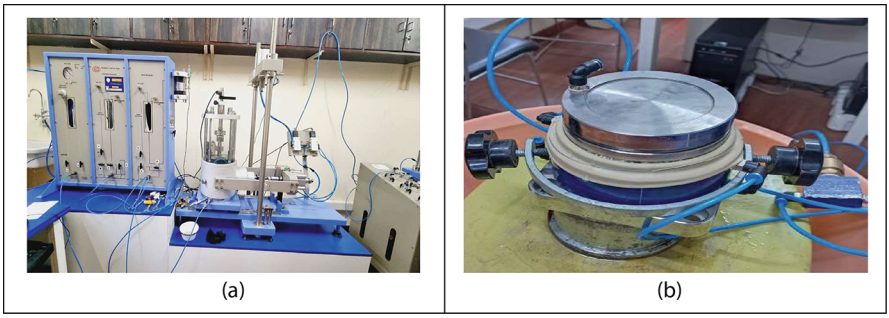

Fig. 5 (**a**) Cyclic simple shear apparatus and (**b**) sample preparation mould

During a test, the required cell pressure and back pressure can be controlled through the computer-based controller unit, which operates on a closed loop control mechanism. In the present study, the pond ash specimen, after compacted into desired relative density of 65%, was confined in a plain membrane. The specimen prepared was of size 10 cm diameter and 3 cm height, making an aspect ratio of 0.3, which is well below the maximum limit 0.4 as per ASTM D8296.

A split mould was used for the sample preparation (Fig. 5b). A simple moist tamping technique is adopted to achieve the desired 65% relative density. The ash sample was placed in the mould, water was added and then the sample was compacted mechanically in three layers. After the sample was placed on the lower plate, a nominal vacuum pressure was applied to keep the sample in vertical position, after which, the mould was removed. After the sample was placed on the mould, the hammer and the normal load cell were placed on top of the sample. The box was then closed and with the upper box and consequently was filled with water. The cell pressure and back pressure were applied in stages by maintaining a variation of 20 kPa. In each stage, Skempton's pore water pressure parameter B was estimated.

The consolidation process had been started with a confining pressure of 100 kPa after Skempton's pore water pressure parameter *B* reached 0.95. At this point, the soil was considered to be fully saturated. When the volume change approached zero, the back pressure valve was closed to end the consolidation process and to maintain an undrained condition during the shearing stage. After the consolidation phase was complete, a strain-controlled cyclic loading was started to be applied.

A cyclic loading in sinusoidal wave forms having peak strain amplitude (δ_c) 3.83% and 5% with frequency of 0.2 Hz was applied on the consolidated pond ash specimen which is under the confining pressure of 100 kPa and 200 kPa. According to Jakka et al. [4], the frequency of load application is set to provide for enough time to equalize the pore pressure.

4 Results and Discussion

The following observations were made from the cyclic simple shear tests on the Parichha pond ash sample.

4.1 Dynamic Properties

The cyclic stress–strain behaviour of pond ash sample subjected to sinusoidal waves of strain amplitude, γ_c 5% with frequency, f of 0.2 Hz under the confining pressure, σ_c of 100 kPa is shown in Fig. 6. It can be observed from Fig. 6 that as the number of cycles increases, the hysteresis loops progressively become flatter indicating higher

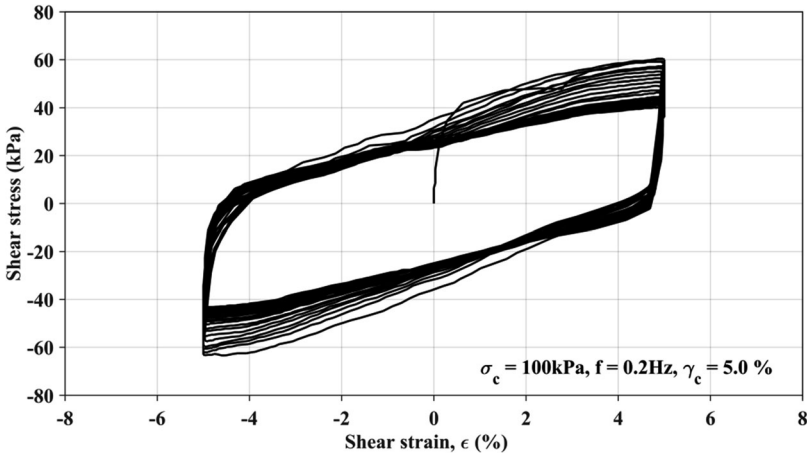

Fig. 6 A typical stress–strain behaviour of Parichha pond ash sample of 65% relative density subjected to 5% cyclic shear strain amplitude under 100 kPa confining pressure

Table 3 Dynamic properties of Parichha pond ash

Shear-strain amplitude (%)	Confining pressure (kPa)	Maximum shear stress (τ_{max}) at the first cycle	Shear modulus (kPa) (G_{sec})	Damping ratio
3.83	100	50	1306	0.2898
3.83	200	67	1747	0.2892
5	100	60	1207	0.3028
5	200	81	1641	0.3019

energy dissipation and gradually increasing inelastic behaviour. Furthermore, each hysteresis loop indicates nonlinear behaviour of the sample with clear indication of strength and stiffness degradation with each loading cycle. The tests were repeated for confining pressure of 200 kPa and shear strain amplitude of 3.83%. The effect of the shear strain and the confining pressure on different dynamic characteristics was examined.

The important dynamic properties including strain-dependent secant shear modulus, damping ratio, and peak shear stresses observed from the tests for different confining pressures (100 kPa and 200 kPa) and strain amplitudes (3.83% and 5%) are provided in Table 3. It can be noted that the dynamic shear modulus increases from 1306 to 1747 kPa, i.e., an increase of about 34% for an increase in the confining pressure from 100 kPa to 200 kPa. Similarly, the peak stress level also shows an increase of about 35%. The damping ratio, on the other hand, is insensitive to the change in confining pressure, showing a change less than 0.2%.

When the effect of strain amplitude is considered, it is observed that for the 100 kPa confining stress, the peak stress increases from 50 kPa to 60 kPa (i.e., an increase of about 20%) for an increase in the shear strain amplitude from 3.83% to 5%. The shear modulus reduces from 1300 MPa to 1200 MPa (i.e., a reduction of 7.7%), whereas the damping ratio increases from 29% to 30% (i.e., an increase of about 3.33%). For the higher confining pressure, i.e., 200 kPa confining pressure case, the influence of strain amplitude is similar, with an increase in peak shear stress of 21%, reduction in shear modulus of about 5.7% and increase in damping ratio as 3.33%. The observations indicate that at higher strain level, the ash sample behaves as softer material with lower stiffness and higher deformation potential, as also expected for any conventional loose to medium cohesionless soil.

4.2 Liquefaction Potential

The pore pressure developed during the undrained loading was using pore pressure transducer attached to the apparatus. From the pore pressure development pattern, the liquefaction potential of the sample was estimated. Figure 7 shows the excess pore pressure ratio versus number of cycles at 5% strain amplitude confined with

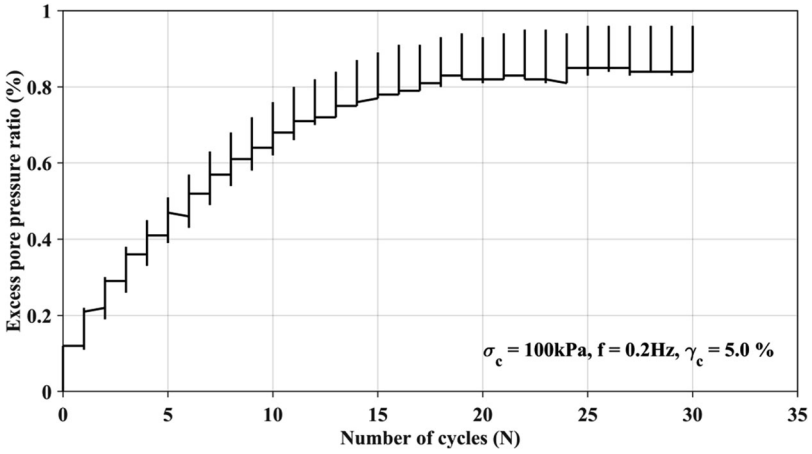

Fig. 7 Excess pore pressure ratio versus number of cycles of Parichha pond ash (65% relative density) subjected to 5% cyclic shear strain amplitude under 100-kPa confining pressure

100 kPa pressure. The gradual increase in pore pressure is observed as normal for any typical cohesionless soil. The maximum pore pressure ratio is observed to reach a value up to 98% at 25th cycle. The number of cycles needed for liquefying the sample is observed to reduce from 29 to 25 when strain amplitude is increased from 3.833% to 5%. This reinforces the strain dependency of the ash sample and increased vulnerability with respect to liquefaction hazard when subjected to large intensity loadings.

4.3 Degradation Index

To quantify the amount of stiffness reduction with increase in strain, a parameter, namely, *Degradation Index*, δ, has been introduced herein. The degradation index, δ, is defined as ratio of the shear modulus of the first cycle and the shear modulus of N^{th} cycle, as shown below.

$$G_{\text{N}} = \delta\, G_1$$

where G_{N} and G_1 are the secant shear moduli, after the N^{th} cycle and the first cycle, respectively.

Figure 8 presents the degradation index versus number of cycles for both 5% and 3.83% strain level cases under 100 kPa confining pressure. It may be observed from Fig. 8 that the dynamic shear modulus constantly decreases with increasing shear strain for both strain amplitude test series. The degradation index is as much as 0.55 (i.e., 45% loss) for 5% strain level and 0.75 (i.e., 25% loss) for 3.83% strain level. Further, when the rate of reduction is considered, it is observed that the rate of

degradation is higher for the 5% strain amplitude case compared to the 3.83% strain amplitude case. Moreover, it is also evident from Fig. 8 that during the initial 5–10 cycles, the rate of degradation is most prominent for both strain amplitude tests, whereas after 10 cycles, the curves reach a plateau and degradation index that remains approximately constant afterwards.

4.4 Comparison with Other Studies

In Table 4, a summary of observations on various critical parameters pertaining to dynamic loading for the chosen Parichha pond ash sample is provided. The results

are also compared with reported values for different ash samples taken from other powerplants located in various parts of India. It can be noted that the properties obtained for Parichha pond ash is within the range reported in the previous studies.

5 Conclusions

The present study focuses on static as well as dynamic characterization of pond ash collected from Parichha power plant in North-Central India. For the dynamic characterization, cyclic simple shear tests with varying shear strain amplitude and confining pressure had been performed. The following key observations were obtained:

- The ash falls into the category of silty sand (SM) as per USCS classification system. The shear strength parameters indicated zero cohesion and a friction angle of 33° indicating it as a medium dense cohesionless material. Chemical and mineralogical compositions indicated that the material falls under Class-F category with low potential for adverse environmental impact, and hence suitable for its usage as geotechnical fill material.
- The dynamic shear modulus was observed to be highly sensitive to the change in confining pressure, showing an increase of about 34% when the confining pressure was increased from 100 kPa to 200 kPa. The damping ratio, on the other hand, remained unchanged.
- The shear strain amplitude has shown reasonable effect on all dynamic properties. The shear modulus was observed to reduce about 7.7%, whereas the damping ratio increased about 3.3%, when strain amplitude increased to 5% from 3.83%.
- The excess pore pressure generation and related strength loss indicated the vulnerability of the material for liquefaction-induced failure. The number of

cycles required to initiate liquefaction were observed as 29 and 25, for the strain amplitudes of 3.83% to 5%, respectively, indicating increased vulnerability of the material during higher intensity earthquake events.

- The modulus degradation was observed to be as much as 0.55 and 0.75, for 5% and 3.83% strain level, respectively. Further, the rate of degradation was prominent during the first 5–10 cycles and then attained almost a constant value for both test series.

1 Introduction

In 2015, the United Nations introduced the 2030 Agenda for Sustainable Development to address the social, economic, and environmental issues of societies by setting 17 sustainable development goals (SDGs) and 169 targets [1, 2]. By introducing this agenda, it was expected to tackle most of the sustainability issues by 2030. However, at the midpoint of this journey, reports regarding the sustainability issues show unsatisfactory and unexpected results. On top of everything, the global mean temperature has increased by about 1.1 °C above preindustrial levels (1850–1900). Moreover, global carbon dioxide (CO_2) emissions from industrial processes grew by 0.9 percent to a new all-time high of 36.8 billion metric tons [3].

The construction industry contributes to some of the issues mentioned earlier [4]. However, the UN has recently stated that to build sustainable cities and societies, efforts should concentrate on implementing inclusive, resilient, and sustainable urban development policies and practices. These should prioritize access to basic services, affordable housing, efficient transportation, and green public spaces for all [3]. Despite this recommendation, civil engineers have recently begun to incorporate sustainability approaches into their projects. In terms of sustainable construction, they have integrated green building materials and techniques [5–7]. Among these, earth-based materials have garnered significant attention from engineers and practitioners [8].

Earth-based materials are cost effective and can mitigate environmental issues. These materials can be incorporated into the construction industry using sustainable techniques for constructing both structural and nonstructural elements of buildings, pavements, and other infrastructures. These techniques, inspired by historical construction methods, include adobe, rammed earth, and compressed earth block [9].

Rammed earth, also known as pisé, is a sustainable construction technique where a wet soil mixture is compacted layer by layer at its optimum moisture content and maximum dry density [9]. Furthermore, the mechanical properties of rammed earth can be enhanced by stabilizing it with additives such as cement [10], lime [11], natural additives [12], and geopolymers [13]. Despite the superior mechanical performance, particularly in terms of compressive strength, of stabilized rammed earth compared to unstabilized rammed earth, both have lower tensile strength due to the inherent properties of soil. To overcome this limitation, rammed earth can be reinforced with both natural and artificial fibers [14].

While rammed earth appeals to engineers due to its sustainability benefits and historical context, the information surrounding its trends, implications, and properties remains unclear. To address these gaps, this research study first evaluates public comments and sentiments toward the implementation of rammed earth in the construction industry using an AI-based tool. Subsequently, the trends related to rammed earth are studied and critically compared. In the second section, the gaps in the analysis of the mechanical properties of rammed earth are identified and will be addressed in the subsequent section. In the third section, the gaps in the mechanical properties of rammed earth are analyzed using soft computing and machine learning methods. Within this process, the dataset includes sustainable rammed earth (with a lower carbon footprint) and conventional rammed earth (with a higher carbon footprint), which could be helpful to interpret the correlations between the sustainability factors of rammed earth and its mechanical properties, especially compressive strength. This interpretation, along with the critical analysis, is included in discussion section of this study.

2 Sentiment Analysis of Social Media

Sentiment analysis or opinion mining is primarily a business tool that can be beneficial for evaluating customer satisfaction with a product. By doing so, companies can identify the weaknesses of their products and take steps toward improving and enhancing their quality. Sentiment analysis is so expansive that it can be conducted on anything from a single text to numerous texts and comments across various platforms. Social media can be a great source of data for sentiment analysis as it contains a vast number of datasets and texts where people share their opinions on specific subjects [15]. The most important social media platforms for sentiment analysis are Reddit, Facebook, X (Twitter), and Instagram [16, 17].

Sentiment analysis is conducted using artificial intelligence techniques such as deep learning (DL) and natural language processing (NLP). In this context, data, primarily text, plays a crucial role in facilitating efficient sentiment analysis. For sentiment analysis of social media, data can be gathered using a technique called web scraping. The extracted data is then analyzed and modeled using NLP. As a result of this modeling, sentiments can be interpreted in two categories: positive and negative, or on an n-point scale (good, neutral, and bad) [15].

In this study, due to the restrictions and security policies on the APIs of reputable social media platforms, especially X, sentiment analysis is conducted using an AI-based tool introduced by North Carolina State University, USA. This platform is capable of visually analyzing sentiments based on emotional models, and it can display a heatmap and word cloud of the sentiments [16].

The keyword "rammed earth" was entered into the query section of the platform, which then analyzed the sentiments surrounding this keyword within the Reddit database. It extracted 102 comments regarding "rammed earth" from 2014 to 2023. Figure 1 shows the sentiment visualization, indicating that the public's attitudes toward "rammed earth" are generally acceptable and pleasant. This result was expected, as the sentiment analysis of keywords related to sustainable development has mostly been positive [18].

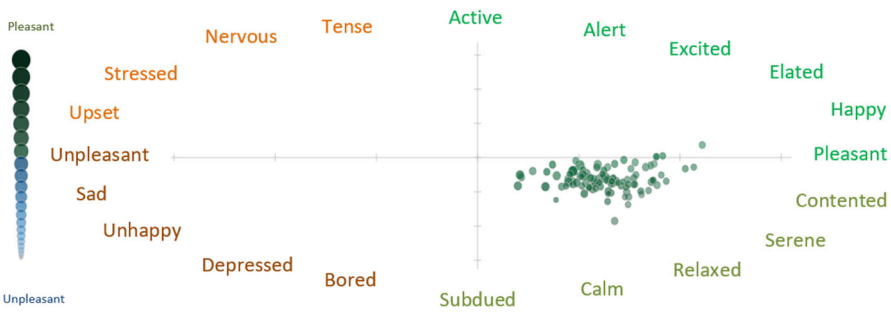

Fig. 1 The visualization of sentiment analysis regarding rammed earth

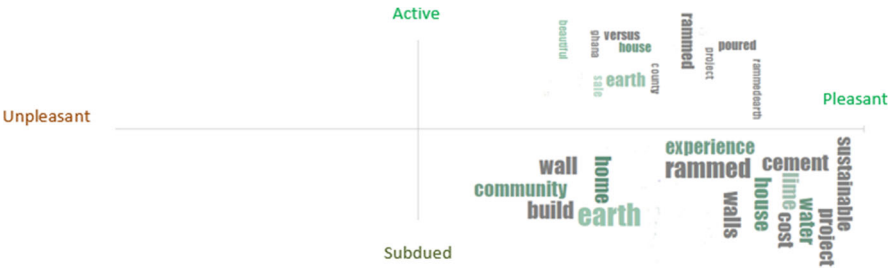

Fig. 2 The word cloud extracted from the sentiment analysis regarding rammed earth

Furthermore, from the extracted data, frequently used words can be highlighted using a word cloud. Figure 2 demonstrates the word cloud of the posts regarding "rammed earth." In the word cloud, the size of each word corresponds to its frequency in the context of rammed earth construction. It can be concluded that most of the posts and comments are shared regarding the sustainability capabilities, especially cost-effectiveness, of cement and lime-stabilized rammed earth elements such as walls. The word "water" has been mentioned as an influential factor on its properties as well.

It is worth mentioning that these results are based on the Reddit database, which is one of the applicable platforms in social media [16]. The results might change if other social media platforms are included in the study.

3 Bibliography of Rammed Earth

This section will provide a bibliography of the rammed earth technique, not only to study the trends in its number of publications but also to identify specific gaps in this material compared to other materials. This bibliometric analysis utilizes the Scopus dataset, focusing on articles published within the last 15 years, from 2008 to 2023.

First and foremost, regarding the search criteria, the keywords "rammed earth," "concrete," "masonry," "compressed earth block," and "timber" have been searched in the Scopus database within the article titles. This includes the field of engineering disciplines and excludes the field of pharmacy and its related fields.

The total number of publications from 2008 to 2023 regarding rammed earth, concrete, masonry, compressed earth block (CEB), and timber are 737, 159,000, 12,392, 181, and 13,556, respectively. Although rammed earth and CEB techniques are highly sustainable and more historical compared to other materials and techniques, concrete, timber, and masonry have gained more attention. The number of publications regarding rammed earth is 0.5% of the number of articles published for concrete. While it is true that the mechanical properties of concrete are superior to those of rammed earth, resulting in better performance against earthquakes and other strong lateral loads, rammed earth has superior sustainability properties. This allows

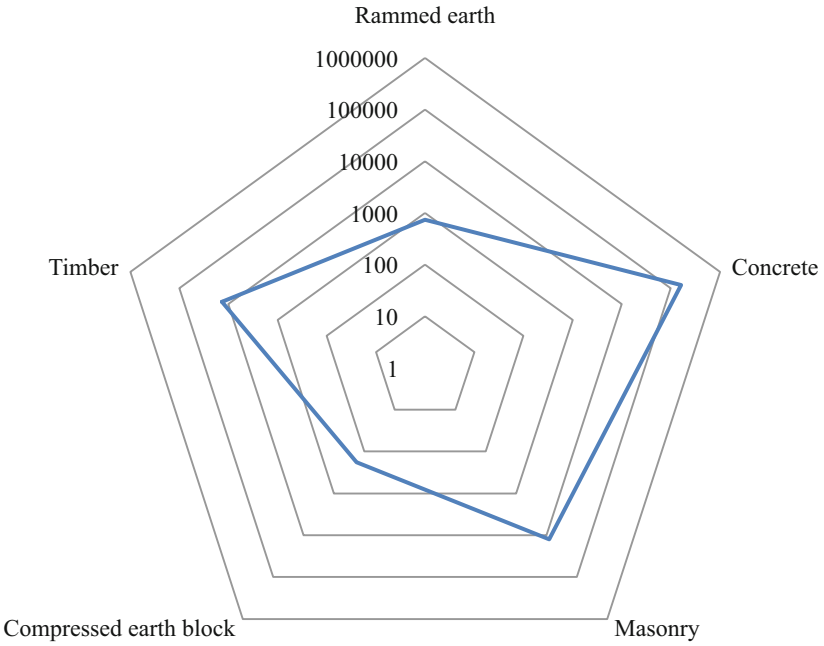

Fig. 3 The total number of publications from 2008 to 2023 on a logarithmic scale

it to contribute to a sustainable and resilient society, which is a pressing need today. Figure 3 demonstrates the total number of publications from 2008 to 2023 on a logarithmic scale.

In addition to the total number of publications regarding these materials, it is crucial to evaluate the trend each year from 2008 to 2023. Figure 4 shows the trend in the number of publications each year from 2008 to 2023 for the mentioned materials. While concrete, masonry, and timber materials have shown an increasing trend up until 2023, rammed earth has experienced fluctuations since 2008.

As a result of the aforementioned statistics, engineers and scholars need to research more on rammed earth and compressed earth blocks in order to identify and address their gaps. However, from the bibliometric study of rammed earth, other gaps could be identified. For instance, as the rammed earth technique requires more energy and time to conduct experiments regarding its properties, the application of soft computing and numerical methods could be beneficial in this regard. According to the Scopus dataset, the number of publications on the application of soft computing methods in rammed earth and compressed earth block research is lower compared to other construction materials such as concrete, masonry, and timber. It is so low that the sum of the number of publications for both rammed earth and compressed earth block is 0.19%, 4.8%, and 5.2% of the number of articles published for concrete, masonry, and timber, respectively. Nevertheless, this result was expected, as based on the results of the bibliometric study in this article, the total number of

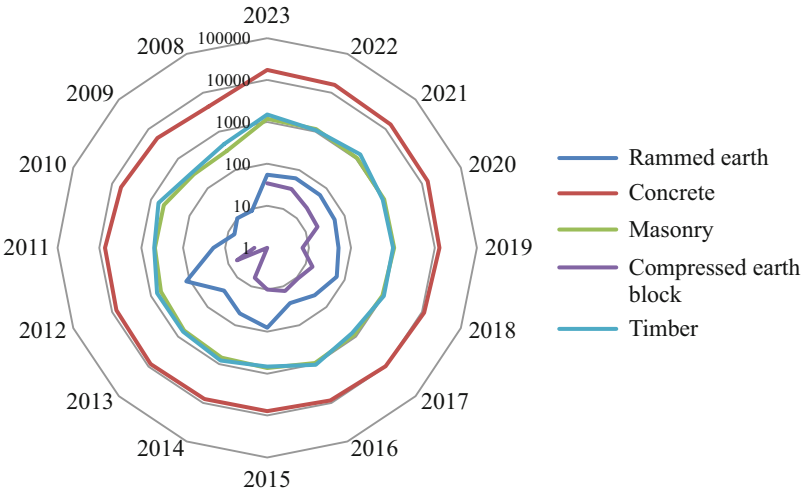

Fig. 4 The trend of the number of publications in each year from 2008 to 2023

publications regarding both rammed earth and compressed earth block is much lower than for other construction building materials. Although in other types of soil-based materials which are more related to geotechnical applications (e.g., soil stabilization), numerous research exist that apply soft computing and numerical methods to their methodology, the focus of this study is just rammed earth in the field of structural and earthquake engineering, or in other words, rammed earth building structures. Furthermore, according to the Scopus dataset, there are only six publications regarding the application of soft computing in rammed earth. Therefore, it can be concluded that it is expected to conduct more research in this field of rammed earth material in order to bridge the gaps.

4 The Analysis of the Mechanical Properties of Rammed Earth Using Data Science Principles and Machine Learning

In Sect. 3, it was concluded that there is a lack of research, especially in the field of soft computing, concerning rammed earth materials compared to other construction building materials. Regarding the use of soft computing in rammed earth and compressed earth block projects, there has been a paucity of research, most of which is discussed in the following paragraphs.

Mustafa et al. [19] used machine learning techniques, namely multi-linear regression (MLR) and artificial neural networks (ANN), to predict the 28-day unconfined compressive strength of both unstabilized and stabilized rammed earth. The dataset for this study consisted of 488 entries with feature vectors including fine, sand, and

gravel content, soil liquid limits, plastic index and linear shrinkage, stabilizer type (none, cement, and lime), stabilizer dosage, optimum moisture content (OMC), maximum dry density (MDD), aspect ratio, and testing condition (dry or wet). This study showed that using ANN resulted in better performance compared to MLR. Narloch et al. [20] predicted the compressive strength of cement-stabilized rammed earth by fitting a deep learning technique, namely a convolutional neural network (CNN), into 4284 SEM images. The accuracy of the model was about 84%, which was a satisfactory performance. Turco et al. [21] modeled an ANN on a study with a dataset of 332 entries. In this study, the feature vector comprised clay content, OMC, cement content, fiber content, fiber length, fiber tensile strength, and the specimen's age. Moreover, the target was the compressive and tensile strength of compressed earth blocks. The results demonstrated better performance in predicting compressive strength rather than tensile strength. Anysz and Narloch [22] and Anysz et al. [23] predicted the compressive strength of cement-stabilized rammed earth using ANN, decision tree (DT), and random forest. The feature vectors for both studies were clay, silt, sand, and gravel contents, cement content, OMC, and MDD. Kardani et al. [24] gathered datasets of 83 and 891 entries for the prediction of compressive strength and stress-strain properties, respectively. In this study, a new feature called loading rate was considered. Moreover, the dataset was trained using XGBoost algorithms and techniques. The results revealed an appropriate performance of using XGBoost, especially with smaller datasets.

A review of the background of studies regarding the application of machine learning in rammed earth materials reveals that many gaps still remain and future studies should focus on these gaps. For instance, the combination of lime and cement, information regarding the types of fibers, clay mineralogy, the shape of the specimen, curing conditions, and novel machine learning methods could all be considered to advance the prediction of the compressive strength of rammed earth.

This study will focus on a part of this gap in the following sections. The compressive strength of rammed earth materials will be predicted using a dataset extracted from Scopus, which includes some features that have not yet been investigated. It is worth mentioning that this dataset includes the application of natural-based materials which can improve the sustainability properties of rammed earth. Through data science principles, the dataset will be preprocessed and then modeled using two machine learning methods, namely artificial neural networks (ANN) and decision trees (DT). Finally, the model will be evaluated using the R-squared metric.

4.1 Data Collection and Analysis

A dataset of an acceptable size, 382, has been provided from the Scopus database by searching according to the keywords "rammed earth" and "compressive strength." The dataset, part of which is shown in Table 1, comprises both feature and target values. The feature values are regarded as the factors affecting the target value. Fine x1 (the combination of clay and silt), sand x2, and gravel x3 contents (%), type of

stabilizer x4, stabilizer content x5 (%), type of fiber x6, fiber content x7 (%), fiber properties including length x8 (mm), diameter x9 (mm), and tensile strength x10 (MPa), moisture content x11 (%), dry density x12 (kg/m3), specimen shape (cylinder (CY), cube (CU), prism (PR)) x13, specimen's aspect ratio x14 (height/width), number of layers x15, the age of the specimen until conducting the compressive test x16 (day), and the duration of curing for each specimen x17 (day) are provided as features that can affect the compressive strength y (MPa) of rammed earth in dry condition. It is worth mentioning that both chemical (cement (C), lime (L), the combination of cement and lime (CL), the combination of cement and additives such as super-plasticizers (CA)) and natural (cow dung (CD)) stabilizers are considered in the dataset. Besides, the natural (N) (e.g., straw, coir, date palm, and Curaua) and artificial (A) (e.g., polypropylene and waste tire textile) are the types of fibers used in the dataset.

After gathering and preparing the dataset, it is essential to extract the statistical information from the dataset and then visualize it for better interpretation. Table 2 shows the statistical information of the dataset.

Furthermore, before determining the correlations between the features and targets, it is necessary to ensure that there are no missing data, outliers, or noise. By coding in Python, it was confirmed that there are no missing data, as the sum of is null values is zero. Moreover, to check and evaluate outliers, the boxplot of each feature and target was compared to z-score values. In the existing dataset, no values were identified as outliers.

The next step is to normalize the dataset. However, due to the existence of nominal and qualitative data, data normalization and the subsequent process of modeling may be affected by this discrepancy in the data. To address this problem,

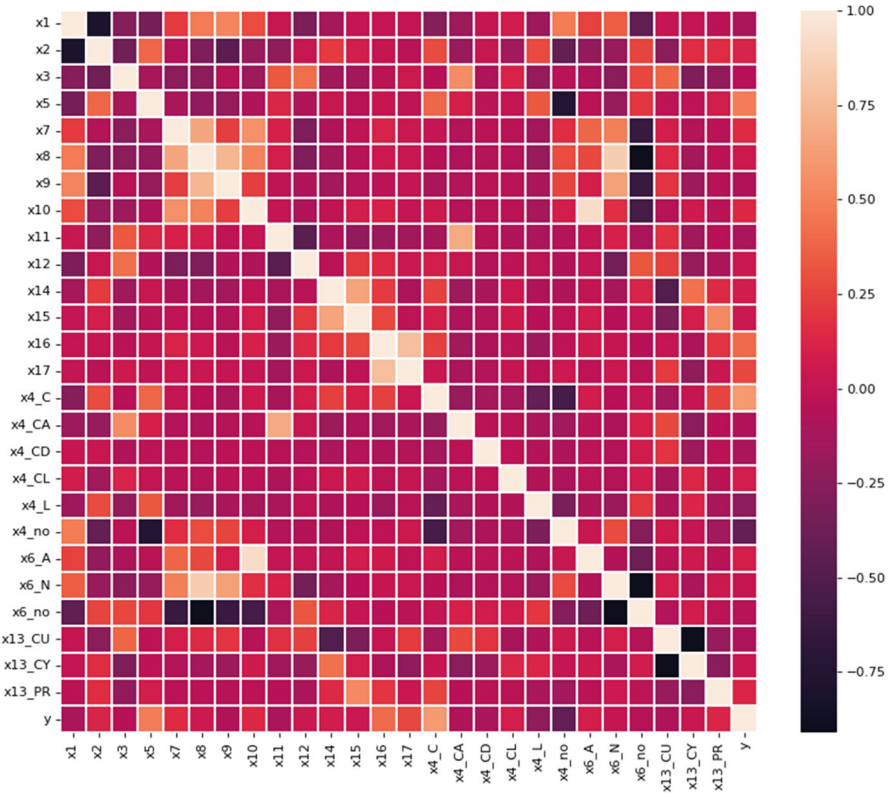

Fig. 5 The correlations between the feature and target values

encoding such data could be a viable solution. Dummy encoding is one of the solutions to appropriately encode the nominal data [25]. Dummy encoding is implemented for the nominal data, after which all the data is normalized using the Min-Max Scaler.

A Pearson correlation was conducted between the normalized features and the target. The Pearson correlation is an effective tool to represent the correlations between the feature and target values. Figure 5 depicts the Pearson correlations of the dataset.

Based on Fig. 5, compressive strength is directly affected by factors including the type and content of stabilizer, as well as curing time. On the other hand, a higher amount of fines can reduce the compressive strength of rammed earth, especially in cases involving cement-stabilized rammed earth.

4.2 Modeling Using ANN and DT

Modeling the scaled dataset is conducted using two machine learning methods, namely artificial neural networks (ANN) and decision trees (DT). The hyperparameters of these two techniques are tuned and optimized using a combination of grid search and cross-validation techniques. Moreover, in ANN, the gradient descent technique is implemented to optimize the rate of change of the weights in the neural networks. After modeling, the performance of the model is evaluated using the R-squared metric. The R-squared values for ANN and DT are 74% and 81%, respectively. The uncertainties in the nature of the soil led to the differences between these two models. Improving the performance of these models could involve employing optimization methods and expanding the dataset. Additionally, integrating additional factors such as soil chemical composition could be feasible.

5 Discussion

Rammed earth, a sustainable material, is less noticed than concrete despite its potential for building resilient societies. With the sustainable development goals (SDGs) unlikely to be met by 2030, focusing on adaptation is crucial for progress. To shed light on this, according to a report from the UN in 2023, approximately 1.1 billion people live in slums or slum-like conditions, and this number is expected to rise to more than 2 billion in the next 30 years. Moreover, air pollution issues are not only confined to urban areas but also affect rural areas [3]. Accordingly, serious policies should be implemented in this regard. Using earth-based materials such as rammed earth and compressed earth blocks (CEBs) could be applicable in these situations as these kinds of buildings are cost-effective and, in some cases, have a negative carbon footprint. Furthermore, with the increase in the world's mean temperature, the majority of wildfires and fire-related disasters will occur [3]. Despite the existence of sustainable building materials such as timber, earth-based materials would be more viable compared to other sustainable building materials in this regard.

Regarding the correlations between the sustainability properties of rammed earth and its mechanical properties, such as compressive strength, some information can be extracted from Fig. 5. This figure suggests that in rammed earth construction, using less cement and more natural materials such as fibers and eco-friendly stabilizers can be sustainable. The type and amount of stabilizer greatly influence compressive strength, with cement being the most effective. However, sustainable alternatives like lime or cow dung also show promise. More research is needed to better understand these natural stabilizers' effects on both sustainability and mechanical strength.

Further research into rammed earth can enhance AI models, making them more reliable. Since rammed earth construction is energy intensive due to compaction, AI can optimize resource use and assist engineers in making efficient decisions in time-sensitive projects.

6 Conclusion

This research article first evaluates the public's opinion regarding the rammed earth technique through sentiment analysis using an NLP-based tool. As a result of the sentiment analysis, the public's attitude toward rammed earth was pleasant and positive. According to the word cloud generated by the analysis, most of the comments are related to the sustainability and stabilization perspective of rammed earth.

Furthermore, through a bibliometric study, the trend of rammed earth research was compared with other construction building materials such as concrete, masonry, compressed earth blocks (CEB), and timber. The results reveal that despite the sustainability capabilities of rammed earth and CEB, their trend is not as high as other materials. Accordingly, an increasing trend in research is needed to make these sustainable and historical materials and techniques applicable. More importantly, this increase in research is expected in the numerical and soft computing perspectives of these materials, as these techniques are required for making sustainable decisions to save time and cost.

Lastly, to address the gaps identified from the bibliometric study, machine learning methods, namely artificial neural networks (ANN) and decision trees (DT), were used, along with data science principles, to predict the compressive strength of rammed earth by considering various features including soil composition (fine, sand, and gravel), type of stabilizer, stabilizer content, type of fiber, fiber content, fiber properties including length, diameter, and tensile strength, moisture content, dry density, specimen shape (cylinder, cube, prism), specimen's aspect ratio (height/width), number of layers, the age of the specimen until conducting the compressive test, and the duration of curing for each specimen. According to the Pearson correlation, the type and content of stabilizer, the curing time, and the age of the specimen highly affect the compressive strength. On the contrary, a higher number of fines in soil composition can negatively affect the compressive strength of rammed earth, especially in cement-stabilized rammed earth. Moreover, the R-squared values of both ANN and DT models were lower than 82%. This performance can be enhanced by utilizing optimization techniques and a larger dataset. Moreover, implementing other features such as soil chemical composition would be viable.

Future studies should focus on both the experimental and numerical perspectives of rammed earth materials. The increasing trend in research can lead to the generation of a large amount of data, thereby resulting in robust AI models.

1 Introduction

A key challenge facing the future of the built environment is the urgent need to reduce the energy consumption of buildings, from material extraction to demolition [1]. The United Nations Environment Programme (UNEP) identifies that buildings are responsible for 40% of energy usage, 25% of water consumption and 40% of resource use globally. The energy performance of buildings in their operational stage is only one aspect of the environmental impact of the built environment. Life cycle

assessment (LCA) is key to a more holistic consideration of building environmental performance. To address whole-life environmental concerns, there has been a shift in recent years toward the development and implementation of bio-based thermal insulators. These nature-based solutions are often plant-based (e.g. hemp, straw, sisal) and biodegradable [2–4]. To address waste streams generated in construction and other sectors the re-purposing of would-be waste products such as straw, wood waste, paper etc. into insulation materials is of importance in the transition to a circular economy. Where such materials can be bound together with natural materials, rather than, for example, plastic-based adhesives, their use and re-use would become better aligned to circular principles. Mycelium has been demonstrated to be a potentially suitable binder for plant-based and other waste materials [5]. Additionally, mycelium-based composites (MBCs) can adapt to regional resource availability which can substantially reduce transportation costs and associated carbon emissions [6, 7]. The thermal and physical properties of these materials are tunable through a selection of species, substrates, growth conditions and manufacturing techniques, thereby enhancing their utility in design optimisation [8, 9].

Mycelium is the vegetative part of a fungus comprised of a mass of branching, thread-like, filaments that form a network structure. As mycelium colonises a substrate it creates a denser, tougher, outer layer due to the exposure to air and moisture evaporation. The result is a lightweight, porous structure with notable thermal insulation properties [10]. Figure 1 presents the stages of the production process and Fig. 2 shows a representative MBC used in this study and its interior and exterior, clearly depicting the distinct core and skin layers.

The reliable assessment of thermal conductivity and the comprehensive characterisation of thermal properties is important for their practical application and wider acceptance. Furthermore, the need to compare the results of thermal measures-.

ments between laboratories and materials databases etc. is self-evident. There are two common approaches to measuring the thermal conductivity of materials, namely, steady-state and non-steady-state [11]. Guarded Hot Plate (GHP) and Heat Flow Meter (HFM) methods are standard steady-state methods [12], widely used in the testing of building materials. Steady-state methods determine thermal

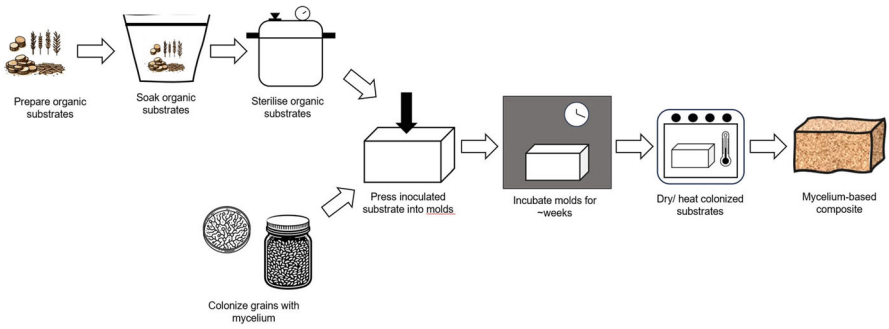

Fig. 1 Mycelium-Based Composite (MBC) manufacturing process

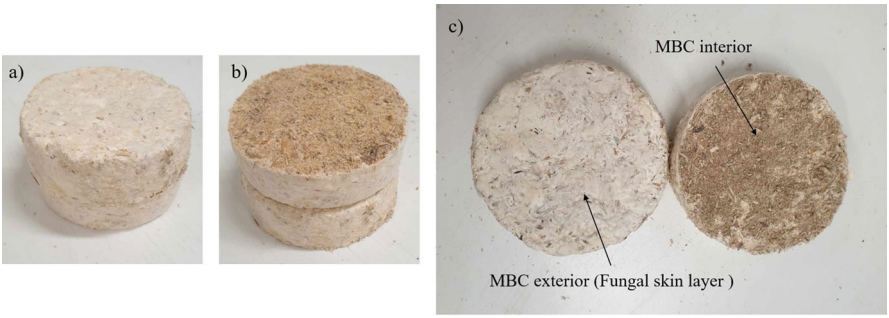

Fig. 2 Two MBC cylinders with an exterior surface removed, as used in this study. In (**a**) their interior surfaces are touching (skin-off configuration), and in (**b**) their exterior surfaces are touching (skin-on configuration). In (**c**) the exterior (fungal skin) and interior are shown. Cylinders are 100 mm in diameter and 30 mm in height

conductivity directly from the proportionality between heat flow and an applied temperature difference under thermal equilibrium. Measurement accuracy requires large samples and a test duration in the order of hours [13]. Due to the requirement for thermal equilibrium, throughout the test specimen, the method is largely insensitive to heterogeneity at the centimetre, or smaller, scale but specimens should be dry as the movement of water vapour will restrict the ability to reach thermal equilibrium [14].

The steady-state thermal conductivity of MBCs has been reported in [15–19]. Schmidt et al. [15] and Wimmers et al. [18] employed the heat flow meter technique, recording thermal conductivity values of MBCs, made using *Fomes fomentarius* and hemp shives, and *Polyporus arcularius, Trametes suaveolens* and *Trametes pubescens* each with birch sawdust, respectively, in the ranges of 0.041–0.046 W/mK and 0.051–to 0.055 W/mK, respectively. Zhang et al. utilised the divided bar method, yielding a measurement of 0.069 W/mK for an MBC based on rye berries with *Pleurotus ostreatus*. Dias et al. and Travaglini et al. both used the Guarded Hot Plate method to measure MBC thermal conductivity of MBCs made using *Ganoderma resinaceum* with Miscanthus and *Ganoderma lucidium* and *Laetiporus sulphureus* respectively with results in the range of 0.088 to 0.104 W/mK and 0.053 to 0.077 W/mK, respectively.

Transient, non-steady, methods measure the feedback response to a short pulse of heat and thus temperature distribution throughout the specimen varies with time. The test duration can be relatively short, as reaching equilibrium is not required. However, computing the heat conduction equation is more complex as it requires resolving time-dependent heat flow Eqs. [20]. Test specimen sizes can be much smaller than those required for GHP or HFM testing, which is a significant advantage in research and development laboratories. The Hot Disk (HD) device, a transient plane source (TPS) technique, is a popular tool for rapid and accurate thermal conductivity measurement [12]. In the Hot Disk device, the sensor performs the

function of the heat source and a temperature measuring device. Although single-sided testing is possible, measurements are optimised when the sensor is sandwiched between two pieces of test specimen material. In this arrangement, the two sample specimens sandwiching the sensor must be of sufficient diameter and depth to ensure that the 'thermal wave' does not reach any boundary of the test specimen during the transient recording period. Studies using the Hot Disk have presented systematic errors when applied to low-conductivity insulation materials [21–23]. These errors are attributed to the idealised model assumptions that the Hot Disk employs for data analysis. Comparisons with steady-state techniques have shown reproducibility errors of up to 30% due to inhomogeneity and poor thermal contact [24]. Analysis using an isotropic model can overestimate thermal conductivity by around 25% and Colinart et al. conclude that even with the anisotropic functionality, the Hot Disk method's sensitivity to volumetric heat capacity measurements remains a source of difficulty when seeking to determine thermal conductivity for heterogeneous bio-based materials [24].

Schritt et al. used a dynamic hot-wire method to measure thermal conductivity at the centre and the edge of MBCs [25]. Measurements showed significant species-dependent differences in the fungal skin thermal conductivity. However, the device settings are not presented and the potential influence of the room environment on the probe at the material edge is not discussed. Whilst it is stated that for the edge measurement, the hot wire was placed between two fungal skins it is unclear what thickness of material was present.

The characteristic skin layer of the MBC has properties such as density and porosity that differ from the bulk core of the specimen. Consequently, the size of the specimen alters the ratio of skin to core material, which influences the measured thermal conductivity. Accordingly, measured thermal conductivity may not be representative of the entire composite, which is significant in the context of scaling up MBCs to the size required for insulation in building elements.

In the current body of research, a total of 17 studies reporting thermal conductivity measurements of MBCs are documented; these present a range of λ values from 0.0321 to 0.180 W/mK. These studies include 12 distinct fungal species and 19 substrates. The lowest recorded thermal conductivity value for an MBC was observed in a composite comprising *Pleurotus ostreatus* mycelium with ash wood chips. The authors attribute this low conductivity to the fungus-substrate combination. However, this conclusion ignores the potentially significant role of the measurement technique employed and the experimental arrangement.

In this study, we seek to (i) evaluate the influence of the fungal skin of MBCs and (ii) undertake a direct, same specimen, comparison of Hot Disk (HD) and Heat Flow Meter (HFM) thermal conductivity measurements. The uncertainty in specimen thermal conductivity introduced by the MBC skin layer is evaluated through HD measurements of 12 MBC specimens. Each specimen was made using the same fungal strain derived from the species (*Trametes versicolor*) and a range of cellulose substrates and measured both with and without the skin layer. The samples range in bulk density from 157 to 233 kg/m^3 and the test arrangement employed the HD

anisotropic measurement module. The anisotropic measurement setup allows for the assessment of thermal conductivity in both the radial and axial directions, offering a comprehensive analysis of the specific influence of the fungal skin and its influence on the specimen's thermal conductivity. The Heat Flow Meter measurements were taken on a single large specimen, which was then cut to enable measurement with the HD apparatus. The values obtained are compared and an effective heat capacity is obtained which can be used in HD measurements to allow for comparison with steady-state results.

2 Methods

2.1 Sample Preparation

The mycelium samples used in this work were provided by Mykor Ltd. The samples were prepared using the following methodology: Mycelium spawn is produced by removing a sample from a mushroom fruit, placing it in an agar dish, and allowing the mycelium to colonise the agar. Cellulose-based waste products are sterilised in a steam autoclave. Mycelium spawn is then weighed and added to the sterilised cellulose. The cellulose and spawn are churned before being used to fill moulds. The spawn is left to colonise the substrate in the moulds for one week. The composites are then de-moulded and heated to 70 °C to stop hyphae growth [26].

The moulds used in this study are cylinders of diameter 100 mm and height 30 mm, and a 500 mm by 500 mm by 105 mm panel with a density 172 kg/m^3 of which a 110 mm by 110 mm by 80 mm cuboid is cut from, which is cut in half for HD measurement. Each sample was formed from a cellulose-based substrate, with samples 1–12 varying in composition with different additives with a density in the range of 157–233 kg/m^3. Figure 2 shows a representative cylinder with the fungal skin present and removed. Sample 13 was obtained by cutting a 110 mm × 110 mm × 40 mm section from the larger sample to enable measurement with the HD is shown in Fig. 4a.

2.2 Hot Disk

The 12 cylindrical samples and the 110 mm × 110 mm × 40 mm cuboid sample (sample 13) were subject to thermal testing using the Hot Disk equipment according to ISO 22007-2:2022 [27]. Samples were tested with the skin layer on and again with the skin layer off. For samples 1–12, the skin layer was removed by slicing it off, and for sample 13 the skin layer was absent on one face as it was cut from the larger sample. Five thermal analysis tests were performed on each sample using a Hot Disk TPS 3500 device in a controlled environment at 23 °C. The samples were allowed to

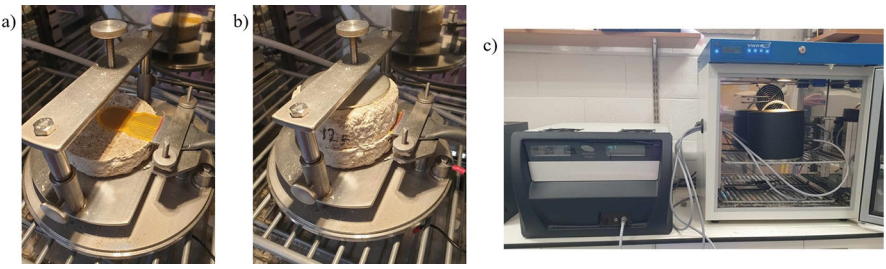

Fig. 3 (**a**) Hot Disk set up for skin-off measurements (an identical sample on placed on top of the sensor). (**b**) Hot Disk set up with sensor sandwiched between identical samples. (**c**) Hot Disk apparatus alongside incubation unit to maintain a stable temperature during measurements

stablise before testing. Between measurements, the samples were allowed to cool for 320 minutes to equilibrate back to 23 °C. The tests were conducted using a 14.6 mm Kapton Sensor. The thermal tests used 40 W with a duration of 640 seconds, ensuring a mean deviation of less than 0.0001 K in all cases. The mean deviation provides an indicator of the quality of the data, where a value of 0.0001 K or less is considered acceptable 'noise'. The measurements were conducted in the anisotropic module of the Hot Disk TPS 3500 which performs measurements in the radial and axial directions. To perform anisotropic thermal conductivity measurements, the volumetric heat capacity (ρC_ρ) was measured using the isotropic thermal conductivity set-up for the HD and used as an input in the anisotropic module to determine the ratio between axial and radial thermal conductivity. Figure 3 presents the setup for the HD measurements conducted in this experiment.

The density of the samples was measured to be in the range of 157 kg/m^3 to 244kgm/^{3}, with a weakly positive correlation between density and isotropic thermal conductivity observed ($R^2 = 0.33$).

2.3 Heat Flow Meter

A single specimen (sample 13) of 500 × 500 × 105 mm was produced for Heat Flow Meter testing according to ASTM-C518 [28] (Fig. 4b), and subsequently cut to form two smaller samples for Hot Disk testing, as described earlier. The specimen was stored in the laboratory at room conditions (approx. 20 °C and 50% RH) for three days prior to testing. The mass of the sample as tested was 4523 g, giving a density of 172 kg/m^3. The test was conducted at mean temperatures of 10 °C and 20 °C with a temperature difference of 20 *K* in both cases and the test duration was 7 hours for each set point temperature.

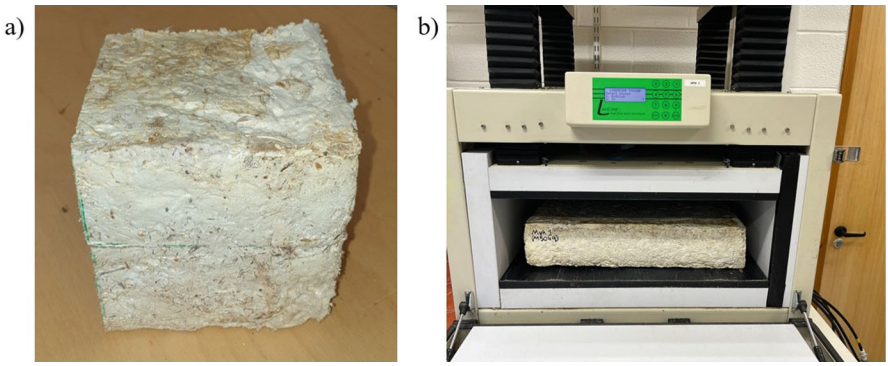

Fig. 4 (**a**) Two 110 × 110 × 40 mm samples cut from larger sample 13. (**b**) Heat Flow Meter testing of sample 13

3 Results and Discussion

3.1 Skin on vs Skin Off

Figure 5 presents the results from the measurements of the anisotropic thermal conductivity measurements of the samples with and without the skin layer in both the axial and radial direction. The difference in λ_{axial} vs λ_{radial} is likely attributable to the material structure, with the difference between the two diminishing at higher densities. In the axial direction, 10 out of 12 samples tested showed a higher thermal conductivity with skin on than with skin off, whereas radially 8 out of 12 samples had a higher measured thermal conductivity with the skin on. This inconsistency suggests that the specific composition of each sample and the characteristics of the fungal skin influence thermal performance in a way that requires further investigation into the material properties of each sample before assumptions can be made about whether the fungal skin layer will lead to an increased or decreased thermal conductivity for any specific MBC. Overall, these results show the presence of a skin layer on the samples introduces additional discrepancies in the measurement of thermal conductivity. This layer, while sometimes removable, presents a challenge in accurately determining the thermal properties of materials, particularly for thin samples. For thicker specimens, the removal of this skin layer may be feasible and can lead to more accurate representations of the material's inherent thermal conductivity, and the thermal conductivity of similar scaled-up samples. However, this is not always possible, especially for thinner samples, where the skin layer constitutes a more significant proportion of the sample's overall structure. Consequently, the thermal conductivity values obtained for samples with the skin layer intact may not accurately reflect the true thermal properties of the material. This limitation underscores the necessity of considering the potential impact of the skin layer when interpreting thermal conductivity measurements, especially when evaluating small prototypes before scaling up dimensions.

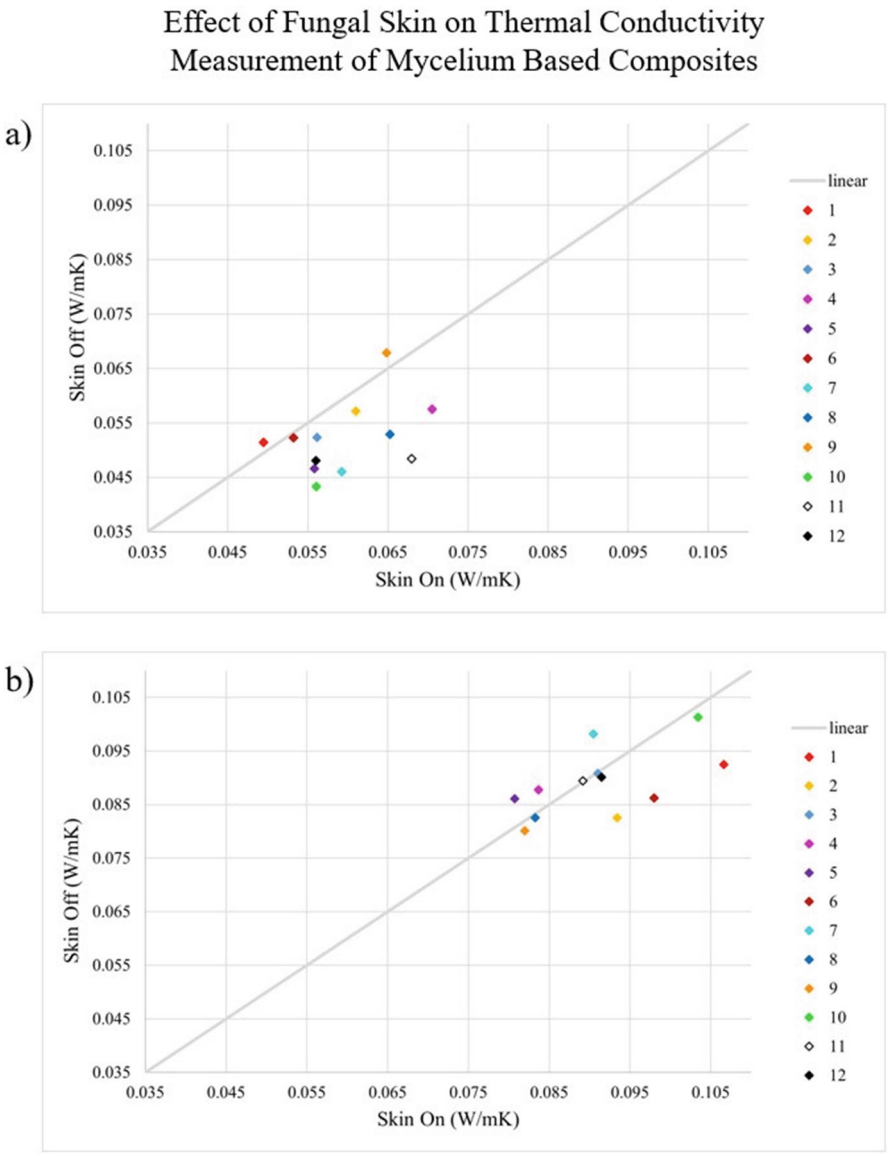

Fig. 5 (**a**) λ_{axial} of MBC samples measured using the Hot Disk Method with and without the fungal skin layer. All errors <0.001 W/mK. (**b**) λ_{radial} of MBC samples measured using the Hot Disk Method with and without the fungal skin layer. All errors <0.003 W/mK

3.2 *Heat Flow Meter vs Hot Disk*

Measured using the Hot Disk anisotropic module, the λ_{axial} of sample 13 with skin on was (0.0775 ± 0.0003) W/mK and with skin off was (0.0695 ± 0.0002) W/mK. Measured using the HFM λ_{HFM} of sample 13 was (0.05536 ± 0.00003) W/mK at 10 °C, and (0.06260 ± 0.00003) W/mK at 20 °C. The isotropic measurement of thermal conductivity (skin on) was (0.0773 ± 0.0001) W/mK which is within error of λ_{axial}, we assume $\lambda_{axial} = \lambda_{HFM}$. Comparing these values, λ measured using HFM at 10 °C, the Hot Disk overestimates thermal conductivity by 40% for the sample with skin on, and 26% for the sample with skin off. In comparison to the HFM results at 20 °C, the Hot Disk overestimates thermal conductivity by 24% for the sample with skin on, and 11% for the sample with skin off. This observation highlights the inherent challenge in comparing the thermal conductivities of samples when different measurement methodologies are employed. Furthermore, the presence of fungal skin introduces an additional layer of discrepancy, particularly pronounced in the case of small samples.

Volumetric heat capacity (ρC_ρ) is used as an input in the Hot Disk anisotropic thermal conductivity measurement. This value can be measured using the isotropic thermal conductivity set-up. The anisotropic measurement is sensitive to ρC_ρ and therefore by using an effective ρC_ρ the values of thermal conductivity measured using the HFM and the Hot Disk can be compared. A specified value of ρC_ρ can be used in the isotropic set-up of the Hot Disk; however, the isotropic measurement is far less sensitive to ρC_ρ with an increase in ρC_ρ of 1% yielding a decrease in thermal conductivity of 0.39%, as calculated by opting to override the default setting of measuring ρC_ρ during the measurement and using varying ρC_ρ values as inputs. By sampling values of ρC_ρ between 0.3 and − 0.5 J/m^{3}K, the value of ρC_ρ that yielded λ_{HFM10} was approximately 0.42 J/m^{3}K for sample 13 with skin on, and 0.39 J/m^{3}K for sample 13 with skin off, and the value of ρC_ρ that yielded λ_{HFM20} was approximately 0.38 J/m^{3}K for sample 13 with the skin on and 0.34 J/m^{3}K for sample 13 with skin off. Figure 6 presents the results of this calibration. Sensitivity analysis

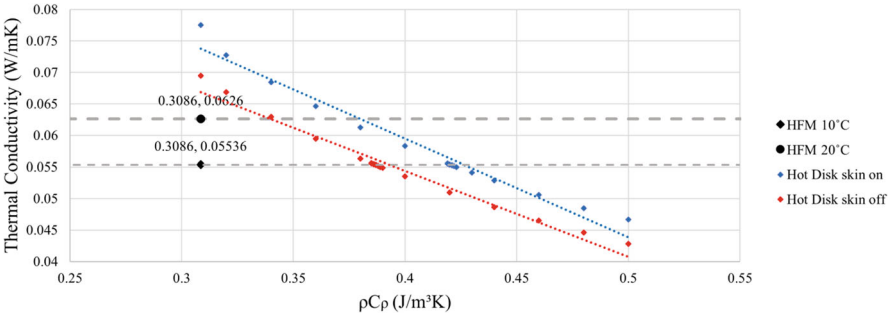

Fig. 6 Axial thermal conductivity of sample 13 (skin on and skin off) as measured using the Hot Disk anisotropic module for various input values of ρC_ρ between 0.3–0.5 J/m^{3}K, and the thermal conductivity measurement using the HFM (assuming a value of ρC_ρ of 0.308 J/m^{3}K as measured using the isotropic Hot Disk set-up)

based on the slope of the linear regression line that describes the relationship between ρC_ρ and λ_{axial}, a 1% increase in ρC_ρ yields a 1.09% increase in λ_{axial} with this relationship being approximately linear over the range of ρC_ρ sampled.

4 Conclusions

In this study, we aimed to resolve some of the uncertainties associated with measuring the thermal conductivity of mycelium-based composites to facilitate their use as sustainable insulation materials. To do this we compared the thermal conductivity measurements of MBC samples with and without the fungal skin layer to assess its influence on thermal conductivity measurement using the Hot Disk apparatus. We then compared the thermal conductivity measured using transient and steady-state techniques by using the heat flow meter to measure the thermal conductivity of a large sample before cutting the sample into smaller dimensions to measure thermal conductivity using the Hot Disk. To calibrate the Hot Disk measurements to the Heat Flow meter we determined an effective volumetric heat capacity for the MBC. The following main conclusions can be drawn:

- The presence of the fungal skin influences thermal conductivity measurements of MBCs. In 10 out of 12 samples measured, the presence of the fungal skin leads to an increase in measured thermal conductivity compared to without the fungal skin. Consideration is therefore needed when measuring the thermal conductivity of small samples with the fungal skin present, as this will influence the measurement and will not scale up to larger samples where the thickness of the skin assumes a different dimension.
- The presence or absence of the fungal skin is not enough to explain the large discrepancy between measurements conducted with the Hot Disk apparatus (transient methodology) and the heat flow meter (steady-state methodology). The choice of measurement technique is the largest source of uncertainty in this instance.
- To allow for comparison between the Hot Disk apparatus results and the heat flow meter results, an effective volumetric heat capacity can be used with the anisotropic Hot Disk set-up measuring axial thermal conductivity. We found that the effective ρC_ρ that allowed for this comparison was 0.42 J/m^{3}K with the fungal skin off, and 0.39 J/m^{3}K with the fungal skin on.

1 Introduction

Cement production is responsible for around 8% of global CO_2 emissions [1]. Two-thirds of these emissions come from limestone calcination during clinker production [2]. To address this issue, one of the main sustainable strategies targeted by cement manufacturers is that of clinker substitution by supplementary cementitious materials (SCMs) [3]. SCMs can either be sourced naturally (clay, natural zeolite, limestone) or industrially (fly ash, granulated blast furnace slag, glass powder) [4]. They have proven to be effective, with limestone calcined clay, in particular, yielding positive results: a 45% substitution of clinker enables a 40% reduction of CO_2 emissions, with the advantage of clay being a widely available material [5, 6]. However, clay is also a valuable resource for other industries, such as agriculture [7]. For that reason, reusing clay waste instead of extracting natural clay to substitute clinker could be a balanced solution tackling both the issue of CO_2 emissions and of resource availability.

In this light, previous studies have proposed the valorisation of mining waste marl as an SCM in cement [8–10]. Marl, a material rich in clay and lime, presents promising pozzolanic properties when calcined, thus enabling the production of mechanically performant calcined marl cement (CMC). It is particularly abundant in Moroccan phosphate mines due to the country's substantial phosphate mining activities. As Morocco endeavours to reduce its environmental impacts according to a planned sustainable transition [11], the valorisation of phosphate mining waste marl as clinker substitutes in cement will be a favourable way to stimulate the circularisation of the country's economy.

To monitor such efforts and help orientate decisions within this context, a life cycle assessment (LCA) can be used. Regulated by ISO 14040 and ISO 14044 standards, it is applied to evaluate, in a systematic manner, the environmental impacts of products or services throughout their life cycle.

In the available literature, there are many LCAs of various SCM-based cements, from naturally sourced [12–16] to industrially sourced ones [17, 18]. Several contexts have been explored: American, Brazilian, Indonesian, etc. Results of these LCAs have supported decision-making in several countries, such as Cuba, in which blended cement manufacturing has been encouraged by prolific research [19] as well as the establishment of new regulations (e.g. ASTM WK70466). As far as waste-clay cement is concerned, only one study has been conducted so far [15]. It compares the environmental impacts of Ordinary Portland Cement (OPC) and various LC3, including ceramic waste clay cement. A systematic review of the LCA of blended cement has compiled all these studies and analysed them from the points of view of methodology and results [20]. Several issues were highlighted, such as the choice of a functional unit (FU) of 1 ton of cement or cradle-to-gate system boundaries, which hinder the representativeness of the models. Based on this, future LCAs of blended cement were recommended to increase the precision of their FU by considering the mechanical and durability properties of cement on the one hand and extending system boundaries to the grave on the other hand. This, in turn, would require data on the service life (SL) of the cement which would enrich the blended cement literature.

This paper thus aims to address these issues through a comparative LCA of waste marl cement, OPC and LC3 in a Moroccan context. The objectives are defined as follows: (1) Estimate the environmental potential of waste marl cement (2) Compare the environmental impacts of waste marl cement with OPC and natural clay based-LC3 (3) Conduct the LCA for two different FUs: 1 ton of cement and 1 ton of cement per MPa per year (4) Estimate the SL of the cements (5) Conduct a sensitivity analysis of the results to the impact method to test the robustness of the study.

2 Materials and Methods

2.1 Life Cycle Assessment

The methodology adopted for the LCA is defined by ISO 14040-14,044. It consists of a goal and scope definition, life cycle inventory (LCI) analysis, life cycle impact assessment (LCIA) and interpretation.

Table 1 Characteristics of the cement under study (V_{ACC}: measured accelerated carbonation, ρ_0: measured electrical resistivity)

Cement	Compressive strength (MPa)	ρ_0 (Ω. m)	V_{ACC} ($mm.d^{-1/2}$)	CaO content (%)	Source
OPC	40	80	0.59	59	Lab
30CMC	37	155	1.27	52	Lab
20CMC	38	145	0.82	57	Lab
LC3	43	219	0.76	41	[21, 22]

Goal Definition This LCA aims to estimate, in a Moroccan context, the environmental potential of calcined marl cement and benchmark it against the conventionally used OPC and the environmentally high-potential LC3.

Scope Definition *System description.* This study focuses on three cement types, with two distinct formulas for CMC. In total, there will be four scenarios compared: OPC with a 0.95 clinker content; LC3 with a 0.70 clinker, 0.20 calcined clay and 0.05 limestone content; 20CMC with a 0.75 clinker and 0.20 calcined marl content, and 30CMC with a 0.65 clinker and 0.30 calcined marl content. The marl used in CMC is waste from the OCP phosphate mine in Benguerir, Morocco. The physico-chemical characteristics of the four cements under study are provided by lab experiments or taken from previous papers and displayed in Table 1. For the lab experiments, concrete with a water/binder ratio of 0.45 and the remaining volume divided according to a fine/coarse aggregate ratio of 0.55 was used for mechanical and durability performance evaluation.

Functional Unit The FU is defined for the first part of the study as 1 ton of cement to enable a simpler collection and clearer listing of data. Later, for the sake of a fairer comparison, the FU is upscaled to "1 ton of cement per MPa per year" by dividing the impact assessment results by the respective compressive strength and SL of each cement. *Reusing waste: a cut-off approach.* The marl used in CMC is a by-product of phosphate rock extraction. In this study, it is assumed to be retrieved directly from a pile of marl waste, sorted and deposited in the mine to be valorised. In the present reality, waste rocks generated by phosphate mining are deposited in a way that makes it difficult for marl to be recovered separately in enough reusable quantities. In any case, this marl remains unexploited by the mine, making it a "burden-free" waste material. A cut-off approach is thus adopted for the modelling: no impacts are allocated to the processes producing marl. On the other hand, the transport of the marl from the mine to the cement plant and the subsequent processing are accounted for. *System boundaries.* The boundaries of the analysed product systems extend from the raw material extraction stage to the production stage. This therefore is a cradle-to-gate LCA. The extracted raw materials, in addition to the recovered marl, are transported to the cement plant for processing: the marl and clay are ground and calcined to be used as SCMs, whereas limestone, iron ore, bauxite and shale are crushed, ground and calcined to produce clinker. The kiln used for clinker production is different from the one used for marl and clay calcination. The fuel used for the

kilns is petroleum coke, which is also extracted, processed then transported to the plant for grinding and burning. For the kiln used to produce clinker, in addition to petroleum coke, used tires are also burned with an 85:15 petroleum coke/tires ratio.

Clinker and gypsum are ground together to produce OPC. Calcined marl or clay is ground with clinker and gypsum to respectively produce CMC or LC3. It must be noted that even though in the second part of the paper, the SL of the cement is considered, the use and end-of-life stages are not modelled as they are assumed to be the same for all four cement.

Life Cycle Inventory Analysis Whenever possible, foreground processes such as marl calcination or clinker production were modelled using primary data—on materials, energy use and emissions—provided by three Moroccan cement plants. Otherwise, secondary data taken from the Ecoinvent database version 3.8 or online literature was used. For marl calcination for instance, CO_2 emissions generated by a 28.8 wt% content of dolomite in marl were estimated using the IPCC emission factor for dolomite calcination equal to 0.47732 t CO_2/t dolomite [23].

Basis for Impact Assessment LCIA calculations were carried out on SimaPro version 9.4.0.3. To have a more complete, detailed and accurate estimation, a midpoint method was adopted: IMPACT World+ midpoint version 1.29. Its impact categories are the following: climate change (CC), fossil and nuclear energy use (FNE), mineral resources use (MRU), photochemical oxidant formation (POF), ozone layer depletion (OLD), freshwater ecotoxicity (FEco), human toxicity cancer (HTc), human toxicity non-cancer (HTnc), freshwater acidification (FA), terrestrial acidification (TA), freshwater eutrophication (FEutro), marine eutrophication (ME), particulate matter formation (PMF), ionising radiation (IR), land transformation (LT), land occupation (LO) and water scarcity (WS).

Basis for Sensitivity Analysis The parameter tested for sensitivity is the impact assessment method. Two scenarios are compared: the base scenario applying IMPACT World+ and an alternative scenario applying ReCiPe 2016 version 1.07.

2.2 Mechanical and Durability Properties

In the second part of the study, the durability of the four cements is accounted for in the LCIA. To that end, the SL of each cement is quantified.

Service Life Estimation Khaldi's model of cement SL estimation, based on reinforced concrete behaviour during carbon induced corrosion, was adopted [24]. It considers SL as the sum of initiation and propagation times of corrosion as shown in eq. (1).

$$\mathrm{SL\ (years)} = t_{ini} + t_{prop} = \frac{1}{K_{eff}}\left(\frac{c}{3.03 k_{HR} V_{ACC}}\right)^2 + \rho_0 \frac{11c/d}{11.61 V_0 k_T k_{RH,prop}} \quad (1)$$

With Keff a wetting/drying cycle parameter, c the concrete cover (mm), k_{HR} and $k_{RH,prop}$ humidity parameters, V_{ACC} the measured accelerated carbonation rate (mm. d-1/2), ρ_0 the measured electrical resistivity (Ω.m), d the reinforcement diameter (mm), V_0 a constant (= 168.9 μAΩm.cm-2) and k_T a temperature parameter (T = 296 K).

SL results were obtained for a relative humidity of 55% and a humidification ToW ratio of 0, in accordance with Benguerir's climatic conditions. SL of the four product systems was calculated and compared based on c and d, with c inferior to d because the concrete cover must be larger than the reinforcement diameter, and c superior to 5 mm due to the NF EN 10080 standard. The data generated by this calculation was further consolidated on Microsoft Excel version 2008. The values for which LC3's and CMC's SL was superior to OPC's alone were retained. This allows for a thorough and complete study of the cements' SL. The (c;d) combination maintained for LCIA considering durability was arbitrarily chosen among the combinations generated during the SL calculations.

3 Results and Discussion

3.1 LCIA Results and Interpretation

FU: 1 Ton of Cement (Fig. 1) *Characterised results.* Characterised LCIA results are scaled to the score of the cement with the highest impact in each category (100%), as shown in Fig. 1. It appears that OPC presents the highest impacts for 13 categories. For these 13 categories, environmental impact scores follow the trend OPC > 20CMC > 30CMC > LC3. LC3 presents the highest impacts for the remaining four categories, particularly MRU, for which the score difference with other cements is substantial. Similar results have been found in a previous study comparing OPC with four other LC3, including a natural clay-based LC3, which

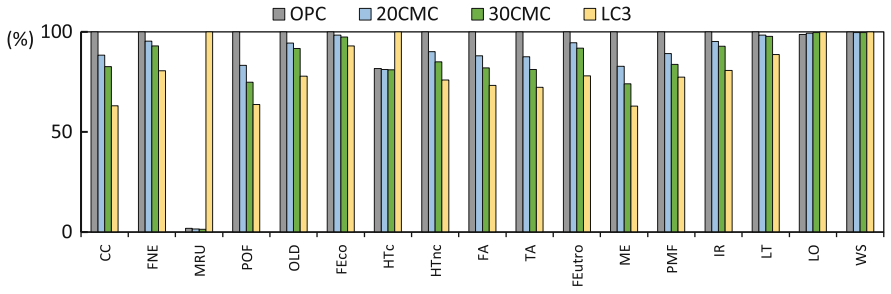

Fig. 1 Life cycle impact assessment normalised results for FU: 1 ton of cement

scored the highest for the abiotic depletion category [15]. *Process contribution analysis.* Apparent gaps between environmental impact scores and trends in the characterised results can be explained with the help of a process contribution analysis. The contribution of each process to each impact category can be seen in Fig. 2. Across all cements, it appears that clinker is mainly responsible for impacts on CC, POF and ME, with a contribution exceeding 75%. This is in line with previous LCAs of various types of cements [13, 17, 18]. On the other hand, fuel is

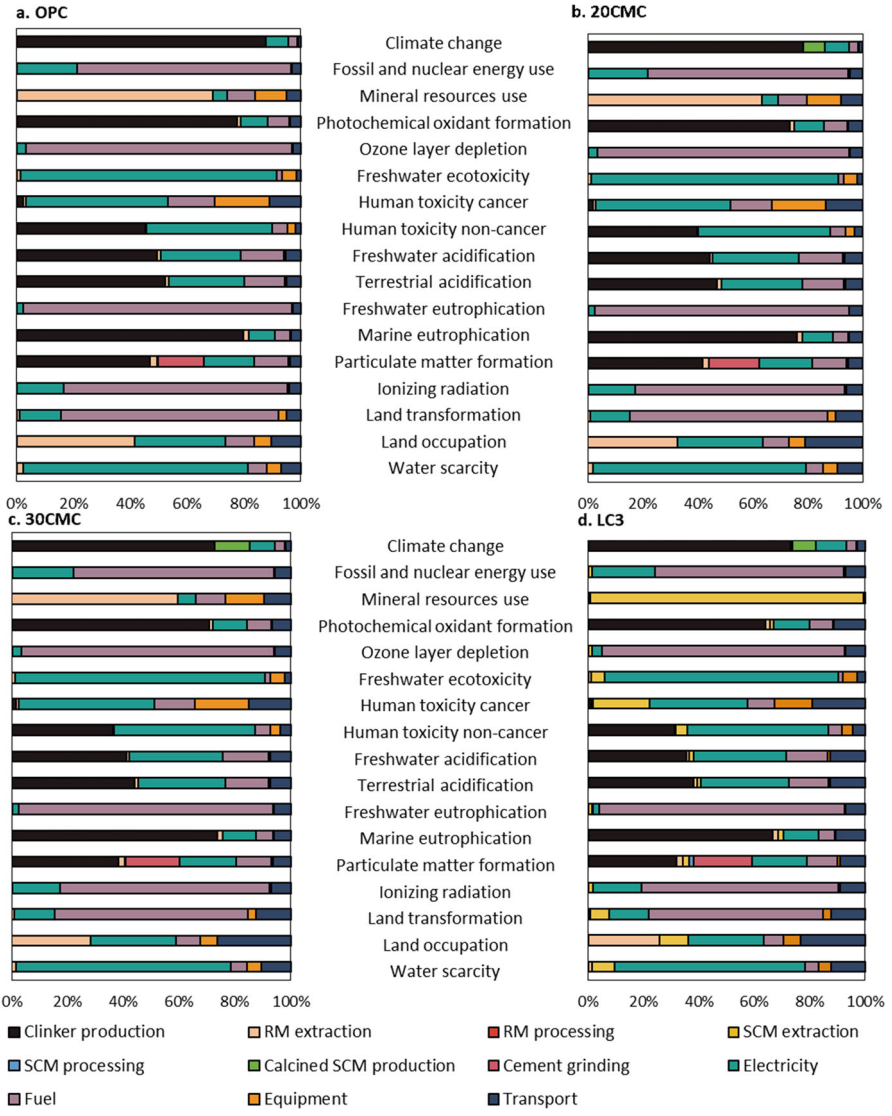

Fig. 2 Contribution analysis results for FU: 1 ton of cement

primarily responsible for impacts on FNE, ODP, FEutro, IR and LT, with a contribution superior to 75%. Moreover, electricity is mainly responsible for impacts on FEco and WS, with a contribution exceeding 70%. Besides, it seems that the impact of SCM calcination on climate change is of less than 10% for the three blended cements under study. Calcined marl's impact on CC was 370 gCO_2eq/kg while calcined clays were 191 gCO_2eq/kg. This is in harmony with what can be found in literature as far as calcined clays are concerned. Malacarne et al. [15] found global warming potentials (GWP) ranging between 66 and 185 gCO_2eq/kg of calcined clay while Pillai et al. [25] found emissions of 127 gCO_2eq/kg of calcined clay. The difference between calcined marl and clay emissions is due to the dolomitic content of phosphate waste marl which carbonates and releases CO_2 to the air. Finally, clay extraction for LC3 appears to be responsible for 99% of the impact on MRU.

Sensitivity Check Sensitivity analysis of the results to the choice of the impact method was conducted to evaluate the robustness of the study. Results for most impact indicators present the same trend for both impact methods. The five exceptions are MRU, WS, ME, LO and FEco which are shown in Fig. 3. *Mineral resources use.* When calculated with IMPACT WORLD+, LCIA results suggest a major problem with the MRU impact indicator for LC3. This poses a challenge for the LC3 low-carbon solution, as it appears to be burdensome for mineral resource consumption.

However, ReCiPe 2016 offers a different perspective, according to which 30CMC helps best with resource consumption, then followed by LC3. The reason behind such striking differences lies in the approach of each impact method to the mineral resource consumption problem. While IMPACT WORLD+ applies the material

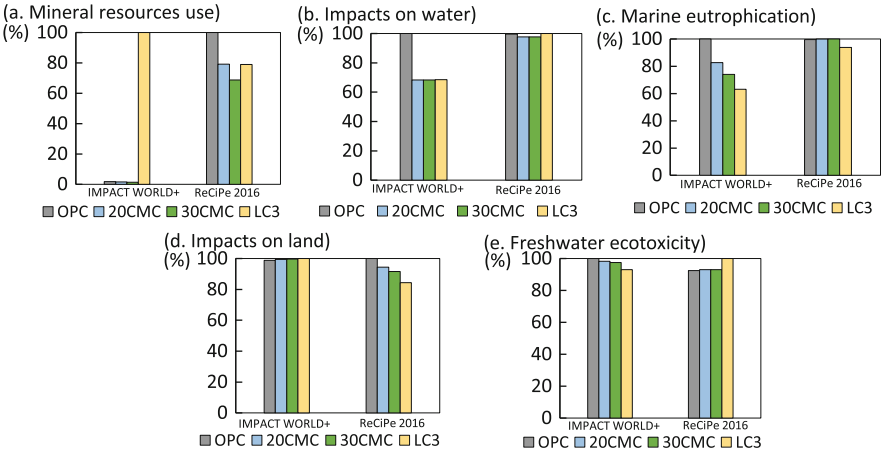

Fig. 3 Sensitivity analysis results for mineral resources use, freshwater ecotoxicity, water consumption, marine eutrophication and land occupation

competition scarcity index (MACSI) as a midpoint indicator for the MRU impact category [26], ReCiPe 2016 uses average surplus ore potential (SOP) as the midpoint indicator [27]. The difference between these two approaches is crucial in understanding the disparity in the results. MACSI looks at resource depletion; it considers the needs of initial users and their ability to meet their needs through the potential substitution of a resource by a depleted one [28]. On another hand, SOP looks at the impact of a mineral's extraction on its future ore production [27]. It is on this basis that characterisation factors (CFs) for clay differ, hence yielding the results in Fig. 3. *Impacts on water.* Results for impacts on water are similar for all four types of cement when the ReCiPe 2016 method is applied. On the contrary, there is a manifest gap between OPC and the three other cements when the IMPACT WORLD+ method is applied. This difference in trend in Fig. 3b lies in the different approaches to water impacts adopted by each method. Indeed, while ReCiPe 2016 considers water consumption as an impact indicator, IMPACT WORLD+ considers water scarcity. Water consumption refers to water that is no longer available in its original watershed [27], whereas water scarcity refers to the water remaining for one user (humans or ecosystems) in a watershed once the needs of another user have been met [29]. *Marine eutrophication.* Results obtained with ReCiPe 2016 show that OPC, 20CMC and 30CMC have a similar score, which is not the case when IMPACT WORLD+ is applied. This difference is due to the fact that unlike ReCiPe 2016, IMPACT WORLD+ considers nitrogen oxides emitted to the air in its ME indicator [25, 26]. *Impacts on land.* IMPACT WORLD+ and ReCiPe 2016 have different impact indicators to assess environmental impacts on land. While IMPACT WORLD+ has two separate indicators——one for land occupation and one for land transformation, ReCiPe 2016 has only one indicator combining the two under the name of land use. This thus explains the difference in trends seen in Fig. 3d. *Freshwater ecotoxicity.* LC3 presents the lowest impact on FEco when IMPACT WORLD+ is applied and the highest impact when ReCiPe 2016 is applied. This is due to aluminium, accounted for by IMPACT WORLD+ (with a CF of 3.2E7 CTUe/kg) but not by ReCiPe 2016 [26]. All in all, it must be underlined that impact assessment methods differ on the basis of their approach to environmental impact mechanisms. This contrast, which results from a difference in philosophies, may lead to major disparities in results at times. However, it also contributes to broader perspectives and richer discussions within the LCA community.

FU: 1 Ton of Cement per MPa per Year *Service life.* The longest SL for OPC, 20CMC, 30CMC and LC3 is respectively equal to 323, 207, 124 and 415 years. In their study, Khaldi et al. [24] have found service lives ranging from 10 to 300 years for (c;d) equal to (25;15) mm. For c ranging from 6 to 29 mm, and d from 5 to 8 mm, LC3 has a longer SL than that of OPC, ranging from 64 to 415 years. In other words, LC3 has a longer SL than OPC for 201 (c;d) combinations. On the contrary, 20CMC and 30CMC respectively have a higher SL than OPC for only 54 and 26 (c;d) combinations, with c varying from 6 to 22 mm for 20CMC; 6 to 16 mm for 30CMC; and d varying from 5 to 8 mm for 20CMC and 30CMC. As can be seen in Table 2,

Table 2 Calculated service life for (c;d) = (10;8) mm

Cement type	t_{ini} (yrs)	t_{prop} (yrs)	Service life (yrs)
30CMC	6	60	65
20CMC	14	56	70
OPC	26	31	57
LC3	16	84	100

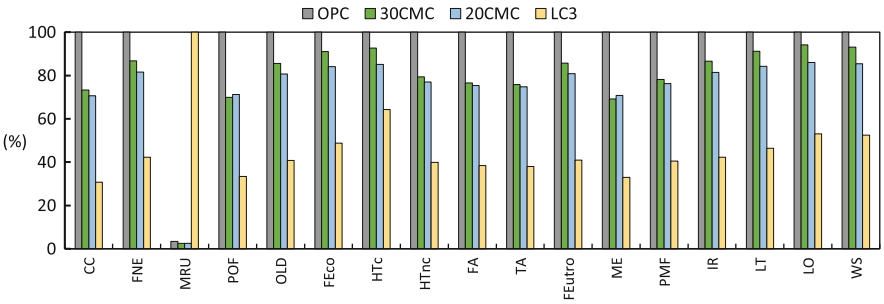

Fig. 4 LCIA impacts for OPC, 30CMC, 20CMC and LC3 for FU: 1 ton of cement/MPa/year

the reason behind this trend is the cements' electrical resistivity which influences the propagation time of corrosion. LC3's electrical resistivity far exceeds that of the other cements, which makes its t_{prop} and thus SL longer. On the other hand, the reason why 20CMC and 30CMC fall behind LC3 and OPC is their reduced resistance to carbonation, which dramatically decreases their t_{ini} and SL. This highlights the strength of LC3 as a low-carbon cement with high durability performance. Moreover, it also stresses the importance of improving CMC's resistance to carbonation since it would allow for a powerful low-carbon and durable solution in the Moroccan context. Lastly, LC3's durability performance can be furthered if its resistance to carbonation is enhanced.

Scaled Environmental Impacts When mechanical and durability performances are considered, OPC appears to be the worst-case scenario for 13 impact categories. It presents the highest impact on CC of 0.200 $kgCO_2eq/t/MPa/year$, whereas LC3 presents the lowest impact of 0.084 $kgCO_2eq/t/MPa/year$, 70% lower than OPC. 20CMC and 30CMC, respectively, present a GWP 29% and 27% lower than OPC. It must be noted that despite having a higher clinker content compared to 30CMC, 20CMC's environmental impacts are lower. That is due to 20CMC's higher resistance to compressive strength and longer SL. Apart from its MRU score, LC3 remains the best scenario even when we modify the FU, with its impact scores lower than 50% for most impact categories, mainly due to its long SL. Overall, it seems that the trends in this figure show that CMC and LC3 are both positive alternatives to OPC, with LC3 being the better of the two (Fig. 4).

4 Conclusion

This study consists of a comparative LCA of waste marl cement, OPC and LC3 in the Moroccan context. It seeks to evaluate the environmental potentials of waste marl cement production, and at the same time addresses several methodological issues pointed out in previous works regarding LCAs of blended cements.

The key takeaways of this paper are the following:

- LC3 proves to be the best low-carbon solution for the cement industry, with a GWP 70% lower when mechanical and durability performances are considered.
- Through the reuse of phosphate waste, CMC enables gains of >95% compared to LC3 and > 20% compared to OPC in terms of MRU.
- SL calculations have shown that LC3 has the best durability performance, followed by OPC then CMC. Taking this parameter into account in the FU leads to different LCIA results, with LC3 presenting the lowest environmental impacts in all cases.
- Reading LCIA results in the light of the chosen impact method is crucial for a fair interpretation. Sensitivity analysis of the impact method offers a broader and more comprehensive view of LCIA results.

The limitations and perspectives highlighted by this study are the following:

- Changing the FU should involve a whole rebuild of the LCI rather than a mere division of LCIA results by new parameters.
- SL results were retained for the case where OPC's SL was the lowest. This limits interpretation as cases where OPC would have a longer SL were not evaluated.
- Further investigation is encouraged regarding waste clay-based LC3 to enable better comparison with CMC, another waste-based blended cement.

1 Introduction

The anthropogenic greenhouse gas emissions (GHG) are at the highest level in human history [1]. Since the last century, GHG emissions due to human activity have increased from about 5 $GtCO_2$-eq/yr. to about 60 $GtCO_2$-eq/yr., where CO_2 from fossil fuels and industry play a major role [2]. Cement production has a share of about 6% of global fossil CO_2 emissions in 2021, 2022 and 2023 [3]. Therefore, reducing the emissions from cement production is mandatory to reach net zero emissions.

Carbon dioxide removal (CDR) is a promising solution for reducing the CO_2 content in the atmosphere. Intergovernmental Panel on Climate Change (IPCC) mentioned Biochar as an available and scalable solution for CDR [4]. One of the most common methods for producing biochar is pyrolysis. Pyrolysis is mainly used to produce biochar from dry biomass through thermochemical conversion in the absence of oxygen [5]. It can be divided into slow and fast pyrolysis differentiated

through the residence time of the biomass in the pyrolization chamber. Various forms of biomass can be used for pyrolysis (e.g., wood waste, screen overflows, rice husk, green waste, food waste, sugar cane, etc.). The chemical and physical properties of the biochar depend on the used biomass, production method, and pyrolysis temperature [6–8].

Screen overflows have a high potential for being used as biochar because in Germany they are mainly used in biomass power plants and waste-fueled power plants. Through pyrolysis, the screen overflow is converted into a higher-level product that can be used in agriculture or building materials, while storing CO_2 and generating power from the pyrolysis gas.

Biochar as SCM changes the behavior of fresh and hydrated mortar and concrete. Zahra Asadi Zeidabadi et al. [9] showed that the addition of biochar enhanced the compressive and tensile strength, whereas the amount added shouldn't exceed more than 5% in relation to the mass of the cement. In addition, Biochar has the ability to increase the durability and hydration of concrete because of the introduction of a large pore volume which enhances the retention capacity and therefore improves the self-curing of the concrete according to Hamid Maljaee et al. [10]. Furthermore, Souradeep Gupta et al. [11] conducted experiments to investigate the flow rate and air content of fresh mortar with biochar. The addition of biochar increased the air content in the mortar and led to a reduction of flowability. These influences of biochar need to be taken into consideration when evaluating its usability in concrete.

The content of aluminosilicates of the respective biochar mainly influences if this biochar can be used as SCM and which amount can be added/substituted for cement. This is due to the pozzolanic reaction of amorphous aluminosilica with calcium hydroxide (CH) to form calcium silicate/aluminate hydrates phases (CSH/CAH) and other reaction products [12]. The amount of hydration products mainly influences the strength, permeability, and durability of the concrete. To determine the suitability of materials for use as SCM, Avet et al. [13] introduced the R^3 test (rapid, relevant, reliable). The R^3 test measures the reactivity of the respective SCM by eliminating the influence of cement [13–15]. The R^3 test is mostly used for calcined clays, blast furnace slag, fly ash, and silica fume with high aluminosilicate contents [16]. The R^3 test simulates the alkaline pore solution of concrete with controlled masses of Ca $(OH)_2$, $CaCO_3$, KOH, and K_2SO_4.

Therefore, this research aims to determine the potential of biochar made from screen overflow as SCM using the R^3 test. Furthermore, the influence of different particle sizes is investigated.

2 Materials and Methods

2.1 Materials

The materials used for the preparation of the R^3-emulsion are calcium hydroxide (≥96%), potassium hydroxide in flakes (≥85%), powdered potassium sulfate (≥99%), and calcite (≥99%) which were obtained from Carl Roth GmbH + Co. KG (Karlsruhe, Germany).

The biochar employed in this study are from two different composting plants, Abfallwirtschaftsbetrieb Alzey Worms (AWB, Alzey, Germany) and Gesellschaft für Abfallentsorgung Lippe (GAL, Lippe, Germany). Each of the composting plants supplies their screen overflow for pyrolysis. The screen overflows are a mixture of wood waste, green waste, paper waste, metal waste, plastic waste, and other fine, partially mineral aggregates <10 mm.

The substrates were pyrolyzed by Carbontechnik Schuster (CTS, Dischingen, Germany) at 750 °C with a residence/dwell time of 210 minutes. After the pyrolysis, the biochar was ground with a mortar and then separated by particle size using a sieve tower. The particle sizes prepared from the two different biochar are <40 µm, 40–125 µm, and 125–250 µm.

The phase composition of the biochar was determined by qualitative X-ray diffraction (XRD) with estimates of the perspective shares of the determined phases and amorphous content using the software Diffrac.Eva Version 6.0.0.7 from Bruker Corporation (Billerica, USA). The corresponding XRD results of the screen overflows are shown in Fig. 1. Both biochar have very similar mineral compositions even though they are sourced from different composting plants. They have an amorphous content of approximately 51.5% for the screen overflow from AWB and 41.7% for the screen overflow from GAL. The major phases are quartz, calcite, albite, and cristobalite as trace mineral. Magnesite occurs only as a trace in the screen overflow from AWB.

The particle size distribution is given in Fig. 2. The distribution shows that even if a sieve with a screen width of 40 µm is used higher particle sizes than 40 µm are measured. This can occur because of the irregular shape and length-to-width ratio of the biochar. While the maximum particle width is 250 µm the respective particle

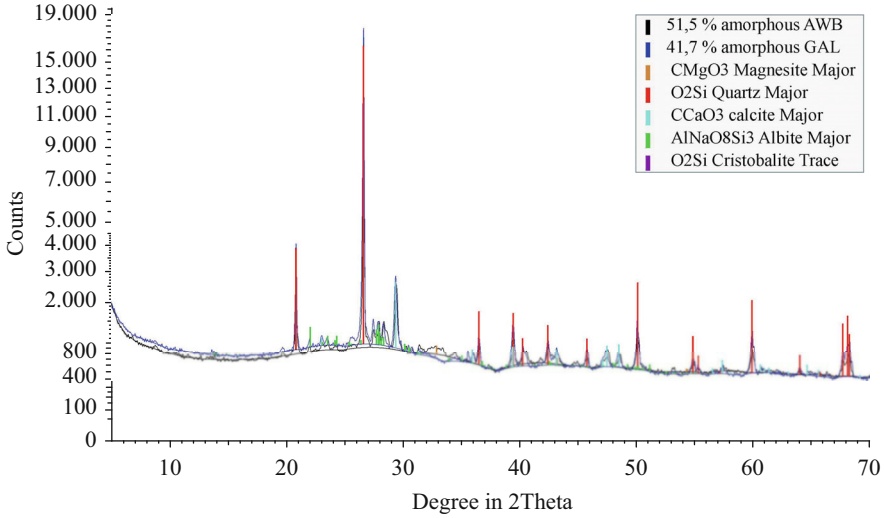

Fig. 1 Powder XRD and qualitative analysis of biochar from screen overflow from both sourced composting plants AWB and GAL

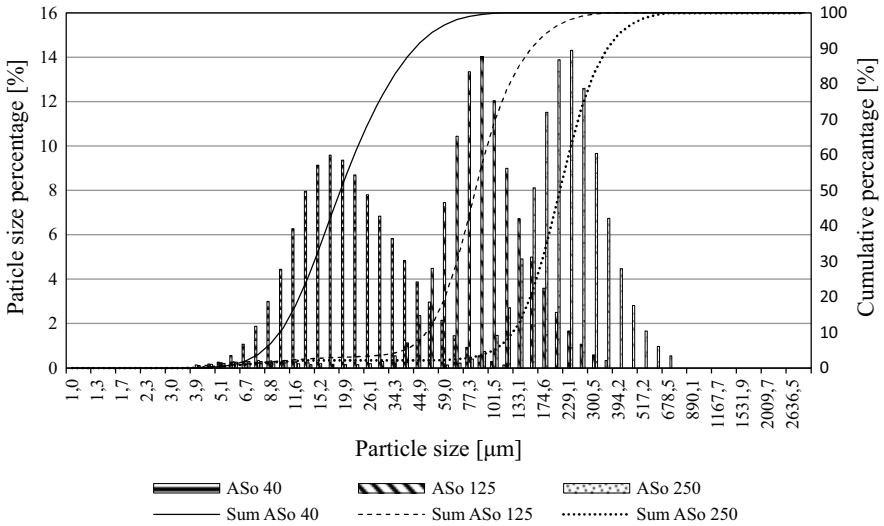

Fig. 2 Particle size distribution of the screen overflow from AWB for the different particle sizes

Table 1 R^3 mix design by Li et al. [16]

Biochar	$Ca(OH)_2$	$CaCO_3$	K_2SO_4	KOH	H_20
11.11 g	33.33 g	5.56 g	1.2 g	0.24 g	60 g

length may exceed 250 µm (i.e., strongly disproportionate oblong particles). Therefore, the sieve analysis with the sieve tower can deviate from the actual measured particle sizes. Especially for the particle size group 125–250 µm, the true particle size measured may be up to 650 µm. For the particle size measurement, the laser scattering particle size distribution analyzer "particle LA950V2" from HORIBA (Kyoto, Japan) was used.

The particle size distribution of the screen overflows from GAL is similar to the results from AWB. The same grinding and sieving technic were used for both biochar.

2.2 Sample Preparation

The biochar was mixed with the R^3 test mixture as proposed by Avet et al. [13] and Li et al. [16] with the respective mix design for the emulsion shown in Table 1. The R^3 emulsion mimics the alkaline pore solution of cement paste and was mixed with the biochar (SCM) according to Weise et al. [15] and Avet et al. [13]. Firstly, the alkaline R^3 emulsion was prepared with powdered calcium hydroxide, potassium hydroxide in flakes, powdered potassium sulfate, calcite, and deionized water. Then the R^3 emulsion was mixed with the biochar [13, 15, 16].

The mixed solutions for thermogravimetric analysis (TGA) and XRD measurements were then stored in an airtight container in an oven at 40 ° C for 7, 14, 28, and 56 days. After the respective storage times, the reaction process was stopped by treating the samples with isopropanol and diethyl ether according to Scrivener et al. [17] and Weise et al. [15] storing them in an excavator for 24 hours before testing by TGA and XRD.

2.3 Measurement Method

The reaction products and the reaction process of the biochar with the R^3 emulsion were tested by TGA and XRD. For TGA, "STA 449 F5 Jupiter" from NETZSCH (Selb, Germany) was used. Alumina crucibles were filled with 40–50 mg of fine powder material after the hydration stoppage. Inert gas (nitrogen) was used to avoid oxidation of the samples during the measurement. The heating program of the TGA measurement started by heating the samples to 40 °C and keeping the temperature constant for 30 minutes. After this initial constant heating phase, the samples were further heated up to 1000 °C at a constant heating rate of 20 K per minute.

For the XRD measurements, the "Bruker D2 Phaser" from Bruker Corporation (Billerica, USA) was used, configured with CuK$\alpha_{1,2}$ radiation (40 kV and 10 mA) and a linear Lynxeye detector (5-degree opening). Powder samples were measured with a step size of 0.02 two-theta in a range of 5–70 two-theta and a measurement time of 2 seconds per step.

3 Results

The pozzolanic reaction of the SCM turns calcium hydroxide and water into hydrated phases. This results in chemically bound water (CBW) incorporated into the reaction products. The formation of calcium carbonate as a result of carbonization during the reaction process and during the drying procedure also consumes part of the calcium hydroxide. The actual amount of new calcium carbonates in the sample is needed to calculate the actual consumption of calcium hydroxide by the pozzolanic reaction of the biochar [18, 19]. The total consumption of calcium hydroxide is an indicator for the pozzolanic reactivity of the samples.

Therefore, the results of the TGA measurements were analyzed according to Weise et al. [19] and Scrivener et al. [17] to obtain the most accurate results possible. These analysis method takes the formation of carbonates out of calcium hydroxide into account. It was assumed that the sample mass remained constant during the whole reaction process.

The mass loss of CH for both biochar after 7 and 56 days is shown in Table 2. The derivate of the thermogravimetric curve (DTG) is shown in Fig. 3 for the screen

Table 2 Mass loss of CH in wt.% of the R^3-samples after 7 and 56 days for all particle sizes measured by TGA

		7 days	56 days	
	Particle size [µm]	CH [wt.%]	CH [wt.%]	ΔCH [wt.%]
AWB	<40	11.57	10.33	1.24
	40–125	11.89	10.74	1.15
	125–250	12.41	11.36	1.05
GAL	<40	12.19	11.13	1.06
	40–125	12.78	12.19	0.59
	125–250	13.96	13.48	0.48

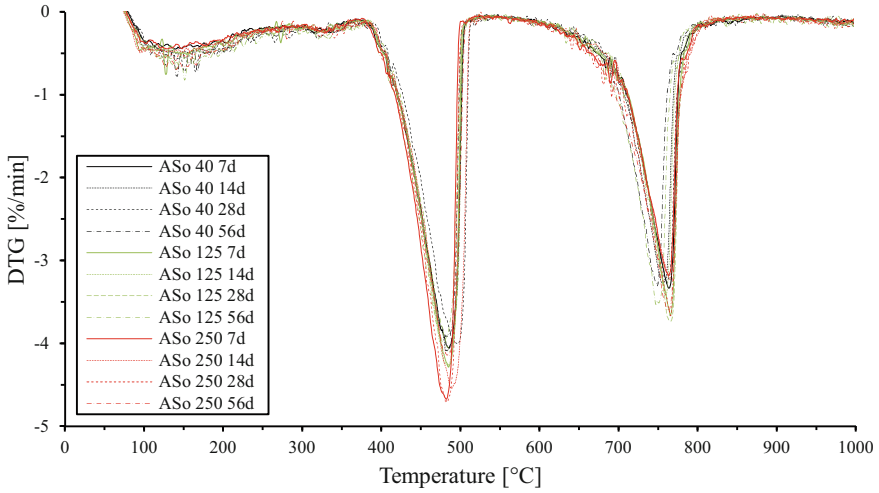

Fig. 3 DTG-R^3 emulsion with biochar (screen overflow AWB) with different particle sizes and reaction days

overflow from AWB. The three different particle sizes (<40 µm labeled as 40, 40–125 µm labeled as 125, and 125–250 µm labeled as 250) are measured after 7, 14, 28, and 56 days.

As shown in Fig. 3 and Table 2, the mass loss of CH (allocated to the mass loss from 400 to 500 °C) is higher with increasing particle size and lower with increasing days of reaction [17]. The consumption of CH increases with decreasing particle size. This shows, that the pozzolanic reactivity increases with decreasing particle sizes [20]. Comparing the mass loss of CH after 7 and 56 days the trend for all the particle size groups shows the same behavior. This indicates that with an increasing amount of time, the amount of reaction products is increasing. An indicator for the higher amount of reaction products (C-S-H phases) is the CBW in these phases [17]. The CBW of the reaction products (mass loss from approximately 100–350 °C) increases with the days of reaction for all samples.

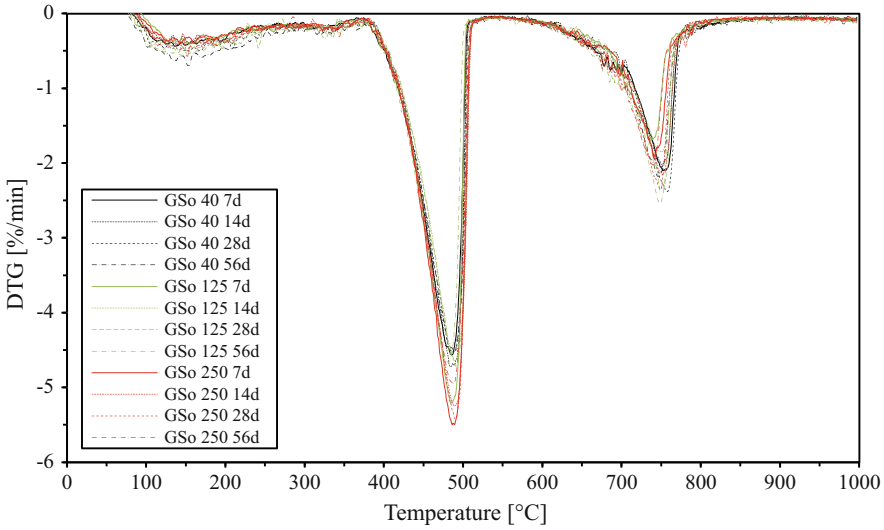

Fig. 4 DTG-R^3 emulsion with biochar (screen overflow GAL) with different particle sizes and reaction days

In Fig. 4, the DTG curve for the biochar from GAL is shown. The mass losses listed in Table 2 and illustrated in Fig. 4 indicate that the reactivity increases with smaller particle sizes like the biochar from AWB. Looking at the time-dependent reaction the behavior is also similar to the biochar from AWB. The reaction products increase with increasing reaction time. As a result, the pozzolanic reaction of the biochar is still ongoing until 56 days.

In total, the CH mass losses are higher for the biochar from GAL compared to the samples from AWB. This indicates that the biochar from GAL is less reactive. The CBW increases with the reaction days of the sample but is also lower compared to the biochar from AWB. The lower reactivity can be explained by the estimated lower amorphous content of the biochar from GAL compared to AWB.

The amount of calcium carbonate in the samples from AWB is higher than in the samples from GAL. The content of calcium carbonate (mass loss from 650 to 850 °C) is about 6 wt.% for GAL and 9 wt.% for AWB. This is caused by a higher calcium carbonate content of the biochar from AWB.

In Fig. 5, the consumption of CH per 100 g SCM is plotted over the content of CBW per 100 g SCM. The samples after 7 days and 56 days are taken into consideration.

The consumption of CH and the content of CBW were calculated according to Weise et al. [19] while taking the carbonization (formation of calcium carbonate from calcium hydroxide) of the R^3 samples into consideration. This is important to not overestimate the consumption of CH by the biochar and therefore the pozzolanic reactivity.

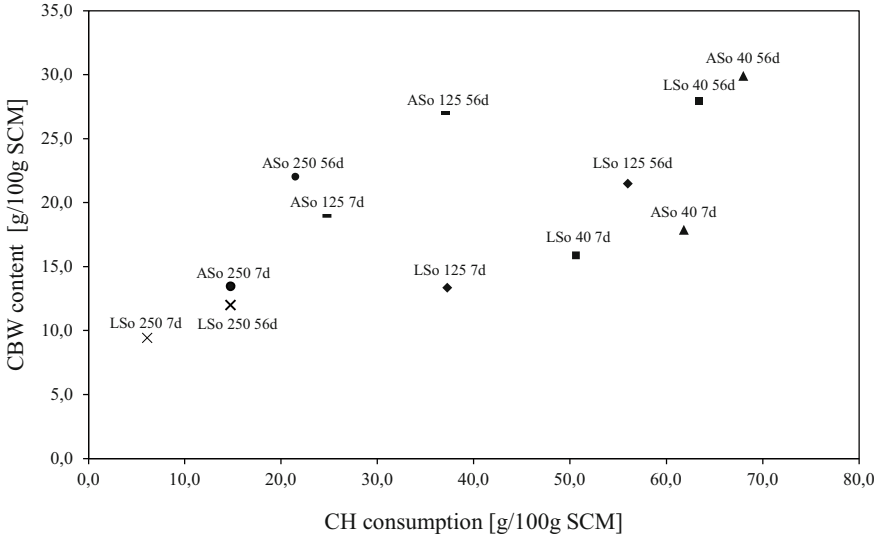

Fig. 5 CBW content over CH consumption in g/100 g SCM after 7 and 56 days

The consumption of CH and the content of CBW per 100 g SCM increase with reaction time. This is also indicated by the results of the DTG curves. The CBW is not consistently increasing with the consumption of CH considering all samples. This could happen because different reaction products are forming for the different particle sizes with different amounts of CBW. Nevertheless, a moderate pozzolanic reactivity is found and the results show that the pozzolanic reactivity increases with smaller particle sizes.

In Figs. 6 and 7, the XRD for the AWB <40 µm and 125–250 µm is shown. The results clearly show the formation of hydration products like ettringite and calcium hemicarboaluminate [21]. Portlandite, calcite, and quartz from the biochar and the R^3 emulsion are also present. The reaction products are similar for both considered particle sizes.

The results from TGA and XRD show the formation of C-S-H and C-A-H phases in small amounts increasing with smaller particle size and hydration days.

4 Conclusion

The results of the R^3 test in combination with TGA and XRD of the biochar show moderate pozzolanic reactivity. Smaller particle sizes have higher reactivity because of their higher surface area. The formation of hydration products still occurs after 56 days of reaction time. Therefore, the longer the reaction time the higher the consumption of CH and formation of hydration products.

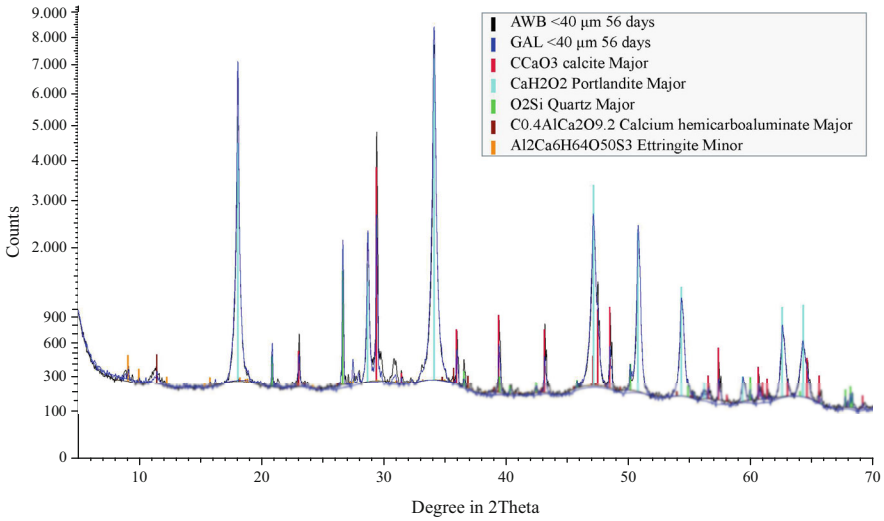

Fig. 6 Powder XRD and analysis for the particle size <40 µm after 56 days of the R^3 test from both sourced composting plants AWB and GAL

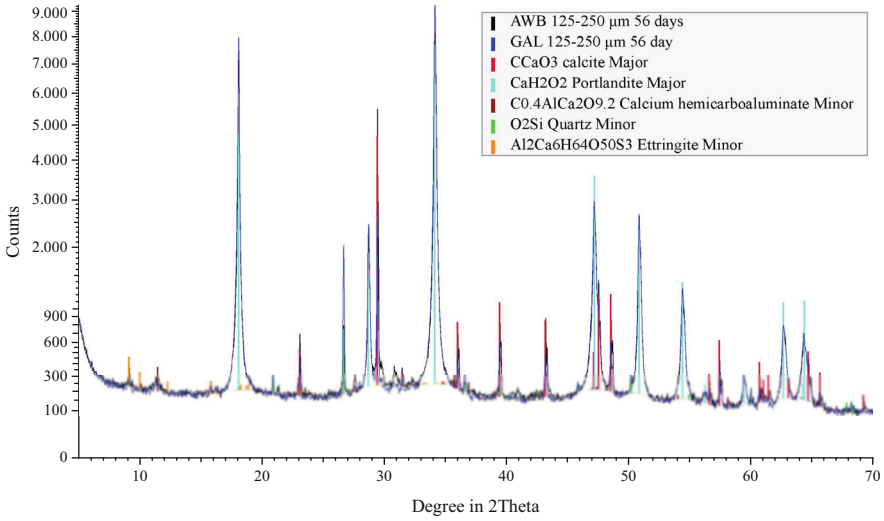

Fig. 7 Powder XRD and analysis for the particle size 125–250 µm after 56 days of the R^3 test from both sourced composting plants AWB and GAL

Nevertheless, there is some uncertainty in the results regarding the correlation between the CBW and the consumption of CH, especially regarding particle sizes bigger than 40 µm. Many variables, such as chemical composition, the proportion of amorphous phases, and the actual particle size distribution, influence the results. Therefore, further investigations are needed to fully understand the reaction mechanism to ensure a correct evaluation of the results.

The amorphous content of the original biochar is directly influencing the reactivity. The higher the amorphous content the higher the reactivity.

Biochar from screen overflows shows potential to be used as SCM. Therefore, an optimization of the pyrolysis which leads to an increased amorphous content of the biochar should be investigated. Furthermore, other pozzolanic reactivity tests should be conducted and compared with the results obtained by the R^3 test.

Acknowledgments The research is related to the Innovation Space BioBall and the industry-research project PYROCEM. The innovation space BioBall promotes bioeconomy in the metropolitan region Rhine-Main and is supported by the Bundesministerium für Bildung und Forschung (BMBF) funding measure "Innovation Spaces Bioeconomy" within the framework of the "National Research Strategy Bioeconomy 2030." The PYROCEM project investigates the innovative use of different biomasses for the production of PYROlyzed biochar as an additive for CEMent-based construction materials with integrated CO_2 reduction. The authors would also acknowledge Luca Salpietro, Yvette Schales, and Helga Janning who helped with the experiments and measurements.

1 Introduction

Concrete, a widely used material in modern construction and infrastructure projects, ranks second only to water in terms of mass consumption. However, several issues need to be addressed. From a technical standpoint, ensuring concrete quality is a complex undertaking. Instances of inadequate compressive strength have resulted in significant rework or, in extreme cases, the complete demolition of structures [1]. Concrete production also accounts for approximately 8–9% of global anthropogenic CO_2 emissions and 2–3% of global energy consumption [2]. Furthermore, the massive consumption of concrete entails significant economic costs.

Concrete mix design refers to determining the composition, proportions, aggregate gradation, water/cement ratio, admixtures, and other factors required to attain desired concrete properties. Traditionally, mix design has primarily focused on

M. Kioumarsi, B. Shafei (eds.), *The 1st International Conference on Net-Zero Built Environment*, Lecture Notes in Civil Engineering 237,
https://doi.org/10.1007/978-3-031-69626-8_48

technical properties, with compressive strength and slump being crucial indicators. However, the mix design also exerts influence over the cost and carbon emissions throughout the concrete's life cycle. The interdependence between the concrete mixture and its technical, environmental, and economic performance implies that an optimal mix design can achieve the most favorable trade-off for specific concrete applications. The question is how we can effectively integrate these three aspects and achieve their optimal balance?

Traditional methods for concrete strength prediction are empirical models, which are not accurate due to limited data. The data-driven machine learning models have been widely used for concrete property prediction, including support vector machine, k nearest neighbors, tree-based models, and artificial neural network, etc. However, few studies use ensemble learning methods such as stacking and voting for compressive strength prediction. Multi-objectives optimization (MOO) algorithms have been widely used for concrete mix optimization due to their fast convergence speed and excellent robustness. This chapter proposes a hybrid framework of ensemble learning and MOO algorithms to produce technically capable, environmentally friendly, and economically efficient concrete.

2 Data

The concrete strength experimental data of measured by [3] is used in this study. The input features include the content of cement (C), blast furnace slag (BFS), fly ash (FA), water (W), superplasticizer (SU), coarse aggregate (CA), fine aggregate (FA) of concrete per unit volume, and the curing age (AG) of the test specimen. The target variable is the compressive strength of concrete. The data distribution of each input feature and relationships between each factor and compressive strength are shown in Fig. 1. The correlation matrix plot is illustrated in Fig. 2. Cement and water have the largest positive and negative correlation coefficients, respectively.

3 Concrete Strength Prediction

3.1 Ensemble Learning

Ensemble learning is a weighted combination of multiple base learners to solve a particular classification or regression problem [4], including boosting, bagging, stacking, and voting. Boosting integrates a set of weak learners into a strong learner to minimize training errors. Bagging uses the bootstrap sampling method to draw training data and calculate an aggregated value of base learner's predictions as the final prediction. Stacking is a meta-learning technique for learning from learners in multiple learning stages. Voting aggregates the predictions of different base models

to output the final predictions, such as majority voting for classifiers and weighted sum for regressors. In this study, two bagging models (Random Forest, Extra Tree), two boosting models (XGBoost and LightGBM), three ensemble strategies (bagging, two-layer stacking, and weighted voting) were used in this study.

Four Base Leaners Random Forest (RF) new dataset with a replacement (bootstrap sampling) from an existing dataset and train several decision tree models with randomly selected features on the new dataset. The predictions of each decision tree model are aggregated into the final prediction. Extra Trees (ET) splits nodes by choosing cut points fully at random and that it uses the whole learning sample (rather than a bootstrap replica) to grow the trees. XGBoost is a gradient boosting tree (GBDT) based algorithm by constructing the objective function of model deviation and regularization term to prevent over-fitting. LightGBM is also a GBDT base algorithm that proposes two novel techniques, i.e., gradient-based one-side sampling (GOSS) and exclusive feature bundling (EFB), to realize faster training efficiency and lower memory usage.

Three Ensemble Strategies Bagging fits the base learner on random subsets of the original dataset and then aggregates their individual predictions to form a final prediction. Stacking uses the predictions of base learner as new training dataset and use a meta learner to learn the data. Voting fits the base learners on the original dataset and obtains a weighted average of each base learner's predictions.

3.2 Bayesian Optimization

Bayesian optimization (BO) was used in this study to optimize the hyperparameters. BO is an iterative stochastic optimization framework for the combined algorithm selection and hyperparameter (CASH) optimization problem [5]. It first builds a probabilistic surrogate model (Gaussian process or tree-based model) mapping from the hyperparameters to the objective metrics. Then, it defines an acquisition function to decide which hyperparameter configuration to evaluate next, balancing the exploration and exploitation during the search process.

3.3 Three-Level Ensemble Learning Framework

The proposed three-level ensemble learning framework is shown in Fig. 3. We split the data into training, validation, and test datasets. Level 1 includes four base learners: RF, ET, XGBoost, and LightGBM. Bayesian optimization is used to optimize the hyperparameters. The hyperparameter search space of the four base learners is presented in Table 1. Level 2 uses the optimized base learners of Level 1 to build six meta learners: four bagging models and one stacking model with default hyperparameters, and one voting model using the cross-validation loss of four optimized base learners as weights. Level 3 ensembles all base and meta learners using stacking and voting methods. Each trained model is applied for predictions based on the test dataset, and best machine learning model is selected after model performance evaluation for model explainability analysis.

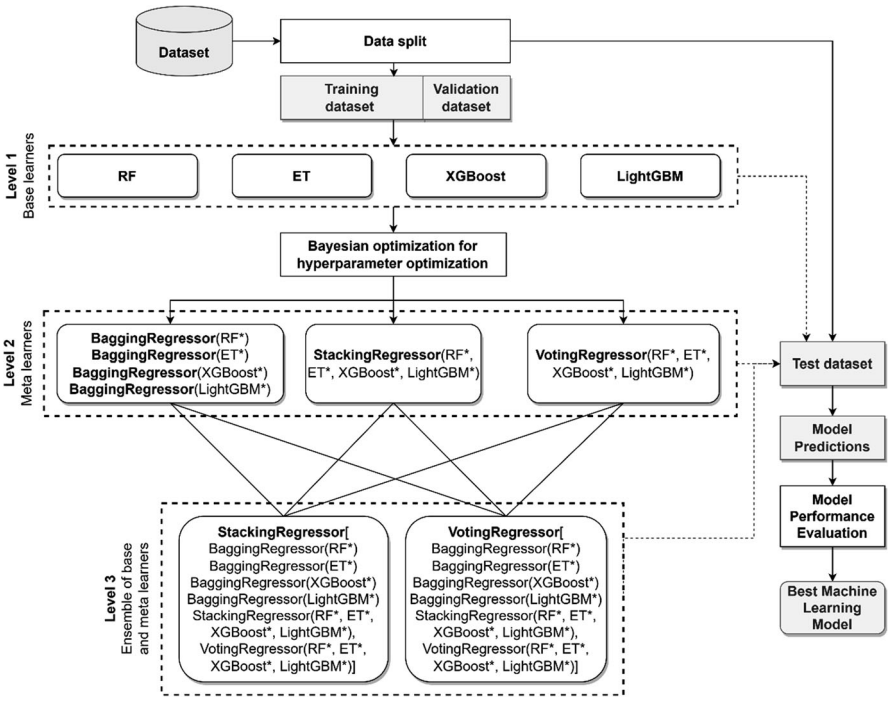

Fig. 3 Three types of ensemble strategies

Table 1 Hyperparameter search space

Model	Selected hyperparameters	Search space
RF	Number of trees in the forest (*n _ estimators*)	Range (50, 150)
	Maximum depth of the tree (*max _ depth*)	Range (10, 100)
ET	Number of trees in the forest (*n _ estimators*)	Range (50, 150)
	The maximum depth of the tree (*max _ depth*)	Range (10, 100)
LightGBM	Maximum number of estimators (*n _ estimators*)	Range (50, 150)
	Maximum tree depth for base learners (*max _ depth*)	Range (10, 100)
	Maximum tree leaves for base learners (*num _ leavess*)	Range (10, 50)
XGBoost	Number of gradient boosted trees (*n _ estimators*)	Range (50, 150)
	Maximum tree depth for base learners (*max _ depth*)	Range (10, 100)

3.4 XAI Methods

SHAP explains the prediction of an instance by computing the contribution of each feature to the prediction by computing Shapley values from coalitional game theory [6]. The SHAP value for feature j of observation x, $\phi_j(x)$, is defined as:

$$\phi_j(x) = \sum_{S \subseteq \{1,2,\ldots,M\} \setminus \{j\}} \frac{|S|!(M-|S|-1)!}{M!} \left[f\left(x_S \bigcup \{j\}\right) - f(x_S) \right] \tag{1}$$

where S is a subset of the features with feature j excluded. M is the total number of features. f is the model's prediction function. Features with large absolute Shapley values are important, and therefore SHAP feature importance (FI) for feature j is calculated as (Molnar 2020):

$$\text{SHAP}_j = \frac{1}{n} \sum_{i=1}^{n} \mid \phi_j(i) \mid \tag{2}$$

where $|\phi_j(i)|$ is the absolute value of SHAP value for feature j of observation i.PDP captures the relationship between the target variable and one or two feature by deriving the feature's marginal effect on the predictions [7]. The partial dependence function for given value(s) of features S shows the average marginal effect on the prediction and is defined as [8]:

$$\widehat{f}_S(x_S) = E_{X_C}\left[\widehat{f}(x_S, X_C)\right] = \frac{1}{n} \sum_{i=1}^{n} \widehat{f}\left(x_S, x_C^{(i)}\right) \tag{3}$$

The x_S are the features for which the partial dependence function should be plotted and X_C are the other features used in the machine learning model $\widehat{f}$. The partial function $\widehat{f}_S$ is estimated with Monte Carlo method by calculating averages in the training data. $x_C^{(i)}$ is actual feature values of other features in which we are not interested, and n is the number of instances in the dataset.

4 Concrete Mix Optimization

4.1 Establishment of Objective Functions

The objectives are to minimize carbon emission $E(X)$, production cost $C(X)$, and maximize compressive strength $S(X)$ of 1 m^3 of concrete during use phase according to mix design X. The compressive strength $S(X)$ is predicted with the ensemble learning methods. The carbon emission $E(X)$ can be calculated as:

$$E(X) = \sum_{m=1}^{M} e_m q_m \tag{4}$$

Where e_m and q_m are the carbon emission factor and content of material m in concrete per volume. Production cost $C(X)$ can be calculated as:

$$C(X) = \sum_{m=1}^{M} c_m q_m \tag{5}$$

Where c_m is the unit price and content of material m in concrete per volume.

4.2 Establishment of Constraints

The constraints include the ratio constraints [Eq. (3)], absolute volume constraint [Eq. (4)], and range constraints [Eq. (5)]

$$R_k^l \le R_k \le R_k^u, k = 1, 2, 3 \ldots, K \tag{6}$$

$$\sum_{m=1}^{M} \frac{q_m}{\rho_m} = 1, m = 1, 2, 3 \ldots, M \tag{7}$$

$$q_i^l \le q_m \le q_i^u, m = 1, 2, 3 \ldots, M \tag{8}$$

where R_i^l, R_i^u are the lower and upper bounds of *i-th* ratio. q_m is the content of material m per cubic meter of concrete. ρ_m is the density of material m. q_m^l, q_m^u are the lower and upper bounds of material m. The parameters of carbon emission factors, unit prices, material density, and constraints are set the same as [9].

4.3 NSGA-II

Non-dominated sorting genetic algorithm (NSGA-II) is an efficient algorithm for solving multi-objective optimization problem. It is a genetic algorithm based on Pareto theory to improve mating and survival selection strategies [10]. The NSGA-II procedures are:

Step 1: Initiate the population.
Step 2: Double the size of initial parent population using mutation and crossover strategies.
Step 3: Sort the generated population into different ranks according to Pareto dominating rule.
Step 4: Calculate the crowding distance between the nearest two solutions in the same Pareto rank and a large crowding distance means a large space for group diversity.
Step 5: Select solutions with higher Pareto rank and crowding distance to form the parent group of the next generation.
Step 6: Repeat from Step 2 to Step 5 until the maximum number of loops is reached.

4.4 TOPSIS-Based Pareto Pruning

A Pareto pruning method applies a set of predefined rules to the resolution process to identify a focused subset of Pareto optimal solutions. In this study, we will use a multi-criteria decision-analysis (MCDA) based pruning method to obtain the optimal solution from Pareto front, namely, technique for Order Preference by Similarity to an Ideal Solution (TOPSIS). It scores the Pareto solution by calculating the distance between the positive and negative points [11]. The smaller the distance from the ideal positive point is, the higher the score is up to one. The ideal positive point and the ideal negative point can be obtained from the following equations:

$$d_{i+} = \sqrt{\sum_{j=1}^{n} \left(F_{ij} - F_j^{\text{ideal}} \right)^2} \tag{9}$$

$$d_{i-} = \sqrt{\sum_{j=1}^{n} \left(F_{ij} - F_j^{\text{non-ideal}} \right)^2} \tag{10}$$

Where d_{i-} and d_{i+} are the distances to the negative and positive ideal points, respectively. n is the number of objectives; i refers to a solution in the Pareto front set. F_j^{ideal} and $F_j^{\text{non-ideal}}$ are the ideal and non-ideal values for the *j-th* objective, respectively. The closeness coefficient is given by the following equation:

$$c_i = \frac{d_{i-}}{d_{i+} + d_{i-}} \tag{11}$$

The Pareto solution with the highest c_i is the final optimal solution.

5 Results and Discussion

5.1 Model Performance Results

A deep neural network (DNN) model with 8 inputs, 3 hidden layers (each with 20 neurons), and one output (8-20-20-20-1) was developed for comparison and the R squared is 0.8348. Table 2 compares the model performance and stacking method in level 2 (L2-Stacking) has the highest model performance in all performance evaluation criteria. Bagging methods are not always better than individual models except XGBoost, while stacking and voting have better prediction accuracy than individual models, indicating the necessity and advantages of aggregating the prediction results of individual models. A deeper level of stacking and voting does not yield better results, which may be due to the accumulation of model error. The L2-Stacking model is used for the following model interpretation analysis.

Table 2 Model performance comparison

Model	RMSE	%RMSE	MAE	%MAE	MAPE	R^2
DNN	6.4858	18.78%	4.7770	13.83%	0.1597	0.8348
L1-RF	4.5853	13.22%	3.2429	9.35%	0.1208	0.9202

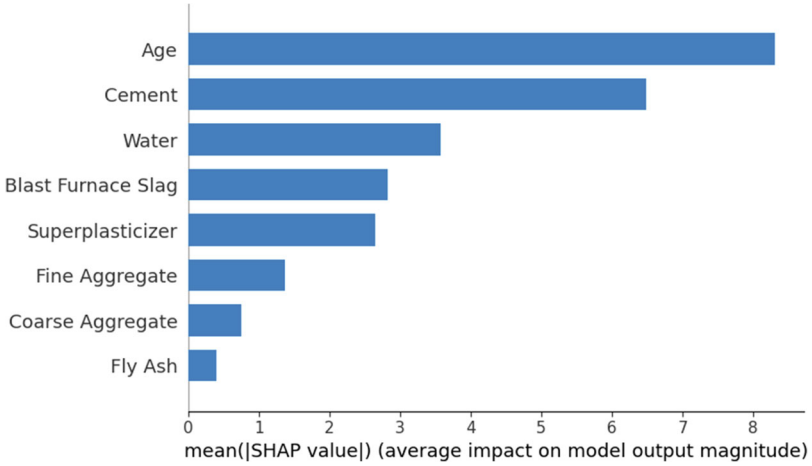

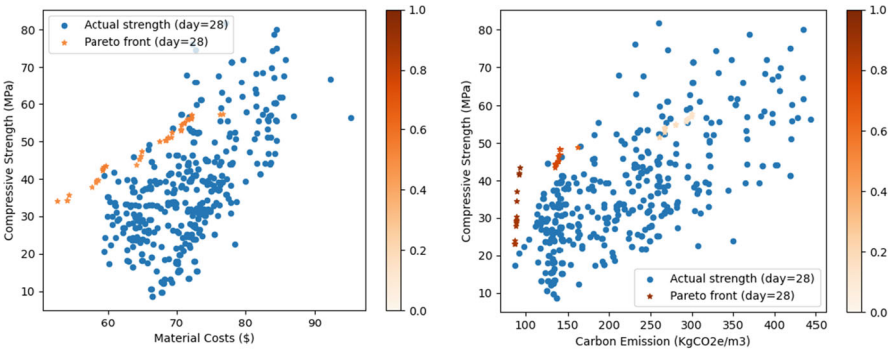

Fig. 4 SHAP summary plot for input features

5.2 Model Interpretation Results

Figure 4 provides the SHAP summary plot for input features and the top three important features are curing age, cement, and water. Fly ash has the least feature importance. To explore the relationships between input features and strength, we provide the PDP results of each input feature in Fig. 5. Most features have nonlinear relationships with the compressive strength, such as fly ash, water, superplasticizer, fine aggregate. It indicates that there might be an optimal content value for these materials to achieve largest strength. The strength increases linearly with more cement and slag. Longer curing time will bring higher compressive strength (Fig. 5).

(a) Cost and strength (b) Carbon and strength

Fig. 5 Partial dependence plots for compressive strength and (**a**) cement, (**b**) blast furnace slag, (**c**) fly ash, (**d**) water, (**e**) superplasticizer, (**f**) coarse aggregate, (**g**) fine aggregate, and (**h**) curing age

5.3 MOOP Solutions for Concrete Mix

The curing age of the concrete was set to 28 days before optimization. Figure 6 shows the Pareto front and actual data points by setting objectives as (a) cost and strength, (b) carbon and strength, respectively. Higher compressive strength brings higher material costs and more carbon emissions. The TOPSIS score of all Pareto solutions are calculated and represented with color bar. The solution with highest score is selected as the optimal concrete mix. It should be noted that the NSGA-II fails to obtain an effective solution at strength higher than 50 MPa, which may be due to the limitation of the collected dataset. Therefore, a larger concrete mix dataset is required to increase the robustness of the optimization model.

6 Conclusion

This study firstly proposes a three-level ensemble learning framework for concrete strength prediction and then use NSGA-II for concrete mix optimization with two objectives: cost and strength, carbon emissions and strength, respectively. Ensemble learning methods such as stacking and bagging have better performance than individual models and should be well considered in the field of concrete property prediction. NSGA-II can effectively obtain the Pareto solutions to achieve a better tradeoff between technical properties and economic costs/environmental impacts. However, a larger concrete mix dataset is needed to increase the robustness of optimization results. Future research directions can be incorporation of domain knowledge into machine learning model, a hybrid of MOO algorithms, more interactive Pareto pruning methods based on decision makers' preference, etc.

1 Introduction

Ultra-high-performance concrete (UHPC) has become increasingly popular in the construction industry due to its exceptional mechanical properties and versatility in construction applications [1, 2]. UHPC offers a promising way to meet the rising need of robust infrastructure solutions with its high compressive strength, low permeability, and high durability [3]. However, the conventional production methods and mixture design of UHPC, which heavily rely on ordinary Portland cement (OPC), raise concerns about its environmental sustainability due to the significant carbon footprint associated with cement production [4–6]. Cement pro-

duction is one of the considerable contributors to global carbon emissions [7–9], given estimates that cement production contributes about 8% of total CO_2 emissions globally [10].

Traditional UHPC compositions typically use OPC amounting to more than 800–1000 kg/m^3 [11, 12]. This extreme OPC proportion is considered unfavorable because of the immense energy required in its production, thus adding to environmental issues. To reduce or substitute the use of OPC in UHPC with alternative cementitious materials [13], researchers have searched for ways to reduce or replace OPC [14–17]. This includes directly replacing a portion of OPC with SCMs [18, 19] such as ground granulated blast furnace (GGBF) slag, fly ash (FA), and silica fume (SF).

This study aims to assess and compare the environmental impact of six UHPC mix designs incorporating SCMs of different proportions of GGBFS, FA, and SF as partial substitutes for Portland cement. A life cycle assessment (LCA) method, which is a standardized method to evaluate the environmental burdens associated with a product or process throughout its entire life cycle, is applied in this study [20].

The subsequent section details the materials and methods employed, material characteristics, and the production of different UHPC mixtures, ensuring a detailed examination of the research scope. Then, the life cycle inventory, system boundary, and impact assessment methodology are explained to maintain transparency and clarity in the evaluation process. Following this, the results section interprets the LCA findings, emphasizing reductions in global warming potential (GWP) achieved by alternative UHPC mix designs. Finally, the article concludes by highlighting the significant findings.

2 Materials and Methods

The materials and methods section is divided into two subsections: (1) Description of UHPC materials, mix design, and compressive strength, and (3) LCA methodology, as follows:

2.1 UHPC Materials, Mixture Design, and Compressive Strength

The formulation of UHPC relies on a unique combination of materials, with Portland cement as the foundation, adhering to ASTM C150-18 standards [21], significantly impacting UHPC strength and durability. SF, acting as a micro-filler from Master Builders Solutions, enhances strength and reduces concrete permeability, while GGBF slag, obtained from Levy Co., contributes to strength development, and offers environmental benefits. FA (Class C) from National Minerals Corporation,

Table 1 Mix design developed for UHPC mixtures, data for 1 m^3 of concrete

MIX ID	Portland cement	Silica fume	GGBF slag	Fly ash	Sand	HRWR	Steel fibers	W/B
UHPC-1	800	200	–	–	1100	37.0	156 (2% vol)	0.2
UHPC-2	600	100	–	300	1100	35.0	156 (2% vol)	0.2
UHPC-3	500	100	400	–	1100	34.5	156 (2% vol)	0.2
UHPC-4	500	100	300	100	1100	35.6	156 (2% vol)	0.2
UHPC-5	400	–	600	–	1100	32.0	156 (2% vol)	0.2
UHPC-6	250	50	500	200	1100	33.2	156 (2% vol)	0.2

known for its pozzolanic activity, is also utilized to improve long-term strength and durability. MasterGlenium 7920, a high-range water-reducing admixture (HRWA), and smooth straight steel fibers are incorporated into the mix.

The UHPC mix design aims to optimize material gradation for high packing density and maintain a low water-to-binder (w/b) ratio. A consistent w/b ratio of 0.2 is applied, following research suggesting optimal cement hydration [22]. Six UHPC mixtures were investigated, with variations in the proportions of GGBF slag, FA, SF, alongside the base components, as detailed in Table 1.

Mechanical properties, including compressive strength, of the UHPC mixes were evaluated, with all mixes falling within the same UHPC class. The results of this evaluation are essential to determine the optimal UHPC mix design, balancing environmental sustainability with desired mechanical properties.

2.2 Life Cycle Assessment Methodology

LCA was conducted to evaluate the environmental impact of different UHPC mix designs. LCA is a standardized framework used to assess the environmental impacts associated with a product or service throughout its entire life cycle [23, 24]. The framework follows four key phases: (1) Goal and Scope Definition, (2) Life Cycle Inventory (LCI) Analysis, (3) Life Cycle Impact Assessment (LCIA), and (4) Interpretation.

For this study, a "cradle-to-gate" LCA approach was employed according to the EN 15804 method [25]. This means the assessment focuses on the environmental impacts of the UHPC mix design, from raw material acquisition to production at the factory gate. Data for the LCA was collected from the Ecoinvent database (version 3.9.1) and analyzed using Simapro software 9.5.

3 Life Cycle Assessment

3.1 Goal and Scope Definition

This study investigates the environmental impact of six UHPC formulations. The main goal is to assess the potential of alternative materials to reduce the GWP associated with UHPC production and inform design strategies that prioritize sustainability. LCI was conducted using a global perspective. The analysis focuses on the cradle-to-gate stages of the UHPC production process, encompassing: (A1) Raw Material Acquisition: This includes the extraction and processing of all raw materials used in the UHPC mix; (A2) Transportation: This considers the environmental burdens associated with transporting raw materials to the production facility; (A3) Processing and Production: This stage covers the energy consumption and emissions generated during UHPC manufacturing. This framework aligns with the "cradle-to-gate" approach outlined in the EN 15804 standard [25].

To ensure a fair comparison, as recommended by ISO 14040 [24], a functional unit of 1 cubic meter (m^3) of UHPC with a specified compressive strength (meeting UHPC class requirements) was established. This functional unit ensures all UHPC mixtures are evaluated based on equivalent performance, facilitating a consistent comparison across production methods, strength classes, and potential applications. Furthermore, for this study, all UHPC mixes were selected for comparable durability characteristics such as surface resistivity, compressive strength, and overall durability. These similarities allow us to isolate the environmental impact of different mix designs while maintaining equal performance capabilities within the same UHPC class.

3.2 Life Cycle Inventory

A conventional UHPC comprises OPC, water and fine aggregates, SF, and reinforcement fibers. Six different UHPC combinations have been developed. All compositions belong to the same compressive strength class. The alternative compositions incorporate different proportions of SCMs as replacements for cement.

The LCI for this study focused on the "cradle-to-gate" stage of the UHPC production process, encompassing all materials, energy consumption, and transportation associated with UHPC mix design. The inventory for the production phase relied on generic data from Ecoinvent 3.9.1, while the concrete production process is modeled based on North American high-strength concrete (50 MPa). However, data for electricity, heat, and raw material markets were adjusted to reflect global or rest-of-the-world averages to ensure global applicability. All major raw materials, energy inputs, and transportation accounted based on Ecoinvent v3.9.1 cut-off datasets, aligning with the data quality and allocation requirements outlined in EN 15804. Transportation of materials to the factory for UHPC production is represented according to market processes in Ecoinvent for each respective raw material.

3.3 Life Cycle Impact Assessment

This study employed the EN 15804 method [25] for the LCIA, specifically the most recent approach, EN 15804 +A2 Method V1.01/EF 3.0 normalization and weighing set. It is categorized as a midpoint method. This midpoint method is recognized as the current industry standard and calculates impact indicators across various environmental aspects.

The chosen impact categories encompass various impact categories, including climate change, ozone depletion, ionizing radiation, photochemical ozone formation, particulate matter formation, human toxicity (both carcinogenic and noncarcinogenic), acidification, eutrophication (freshwater, marine, and terrestrial), freshwater ecotoxicity, land and water use, and resource depletion (fossil fuels and minerals & metals).

This LCIA approach served a dual purpose. Firstly, it enabled the calculation of specific environmental impacts, particularly the GWP. Secondly, it facilitated the proposal of optimized UHPC alternatives based on characterization and normalization results at the midpoint level. This streamlined approach condenses diverse environmental burdens into a single metric, boosting result interpretation and enabling a comparative assessment of the sustainability implications associated with different material usage scenarios within UHPC formulations.

3.4 Results and Interpretation

This section will provide an overview of the results of the life cycle impact assessment. It summarizes the results obtained in the LCIA of 1 m^3 UHPC. LCIA results provide a comprehensive understanding of the environmental performance of different UHPC mixtures.

Figure 1 shows the weighted environmental impacts of UHPC alternatives, exhibiting higher values across most impact assessment categories for UHPC1,

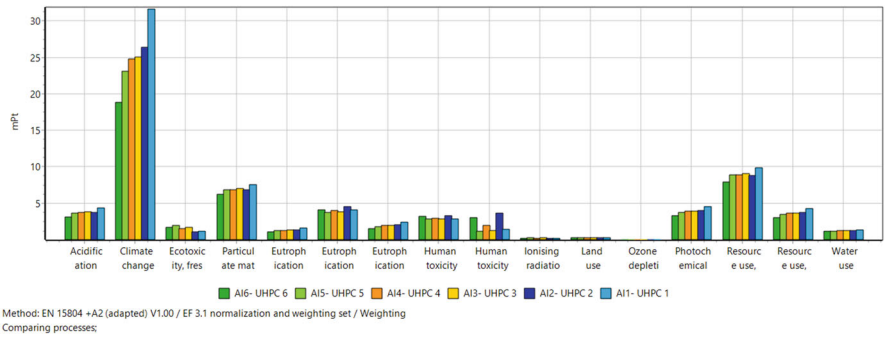

Fig. 1 Impact contribution analysis of UHPC mixture

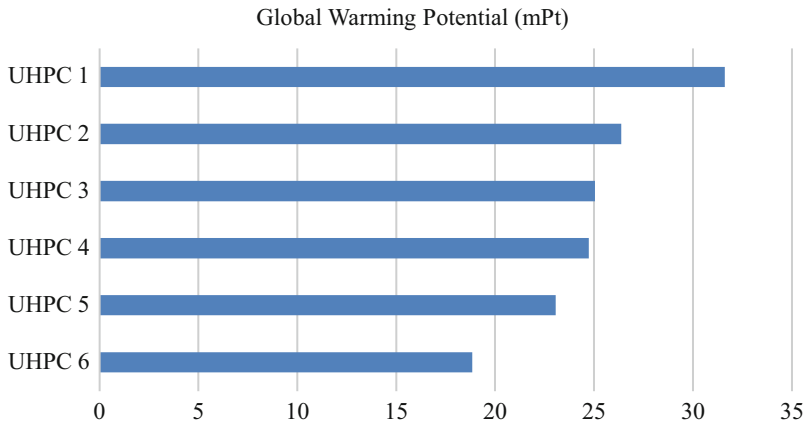

Fig. 2 Global warming potential of UHPC mixtures

except for ionizing radiation and human toxicity. However, the effects of all damage categories including these two mentioned ones, are far less than those of climate change and GWP. This underscores the importance of addressing GWP in UHPC production.

Figure 2 illustrates the GWP of six UHPC mix designs. UHPC1 which contains 800 kg of OPC and 200 kg of SF in 1 m^3 of UHPC has the highest GWP. UHPC 6 including 250 kg OPC and 750 kg SCMs (500 kg GGBF slag, 50 kg SF, and 200 kg FA) has the lowest GWP. UHPC 5 ranks second in terms of having the lowest GWP. This mix design contains 400 kg OPC and 600 kg GGBF slag. As the content of OPC reduces, the impact of GWP and climate change decreases. UHPC 3 and UHPC 4 have almost similar GWPs (same OPC proportion); however, they are a bit lower for UHPC 4 due to 100 kg FA content.

As the amount of superplasticizer is a bit different in each UHPC mixture, and it may affect the results to some extent, in Fig. 3, this effect has been excluded, and only the effect of OPC replacement with SCMs on GWP is considered. By replacing 75% of OPC with SCMs, climate change and GWP can be minimized by almost 40% (UHPC 6).

4 Discussion

This study investigated the environmental impact of incorporating SCMs such as GGBF slag, FA, and SF as partial replacements for OPC in UHPC formulations. A LCA was conducted to assess the environmental impact of six innovative UHPC compositions. The findings demonstrate that significant reductions in GWP, a key indicator of climate change impact, can be achieved by strategically incorporating SCMs at tested amounts in the laboratory.

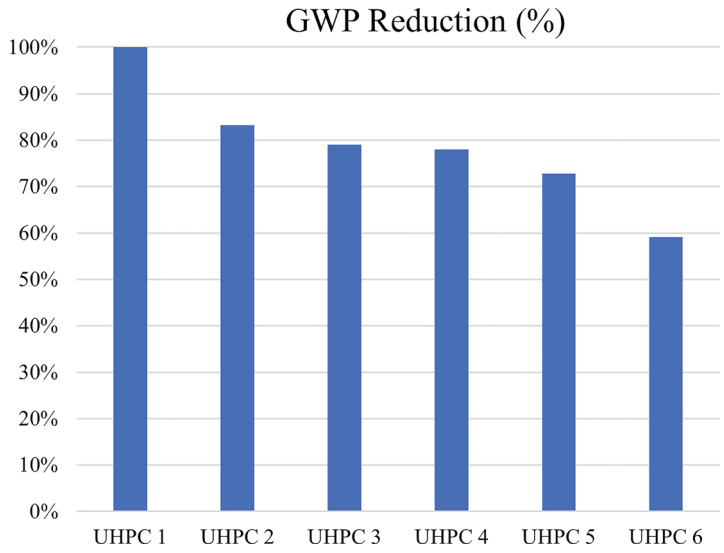

Fig. 3 Global warming potential percentage reduction of UHPC mixtures

16.7 to 40.4 % of reduction in GWP was achieved by replacing OPC with different proportions of GGBF slag, FA, and SF. Replacing three-quarters of the OPC with SCMs, climate change and GWP reduced by up to 40%. This finding is consistent with other research highlighting the potential of SCMs to minimize the environmental impact of concrete production. This finding reinforces the notion that OPC production is a major contributor to the environmental impact of UHPC due to the high energy consumption and CO_2 emissions. Existing research also shows that replacing a significant portion of OPC with SCMs in UHPC can significantly reduce the environmental impact, particularly in terms of CO_2 emissions and GWP [26, 27]. In a study by Miller [28], the author states that the replacement of significant amounts of SCMs does not invariably lead to a consistent reduction in greenhouse gas emissions during the production of UHPC on a per unit strength basis. This indicates complexities and trade-offs are involved in optimizing concrete mixtures for both strength and environmental sustainability. Therefore, mix designs tested in the laboratory and categorized within similar strength classes are crucial. Researchers and engineers can identify the optimal balance between strength and environmental sustainability by evaluating mixtures with comparable strength classes, ensuring that concrete structures meet structural requirements while minimizing their carbon footprint.

A key strength of this study lies in the innovative mix design that incorporates various SCMs in different ratios. These novel UHPC formulations have been experimented in the laboratory to evaluate their mechanical properties, particularly compressive strength, ensuring they meet the specified class requirements. This combination of environmental assessment through LCA and mechanical performance testing strengthens the overall significance of this research.

One limitation of this study is the focus on the "cradle-to-gate" LCA stage. While this approach provides valuable insights into the environmental impact of UHPC production, a more comprehensive assessment could include the "use" and "end-of-life" stages. Future research could explore the potential benefits of incorporating recycled content in UHPC formulations and investigate the environmental implications of the entire UHPC life cycle. Furthermore, exploring regional consideration of material characteristics, investigating the long-term durability of these innovative mixtures, and considering a life cycle cost analysis for a more comprehensive understanding of environmental and economic benefits can be considered.

5 Conclusion

This study successfully demonstrates that incorporating SCMs as partial replacements for OPC in UHPC formulations presents a viable strategy for reducing the environmental impact of UHPC production, particularly concerning GWP. A structured LCA focused on a cradle-to-gate perspective, encompassing raw material extraction, transportation, and production phases. EN 15804 standard and the Simapro software, incorporating data from the Ecoinvent v.3.9.1 and EPDs, were utilized for the assessments. By strategically utilizing SCMs like GGBF slag, fly ash, and silica fume, UHPC production can become more sustainable while maintaining the desired performance characteristics. These findings highlight the importance of exploring alternative cementitious materials and optimizing mix designs to promote sustainable practices in the construction sector. Future research can further explore the potential of SCMs in UHPC formulations, considering incorporation of recycled content, optimal replacement levels, and life cycle cost implications.

1 Introduction

Supplementary cementitious materials (SCMs) such as fly ash and Ground Granulated Blast Furnace slag (GGBS) have proven to be successful partial replacement to cement, but their availability is declining due to shutting down of the coal-based power plants in various parts of the World. Use of glass in buildings has been increased in recent years [1, 2] which eventually contributes to high volumes of waste glass from construction and demolition (C & D). Recycling waste glass as a partial replacement to cement is a useful recycling method for construction sector waste glasses, which are usually not recycled [3]. Although attempts were made to use waste glass coarse aggregate is concrete, the effects of Alkali Silica Reaction (ASR) prevent the successful application of the technology [4].

There have been studies on the use of glass powder as partial replacement to cement (up to 20% of cement replacement with glass powder) in concrete where the results showed comparable compressive strength as the reference concrete [5, 6]. The cementitious characteristic of glass powder was believed to be due to the formation of calcium–silicate–hydrate (C–S–H) as a result of the reactions between the Silica (SiO_2) in glass powder and the Portlandite (by-product from cement hydration) [5, 6]. However, the formation of C–S–H from the reaction between glass powder–Portlandite is not well understood. No research which investigates the chemical reactions between glass powder and Portlandite has been reported in the literature. Understanding of the reaction between glass powder–Portlandite is required to go beyond the current wisdom of 20% cement replacement with glass powder.

The present combined theoretical and experimental study investigated the compressive strength gain and the formation of C–S–H of calcium hydroxide (CH) (representative of Portlandite available from cement hydration in a real concrete mix) and glass powder (GP) mixes. Results from a mole-concept based theoretical analysis of the chemical reaction were used to determine a mix design for CH and GP mix (this mix is denoted by CH–GP in the present paper). Reference mixes, 100% calcium hydroxide with water (denoted as 100CH) and 100% CEM-I (denoted as 100CEM-I), were used for the comparisons. The compressive strength of CH–GP, 100CH and 100CEM-I mixes was investigated and the formation of C–S–H in CH–GP specimens was studied using XRD analysis.

2 Materials and Properties

2.1 Glass Powder

The washed and cleaned waste glass was crushed using a Jaw crusher machine available at the University of Manchester [7] (400 kW power and 200 rpm). The crushed waste glass was then prepared as a powder of particle size less than 75 μm using a vibratory ball milling machine [8] equipped with Zirconium ball media. The glass powder of particle size less than 75 μm was chosen in the present study because the results reported in literatures suggest this particle size reacts in cement/concrete mixes and ensure no adverse effect due to ASR [5, 6]. The glass powder obtained after milling is shown in Fig. 1a. The particle size distribution of the glass powder was investigated using a Mastersizer 3000, Laser Particle size analyzer [9] where it was determined that 50% of the glass powder particle size was <40 μm and 90% was <75 μm.

The oxides of Silicon and Calcium of the used glass were determined using X-ray Fluorescence (XRF) method [10] where the oxides of Silicon and Calcium were 70.4% and 10.1%, respectively shown in Table 1.

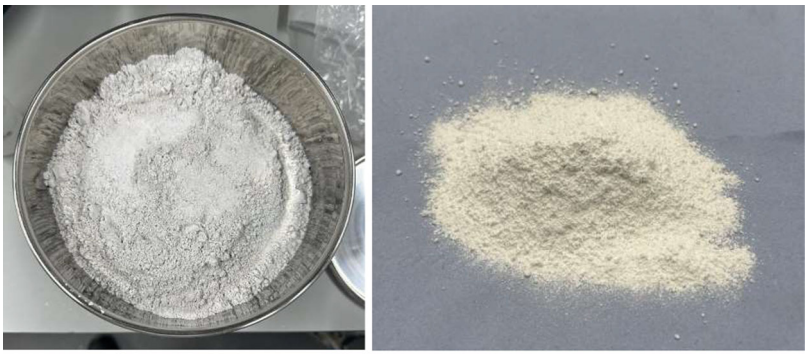

Fig. 1 (**a**) Glass powder (**b**) Calcium hydroxide powder

Table 1 The main chemical compounds of the glass

Chemical compounds	SiO_2	CaO	Al_2O_3	$Na_2O + K_2O$	Fe_2O_3	SO_3
% content	70.4	10.1	3.7	12.5	<1	1–2

2.2 Calcium Hydroxide Powder

Calcium hydroxide powder with particle size less than 100 μm was used in the present study because it was the nearest particle size to that of the glass powder (75 μm) available to purchase from a commercial supplier [11]. The similar sizes of both materials were usually expected to ensure chemical reactions given their similar surface areas [12]. The specific gravity of the calcium hydroxide powder is 2.24 g/cm^3 at 20 °C with a bulk density of 540 kg/m^3. The used calcium hydroxide powder is shown in Fig. 1b.

2.3 Cement (CEM-I)

The cement used in this study was CEM-I, grade 52.5. The percentage amount of C_3S and C_2S in the CEM-I cement was experimentally determined to be 54 and 20.7, respectively [13]. The particle size distribution of the cement was investigated using a Mastersizer 3000, Laser Particle size analyzer [9] where it was determined that 50% of the cement particles were less than 18 μm in size and 90% of the particles were less than 67 μm.

3 Glass Powder Reaction with Calcium Hydroxide: The Theoretical Analysis

The equation of the chemical reaction between calcium hydroxide and silica from glass powder in the presence of water can be represented as:

$$\begin{array}{ccc} 3\left[Ca(OH)_2\right] + & 2SiO_2 + H_2O \rightarrow & (CaO)_3(SiO_2)_2(H_2O)_4 \\ \text{CH} & \text{S} & \text{C}-\text{S}-\text{H} \\ 3\times(40+(16+1)\times2) & 2\times(28+16\times2) & (40+16)\times3+(28+16\times2)\times2+(1\times2+16)\times4 \\ 222 & 120 & 360 \\ \text{z} & 0.54\text{z} & 1.62\text{z} \end{array} \tag{1}$$

As can be noted from Eq. (1), C–S–H (i.e., the same main chemical compound resulted in from hydration of regular cement) is expected from the chemical reaction between glass powder and CH. The microstructure of C–S–H is complex and not unique. For example, based on the results of research investigations focusing on cement hydration, it is believed Ca/Si ratio of ~1.5 in C–S–H ensures high degree of polymerization of the silicate chains ensuring crystalline/ordered microstructure, thereby resulting in high strength in concrete [12, 14]. Although C–S–H with Ca/Si ratio greater than 1.5 and less than 1.5 could also form, their strength contributing characteristics is expected to be less than that of the C–S–H with Ca/Si ratio 1.5 [12]. Therefore, considering C–S–H with Ca/Si as 1.5 to be the most desirable in terms of strength contribution, the present study aimed to achieve C–S–H with Ca/Si = 1.5. As demonstrated in Eq. (1), the C–S–H with Ca/Si ratio of 1.5 can be expected with the weight ratio between SiO_2 (S) and $Ca(OH)_2$ (CH) at 0.54 (S/CH ratio) on the reactants side (i.e., left hand side) of the equation.

3.1 Mix Design of Calcium Hydroxide and Glass Powder

Given glass powder contains CaO (see Table 1). It was assumed that this CaO would also contribute to $Ca(OH)_2$ in the mix in addition to $Ca(OH)_2$ directly provided to the mix as $Ca(OH)_2$.

Let assume the required amount of direct $Ca(OH)_2$ was y and CaO from glass powder was x (considering the chemical compounds shown on Table 1, the amount of Silica was about 7 times that of CaO, so the amount of SiO_2 was $7x$ and total weight of glass powder was $10x$).

$$\begin{array}{ccccc} \mathrm{CaO} & + & \mathrm{H_2O} & \rightarrow & \mathrm{Ca(OH)_2} \\ 40+16 & & 1\times 2+16 & & 40+(16+1)\times 2 \\ 56 & & 18 & & 74 \end{array} \quad (2)$$

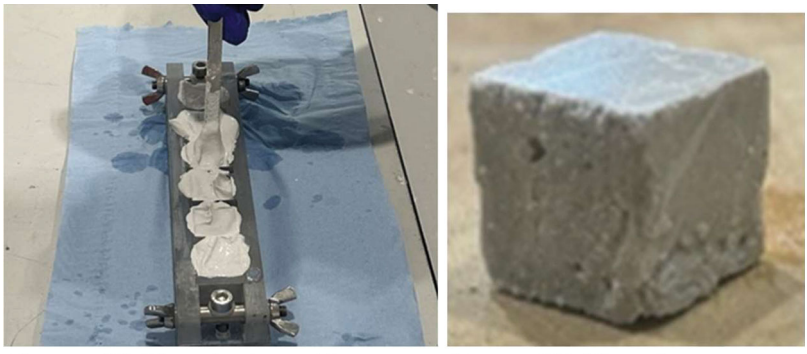
Based on Eqs. (1) and (2),

$$\left(\frac{74}{56}\right)x + y = 222 \ \left(\text{i.e. total } \mathrm{Ca(OH)_2} \text{ in Eq.}(1)\right) \quad (3)$$

$$7x = 120 \ (\text{i.e., total } \mathrm{SiO_2} \text{ in Eq.}(1)) \quad (4)$$

On solving Eqs. (3) and (4),

$$x = 17.14, \quad y = 200$$



Therefore, required glass powder $= 10x = 10 \times 17.14 = 172$ and $\mathrm{Ca(OH)_2} = 200$

Therefore, CH–glass powder mix with 46% wt. of glass powder (i.e., 172/372) and 54% (i.e., 200/372) wt. of $\mathrm{Ca(OH)_2}$ was required.

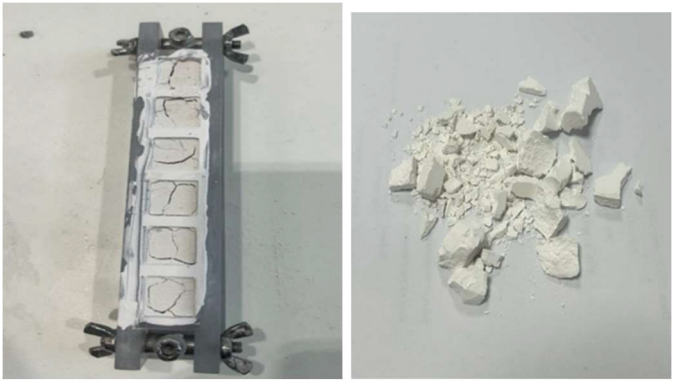
4 Experimental Program

4.1 Specimen Preparation

The glass powder was mixed with calcium hydroxide and about 5% of water by weight (this quantity of water ensured the desired consistency of the paste) to prepare CH–GP test specimens. Cubes (2 cm) were cast (see Fig. 2a), and the specimens were taken out of the molds ~24 h after casting and kept in water for final curing. Figure 2b shows a CH–GP specimen obtained after opening the molds. The first category of reference specimens of the same size was made by mixing calcium

(a) CH-GP casting in moulds (b) CH-GP specimens

Fig. 2 (**a**) CH–GP casting in molds (**b**) CH–GP specimens

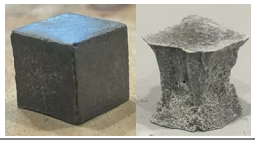


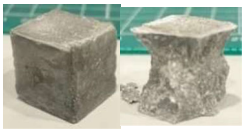
hydroxide powder with water (denoted by 100CH in the paper). Similarly, the second category of reference specimens with 100% CEM-I (denoted by 100CEM-I) were also prepared. The experimental program focused on two main investigations: (1) compressive strength and (2) formation of C–S–H using XRD analysis.

4.2 Results and Discussion

Compressive strength The compressive strength of the test specimens was determined using a compression test carried out on a displacement controlled at a rate of 0.3 mm/min (a rate as suggested in the literature [12, 15]). The reference 100CH specimens were cracked soon after they were cast (see Fig. 3a) and the specimens were broken into pieces once they were taken out of the molds (see Fig. 3b). Therefore, no compression tests were carried out on 100CH test specimens and it was assumed that the compression strength of the 100CH test specimens was zero.

At least three test specimens of CH–GP and 100CEM-1 categories were tested at 3, 14, 28 and 90 days after curing. Given the reaction between glass powder and calcium hydroxide were reported to be slow compared to that of the cement hydration [5, 6], it was decided to monitor the compressive strength gain and the formation of C–S–H in both CH–GP and the reference 100CEM-1 specimens for longer duration than usual 28-day reference for regular concrete. The present study is still ongoing and only the results up to 90 days after curing are reported in the present paper.





The color of the CH–GP specimen was more whitish compared to the 100CEM-I specimens during the entire curing period. This could be attributed to the less presence of Fe_2O_3 in glass powder (~1%, see Table 1) compared to that in cement

(a) 100CH specimen in moulds (b) Broken pieces of 100CH

Fig. 3 (**a**) 100CH specimen in molds (**b**) Broken pieces of 100CH

Table 2 Failure characteristics of 100CEM-I and CH–GP specimens before and after compression test

	3 days		14 days	
CH–GP	Before	After	Before	After
				
100 CEM-I				
	28 days		90 days	
CH–GP	Before	After	Before	After
				
100 CEM-I				

(~5% of Fe_2O_3 in cement) [12, 13]. The cubes edges of the CH–GP specimens were blunt compared to the sharp edges in 100CEM-I specimen.

Table 2 shows the failure characteristics of the test specimens at 3, 14, 28 and 90 days. All specimens, expect CH–GP specimens at 3 days of curing, failed in brittle manner. The brittle failure of the CH–GP specimens (i.e., at 14 days and later) suggests the microstructure of the specimens was similar to that of the 100CEM-1 specimens. The crumbling nature of failure of the CH–GP specimens at 3 days after casting suggests a different microstructure compared to 100CEM-1 specimens and CH–GP specimens at later days of curing. The authors believe this was due to the ongoing development of the microstructure of the CH–GP test specimens at early days of curing and the more stable microstructure would only fully develop at a later stage of curing

The average compressive strength of the CH–GP specimens at 3, 14, 28, and 90 days were 3.8 (range 3.9–4.1 MPa), 5.0 (range 4.7–5.3 MPa), 7.8 (range 7.6–8.1 MPa) and 12.3 (range 11.8–12.9 MPA), respectively. The average compressive strength of 100CEM-I specimen at 3, 14, 28 and 90 days were 32.1 (range 29.5–34.9 MPa), 41.6 (range 40.2–43.4 MPa), 56.1 (range 53.5–58.6 MPa) and 65.4 (range 63.6–67.4 MPa), respectively. Figure 4a shows the recorded compressive strength data of both CH–GP and 100CEM-1 test specimens. Although the

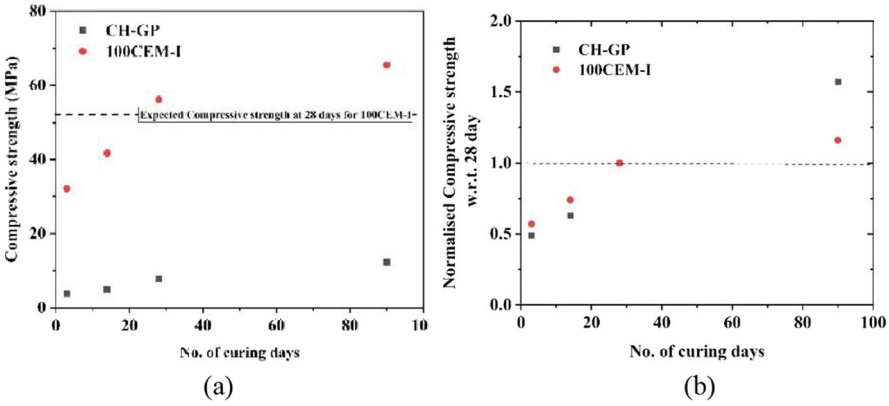


Fig. 4 (**a**) Average compressive strength of CH–GP and 100CEM-I (**b**) Normalized compressive strength w.r.t 28 days of CH–GP and 100CEM-I

compressive strength of 100CEM-1 specimens was significantly higher than that of CH–GP specimens on all test days, the results confirm notable compressive strength of CH–GP specimens. Given it was previously observed that 100CH (i.e., hydrated $Ca(OH)_2$ only) test specimens showed almost zero compressive strength, the observed compressive strength in CH–GP specimens was owing to a chemical reaction between calcium hydroxide and glass powder with possible formation of C–S–H. Figure 4b shows that the 90 days compressive strength of CH–GP mixes was 57% higher than its 28-day strength, whereas the 90-day compressive strength of 100CEM-I specimens was 16% higher than its 28-day strength. This result suggests the strength contributing compounds in CH–GP specimens were likely form at later days (after 28 days) of curing.

X-ray Diffraction (XRD) analysis The XRD analysis of CH–GP, 100CEM-I and 100CH were conducted to identify the formed C–S–H and the remaining content of CH in CH–GP and the reference test specimens. The XRD results were obtained using Bruker D8 Autochanger + X-ray diffractometer equipped with graphite-monochromatized Cu Kα radiation, operating at 40 kV and 100 mA available at the University of Manchester [16]. The powdered form of the crushed samples obtained after compressive strength tests were used in the XRD investigation. The results of the XRD analysis of the CH–GP specimens showed in Fig. 5a suggest that XRD peaks of calcium hydroxide (at 2Θ angles namely 29.369, 34.936, 47.448 [12]) decreases and the XRD peaks for C–S–H (at 2Θ angles namely 28.943, 29.004, 30.008, 29.746, 49.537 [12]) increases with the increase of the curing time of the specimen. The decrease in the amount of $Ca(OH)_2$ in the mix suggests a possible reaction in the mix where $Ca(OH)_2$ was consumed for the chemical reaction. On the other hand, the presence of C–S–H peaks suggest the formation of C–S–H in the mix, and similar C–S–H peaks were noticed in 100CEM-I specimen at same 2Θ angles (28.943, 29.004, 30.008, 29.746, 49.537) shown in Fig. 5b. This suggests that the C–S–H formed in CH–GP specimens were of the same type produced in

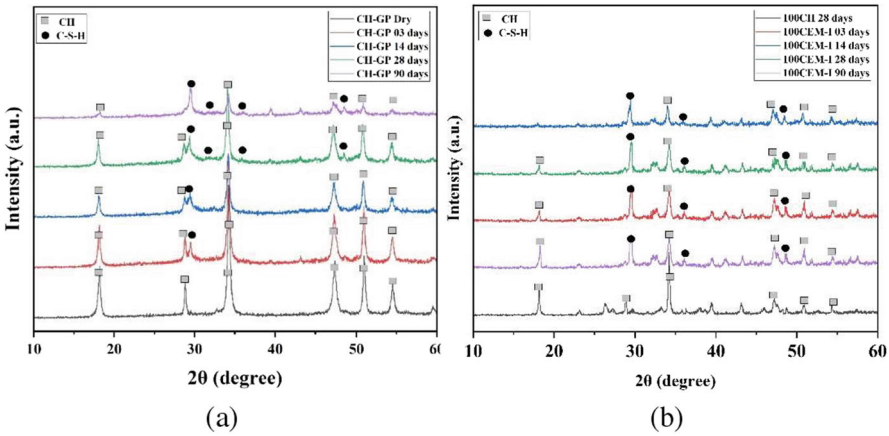

Fig. 5 (**a**) XRD peaks of C–S–H and CH in CH–GP specimen (**b**) XRD peaks of C–S–H and CH in 100CEM-I and 100CH specimen

100CEM-I specimens. Further, the increment in the C–S–H peaks with time (3–90 days) in CH–GP specimen showed increment in the quantity of the C–S–H formation which aligns with the findings noticed in compressive strength results where the strength increased with time. Therefore, it could be concluded that the compressive strength noted in the CH–GP specimens (shown in compressive strength section in Sect. 4.2) were likely due to the C–S–H in the mix. Further, Fig. 5b shows no XRD peaks of C–S–H in 100CH specimens which suggest there was no or negligible C–S–H formation in 100CH specimens.

5 Conclusions

The present experimental study aimed to understand the chemistry of the reaction between calcium hydroxide (CH) and glass powder (GP) to quantify the gain in the compressive strength and to identify the formation of C–S–H using XRD investigation. The results of the CH–GP mixes were compared with 100% CH and 100% CEM-I specimens.

- CH–GP specimens possessed noticeable compressive strength whereas no strength was noticed in 100CH specimens. The results suggest a likely chemical reaction between calcium hydroxide and glass powder which led to the formation of strength contributing compound C–S–H.
- The brittle failure of the CH–GP specimens (except 3-day cured specimens) suggests the microstructure of the specimens was similar to that of the 100CEM-1 specimens. The results suggests there was an ongoing development of the microstructure of the CH–GP test specimens and more stable microstructure developed at a later stage of curing.

- The 90-day compressive strength of CH–GP mixes was 12.3 MPa which was lower than the same 90-day strength of 100CEM-I (65.4 MPa). However, the 90-day strength of CH–GP specimen was 57% higher than its 28-day strength (the observed strength increase of CEM-I specimens within the same period was 16%). This suggests the major strength imparting compounds in CH–GP specimens formed at later stages of curing.
- The XRD analysis confirms no peaks of C–S–H in the 100CH specimen but clear intense peaks of C–S–H in CH–GP specimens. The C–S–H peaks in CH–GP specimens were similar to the C–S–H peaks noticed in 100CEM-I specimens and they were increasing as the curing period increases from 3 to 90 days. This implies that the compressive strength gain in CH–GP specimens could be attributed to the formation of C–S–H in the mix.

Acknowledgments Gaurav Chand wishes to express his gratitude to Government of India for supporting his PhD study (K-11015/46) at the University of Manchester, UK, and SIBELCO Sheffield for providing waste glass and X-ray Diffraction Suite, University of Manchester, for the facilities to carry out the XRF experiment under the technical support of Mr Gary Harrison.

1 Introduction

1.1 Steel as a Construction Material

Steel is considered as one the most important materials in the construction industry second to only cement concrete. With its incredible mechanical and structural properties, steel is widely used in different sectors of construction. Although concrete structures form a massive share (60%) of the buildings across the world, most concrete structures use steel in the form of either reinforcement bars or prestressing steel [1]. In 2023, 1.89 billion tonnes of steel were produced around the world with China alone producing a little over 1 billion tonnes [2]. According to the World Steel Association (WSA), 52% of the total steel produced goes into the building and infrastructure sector [2]. Reinforcement bars make up to 44% of the steel in the

building sector, followed by structural products such as cladding, roofing, etc. that make up to 31% and structural steel sections make up to 25% [3, 4]. In the infrastructure sector, reinforcement bars make up to 60% of this sector with structural steel, rail sections, and steel plates making up the remainder 40% [4]. These numbers clearly show that, from a design perspective, steel is primarily used as reinforcement bars in concrete structures and as structural steel sections.

1.2 Water Footprint of Steel Industry

Choudhury et al. evaluated the optimization of water footprint in steel industries [5]. This study reported that the average intake of water during the manufacture of every tonne of steel is estimated to range from 71 to 706 ft^3, not including the wastewater generation. This demand of water is used essentially for cooling purposes as "*make-up water*" which is used for compensating the water lost in the evaporations and mechanical losses and does not require any treatment. The water utilized for unit operations such as rolling and coking operations generates wastewater with several pollutants. These contaminants and toxic substances vary based on the operation and the point of generation of the wastewater. Treatment of wastewater contaminants generates hazardous sludge which is required to be recycled and managed. The study reports that blast furnace, coke plants and sinter plants have the most water footprint among the different operating units in steel manufacture. Efficient methods such as electrochemical precipitation, adsorption, membrane bioreactor facilities, and oxidation can be used to recover and treat the wastewater. This recovered water can then be utilized as make-up water for cooling purposes. The authors identified the beneficial use of several compounds in sludge such as Fe_2O_3 and CaO that are needed in the steel and cement industries and Nitrogen which is used to produce soil fertilizers. Despite the methods of recycling and recovery, the leachable heavy metals in sludge are a challenging issue.

Optimizing water footprint is a crucial step in the conservation of water. Water is a valuable resource, and NAE highlighted that providing clean water is one of the challenges for engineering [6]. Identifying that the construction industry utilizes water and a definition for water footprint of steel can help in estimating and conserving the resource. The estimation of water footprint is based on various stages of the use of water: the use of water during the manufacture of the product, the water utilized during the use of the product, and the use of water during the manufacture of the raw materials used for the product [7]. Therefore, a cradle-to-grave analysis of the manufacture of steel and its utilization during the function of the building is needed to compute the direct and indirect water use. This includes the water utilized during all the three stages, namely the manufacture of steel, the use of the building which uses the steel in its functionality, and during the manufacture of the raw materials used to produce the steel. The manufacture of coke, which is a part of the process of the manufacture of steel is one of the most water intensive processes [8]. In fact, the water utilized in the production of coke needs to be treated before it

can be reused whereas 90% of the water used in beneficiation can be recirculated. The steel industry values its role in water management and strives to improve water conservation. More than 90% of the water used in cooling operations is recycled with the losses arising due to evaporation [9].

1.3 High-Strength Low-Alloy Steel

Given the development in environmental policies, there is a need for lightweight materials that can be beneficial to improving the environment impact and pressure from the respective industry. Branco and Berto explain how high-strength low-alloy (HSLA) steels can offer a better solution for an environmentally friendly structural material [10]. The high strength, formability, hardness, good fatigue behavior, and toughness, in addition to its resistance to corrosion and weldability, make them an efficient choice from utility and environmental standpoint. HSLA steel has mechanical properties that make them comparable to superalloys. The microalloying processes make the production of HSLA steel often more expensive than mild steel; however, the enhanced strength and other mechanical properties help in improved strength-to-weight ratio thereby reducing the quantity of material required, making HSLA cost-effective [3, 11]. Graedel and Miatto highlight that vanadium can be used to improve the performance of metals [12]. Vanadium is used to strengthen steel as an alloying element because of the improved toughness, strength, and better resistance to corrosion [13]. This helps in making the steel sections lighter with less use of material, thus having groundbreaking implications in the construction industry. Studies also show the benefits of microalloying vanadium in steel reinforcement bars and sections and the role of vanadium HSLA steel in decarbonizing the construction industry [3, 14].

2 Research Methodology

The aim of this paper is to study the embodied water impact of using high-strength low-alloy steel instead of mild (carbon) steel in buildings. The research objectives of this study are:

1. Develop an input–output-based hybrid (IOH) model to compute not only the embodied energy (EE) and carbon (EC) but also the embodied water (EW) of steel, concrete and microalloying material.
2. Compute the embodied water at a building level to understand the trade-off in using HSLA steel instead of mild steel from not only EE and EC but also from EW perspective.

An input–output-based hybrid (IOH) model is developed using the most recent US census data [15]. The model uses macroeconomic data between different industry sectors. The economic flows are converted into energy as well as water flows

using the energy and water tariffs, respectively. The benchmark input–output data in the form of *Use*- and *Make*- tables from United States Bureau of Economic Analysis (USBEA) is collected [16]. The *Use*- and *Make*- tables present how commodities are used as inputs and are manufactured by each industry, respectively. It is important to account for industry scrap and adjust the *Make*- table to ensure that the Market share is computed accurately. The *Use*- and *Make*- coefficient matrices are calculated using the total values for each industry and are then used to determine the direct requirement matrix that presents the monetary value of a commodity used to manufacture another commodity worth one monetary unit. Using the principles of Leontief's inverse matrix, the direct requirement matrix is used to determine the total requirement matrix. This matrix shows the total monetary value of a commodity to produce a dollar worth of another commodity by an industry which includes both direct as well as indirect components. Detailed description of the development of the IOH model can be found in literature [17–19].

The total requirement matrix is expressed in the form of monetary units and cannot be directly used for consistent estimations because the cost of the commodities does not reflect the energy and water flows within the system. Therefore, the representation of the total requirement matrix quantifying the energy and water commodities utilized by the steel industry needs to be converted from a monetary representation to physical unit representation in MBtu for energy and Gal. for water. This is achieved by using the reported data of the energy and water usage and prices [20–22]. The data converted into the physical units is then used by the IO model. Several research studies have explained the procedure of collecting data of the amount of energy and water consumption [17–19]. The model incorporates information from various reports, articles, and online databases reported by various federal organizations such as the United States Department of Agriculture (USDA) [23], United States Department of Energy (USDOE) [24], United States Census Bureau (USCB) [15], and United States Geological Survey (USGS) [21, 22, 25]. Another advantage of embedding the data in physical units instead of price units is that the output generated is per unit dollar and is simply multiplied with the cost of the materials and items to generate the energy and water use. Wastewater and sewage form the other area that utilizes water, and it needs to be accounted for in the computations of embodied water. Therefore, in this study, the aggregated water commodity is separated into the water use component and the other component encompasses all the other commodities such as wastewater and sewage. The annual revenue for the total aggregate water was divided based on the portion of water utilities for disaggregation purposes. The data was incorporated into the *Use*- table to obtain the results of embodied water intensities that are reported in million gallons per dollar. The total EW is quantified by multiplying the costs of the materials.

After computing the embodied water and embodied energy, Energy Information Administration (USDOE) was referred to for the carbon emission factors (CEFs). These CEFs are used to quantify the EC of the materials. To compute the total EW, EE and EC, a cradle-to-site analysis is conducted that encompasses the extraction of raw materials, transportation of the materials, the manufacturing process, and the delivery of the material to the destination.

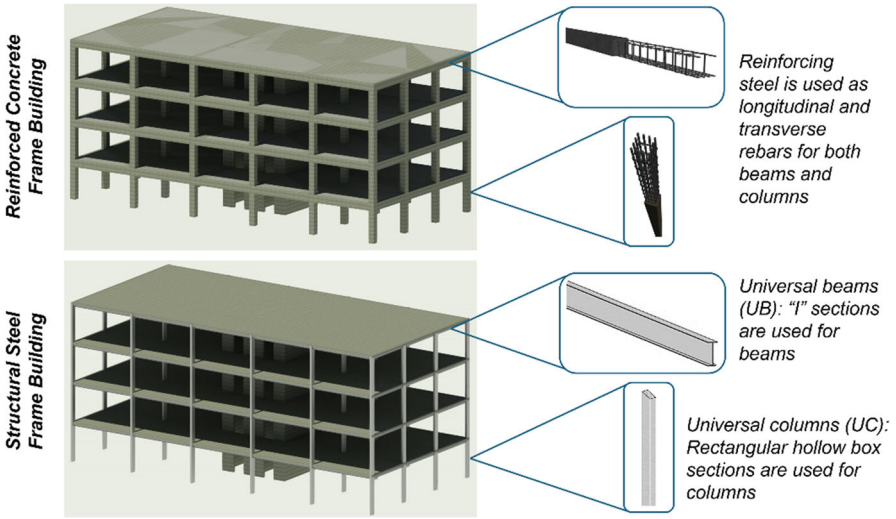

Fig. 1 The two 3-story buildings that are modeled to study the embodied impacts of HSLA steel. Reinforced concrete building (top) and structural steel section (bottom)

The IOH model is also extended to compute the total EW, EE, and EC of a case study, a 3-story building. Figure 1 shows the two building models developed to perform the structural analysis of the system. The analysis helps to calculate the total quantity of steel and concrete required to achieve the same load-carrying capacity. The design conforms to the Eurocode standards [26–29]. The two buildings represent the two commonly used frameworks: reinforced concrete and structural steel section frames. It is important to note that the quantity of materials and thereby the embodied impacts of only the structural frame, i.e., beams and columns are calculated to ensure consistency in comparison between the steel sections and reinforced concrete frameworks.

For the case study building in this paper, vanadium microalloyed steel is considered as HSLA steel. As shown in Fig. 1, the reinforced concrete frames are made of concrete and steel reinforcement bars in both longitudinal and transverse direction. Grade 250 (250 MPa) steel is used as reference mild steel for analysis while Grade 400, 500, and 600 (400, 500, and 600 MPa) steel are used to represent the vanadium microalloyed HSLA steel. Steel sections conforming to BS4 Part 1 1993 are used for the section steel frames with I-sections from universal beams and hollow box sections from universal columns selected for analysis [30]. Grade 235 (235 MPa) steel is used as reference mild steel for analysis while Grade 350 and 450 (350, 450 MPa) steel are used to represent the vanadium microalloyed HSLA steel. A 5 × 3 bay building with 4 m story height is modeled with H-type roof, C1 building category and loading details conforming to EN 1991 [27]. Weight percent of vanadium required to manufacture the respective steel grades were derived from the machine learning model presented in literature [3].

The IOH model is used to compute the total embodied water and energy per unit dollar of commodity. It is important to calculate the EW and EE of concrete, steel, and the microalloying material which is vanadium for the case study building. Revenue data for Iron and steel and ferroalloy manufacturing commodity (NAICS 331110) from USCB [15] is used to disaggregate the commodity into iron and steel mills (331111) and electrometallurgical ferroalloy product manufacturing (331112). To incorporate vanadium microalloying commodity into the IOH model, the total vanadium production, average consumption of vanadium in steel and average price of vanadium are obtained from USGS mineral commodity summaries [31]. This information is used to further disaggregate vanadium from electrometallurgical ferroalloy product manufacturing (331112). Thus, the IOH model is now modified to incorporate alloy steel and vanadium separately.

3 Results and Findings

The modified IOH model is used to obtain the embodied water (EW), energy (EE), and carbon (EC) of the different commodities such as concrete and steel used in the construction of a building as well as vanadium which is used as a microalloying material in steel to produce HSLA steel. Figure 2 presents the EW, EE, and EC of concrete and structural steel per kg of the respective commodity. For each commodity considered, the result obtained from the IOH model is multiplied with the price per unit weight of each commodity, collected from market reports [31–33] to compute the embodied impact per unit weight as presented in Fig. 2. Concrete and steel have EW less than 2 Gal./kg. Similarly, the EE of concrete and steel is 1.23 and 20.53 MJ/kg, respectively.

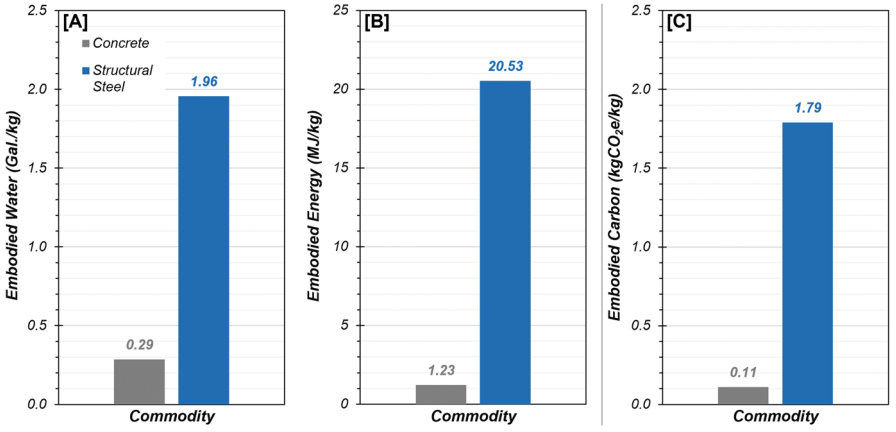

Fig. 2 Embodied impacts of concrete and structural steel commodities per unit weight of the respective commodity obtained from the input–output-based hybrid (IOH) model. (**a**) Embodied water (Gal./kg); (**b**) Embodied energy (MJ/kg); and (**c**) Embodied carbon ($kgCO_2e/kg$)

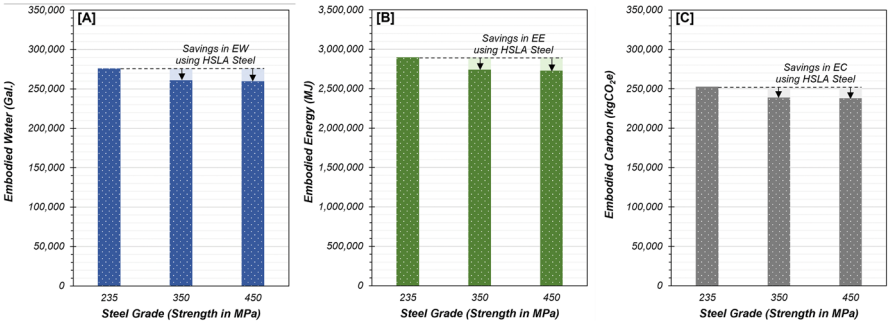

Fig. 3 Embodied impacts in a 3-story building with structural steel section frames analyzed using different grades of section steel (Grade 235 is the reference mild steel structural section grade). (**a**) Embodied water (Gal.); (**b**) Embodied energy (MJ); and (**c**) Embodied carbon ($kgCO_2e$)

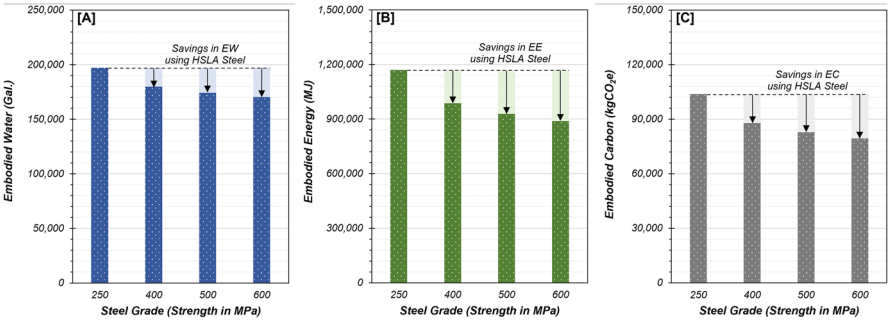

Fig. 4 Embodied impacts in a 3-story building with reinforced concrete frames analyzed using different grades of reinforcement bar steel (Grade 250 is the reference mild steel reinforcement bar grade). (**a**) Embodied water (Gal.); (**b**) Embodied energy (MJ); and (**c**) Embodied carbon ($kgCO_2e$)

Figure 3 presents the total EW, EE, and EC of the 3-story building with structural steel section frames. It may be observed from the figure that with respect to the reference grade 235 (mild steel) the vanadium microalloyed steel grades 350 and 450 have lower embodied impacts. The percentage vanadium content for the steel grades were taken as 0.035% and 0.11% for grade 350 and 450, respectively, from the machine learning model in literature [3]. There are ca. 15,000–16,500 Gal. savings in EW, ca. 156,700–168,700 MJ savings in EE, and ca. 13,600–14,700-$kgCO_2e$ savings in EC with the use of HSLA steel instead of mild steel sections.

Figure 4 presents the total EW, EE, and EC of the 3-story building with reinforced concrete frames. It may be observed from the figure that with respect to the reference grade 250 (mild steel) the vanadium microalloyed reinforcement bar steel grades 400, 500, and 600 have lower embodied water, energy, and carbon. The percentage vanadium content for the steel grades were taken as 0.013%, 0.095%, and 0.177% for grade 400, 500, and 600, respectively, from the machine learning model

presented in literature [3, 14]. There are ca. 17,000–27,000 Gal. savings in EW, ca. 183,000–281,000 MJ savings in EE, and ca. 16,000–25,000 kgCO_2e savings in EC with the use of HSLA steel instead of mild steel reinforcement bars.

4 Discussion and Conclusion

The embodied energy and carbon results for vanadium, steel, and concrete obtained from the IOH model are compared with results obtained in literature to understand variability. The EE results of vanadium (412 MJ/kg), steel (20.53 MJ/kg), and concrete (1.23 MJ/kg) are within 20%, 2%, and 50% of the reported values in literature [34, 35]. The EC results obtained from the IOH model are within 10% for vanadium and concrete and within 25% for steel, when compared with results from previous studies [34–36]. The results calculated using the input–output-based hybrid (IOH) model from IOH model are thus within reasonable limits of the values reported in literature except for EE of concrete. The high variability observed in concrete material may be due to the dependency of these values on the strength and mix design of the concrete. The system boundary coverage differences of the IOH methods and the approaches of the referred studies may also add to this variability. Looking at the comparable IOH-based EE and EC values, it can be expected that IOH-based EW values may also show reasonable variability. Since EW of vanadium is not available, we compared the results of EW of steel and concrete with previous studies. The calculated IOH-based EW of steel (1.96 Gal./kg) is more than double of the reported value of 0.7 Gal./kg [37]. This may be due to a much wider system coverage of the IOH model. In the case of concrete, the calculated EW value of 0.29 Gal./kg is comparable to 0.26 Gal./kg value reported in literature [38].

Building level analysis clearly presents the benefits of using HSLA steel in terms of savings in EW, EE, and EC. However, it is important to observe that the savings in EW may not directly reflect the benefits in terms of EE and EC savings. Figure 5 presents the percentage savings in using HSLA steel in lieu of mild steel. From Fig. 5 (left), it may be observed that the use of HSLA steel sections help in savings of

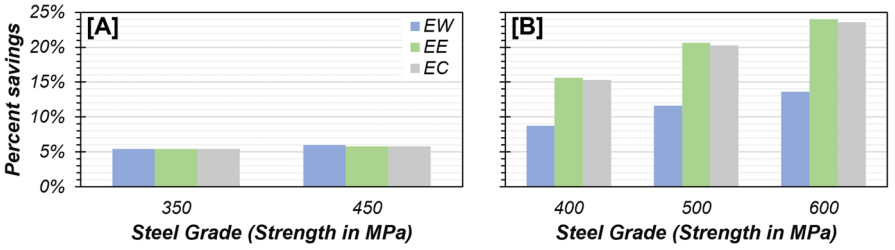

Fig. 5 Percentage savings in embodied water (EW), embodied energy (EE), and embodied carbon (EC) of using HSLA steel instead of mild (carbon) steel. (**a**) Steel section frames (Grade 235 is the reference mild steel structural section grade); and (**b**) Reinforced concrete frames (Grade 250 is the reference mild steel reinforcement bar grade)

ca. 5–6% of EW, EE, and EC. However, from Fig. 5 (right), it is evident that HSLA steel reinforcement bars help in savings of ca. 9–14% of EW and ca. 14–24% of EE and EC. The figure also underscores that the percentage savings in EW and EE are not similar for steel sections and reinforcement bars. The primary difference between the two types is due to the presence of concrete in the latter case. The quantity of concrete used in reinforced concrete structures is massive, and therefore, its water and energy use influences the total EW and EE of the building.

Thus, it is important for design engineers to ensure that the environmental sustainability in design is achieved by considering not only embodied energy and carbon but also the embodied water footprint of structures. Water intensive manufacturing of materials such as steel draws attention to the need for a comprehensive life cycle assessment to account for the water footprint. The robustness of the analysis may be improved by performing a sensitivity study to understand the impact of other key parameters such as material sources and transportation aspects on the tradeoff between EW and EE. The present study shows the benefits of using HSLA steel in buildings from embodied water perspective. Thus, one may conclude that the use of HSLA steel in buildings provides high potential for efficient design with the goal of attaining NetZero structures.

1 Introduction

Timber concrete composite (TCC) structures provide an innovative alternative to conventional floor slabs by merging the advantages of pure timber and pure concrete into a singular structure. Special shear connectors are used to connect the timber and concrete element making this system suitable for medium to long span (7–15 m) floors [1]. TCC structural elements are commonly employed in horizontal components like building floors or bridge decks, designed to withstand uniaxial bending in one-way spanning elements. Typically, timber is placed in the tension zone, while concrete occupies the compression zone. However, variations exist, including reversed TCC structural elements with concrete positioned in the tension zone [2] and TCC wall systems [3, 4]. In addition, recently [5] has developed and investigated a novel two-way panning slab system.

TCC is first introduced to the construction industry for refurbishment of old timber floors in Europe, where special shear connectors are placed on existing timber beams and the floor is strengthened by adding concrete on top [6]. A TCC system with nails as shear connectors was first patented by Paul Müller in the year 1922 [7]. After years of stagnation, interest in TCC systems has resurged as an appealing option in new building and bridge construction [1, 8].

The growing interest in TCCs can be attributed to their capacity to offer significantly increased stiffness, improved acoustic separation, and higher thermal mass in comparison to timber-only floors [9]. In contrast to reinforced concrete floors, TCCs offer advantages such as reduced weight, resulting in decreased loads on foundations and seismic forces. Additionally, they provide the potential for prefabrication, lower embodied energy, and reduced CO2 emissions, attributed to timber's carbon-neutral nature [1].

Research in previous years has focused on the performance aspects of TCC systems such as the shear connection methods [10–13], stiffness [14], load-bearing capacity [15], acoustic performance [16], fire resistance [11, 17], and dynamic response [18, 19]. However, limited studies have been conducted on the environmental impacts of TCCs. Furthermore, no comprehensive literature review has been undertaken on the environmental impact of TCCs. The current study aims to review existing research on TCCs, specifically focusing on environmental impact assessment through the utilization of the life cycle assessment method.

2 Method

The literature search is conducted electronically using two online databases: Web of Science and Scopus. Additionally, a search for grey literature was conducted online across various databases. Despite the growing popularity of Timber Concrete Composite (TCC) structures, there is a lack of studies specifically addressing the life cycle assessment (LCA) of TCCs. Consequently, this study includes 11 peer-reviewed articles that specifically focus on the LCA of TCC structures.

The systematic procedure outlined in Fig. 1 was adopted for conducting the literature survey, following the guidelines proposed by [20].

3 Environmental Impact of Building Materials

The building and construction industry alone consumes 50% of global raw material extraction [21] and contributes to 37% global carbon emissions with 23% resulting from operational energy and 14% resulting from embodied carbon related to production, transport, construction as well as the end-of-life process of construction materials [22]. To reduce emissions, the industry must decrease the carbon footprint

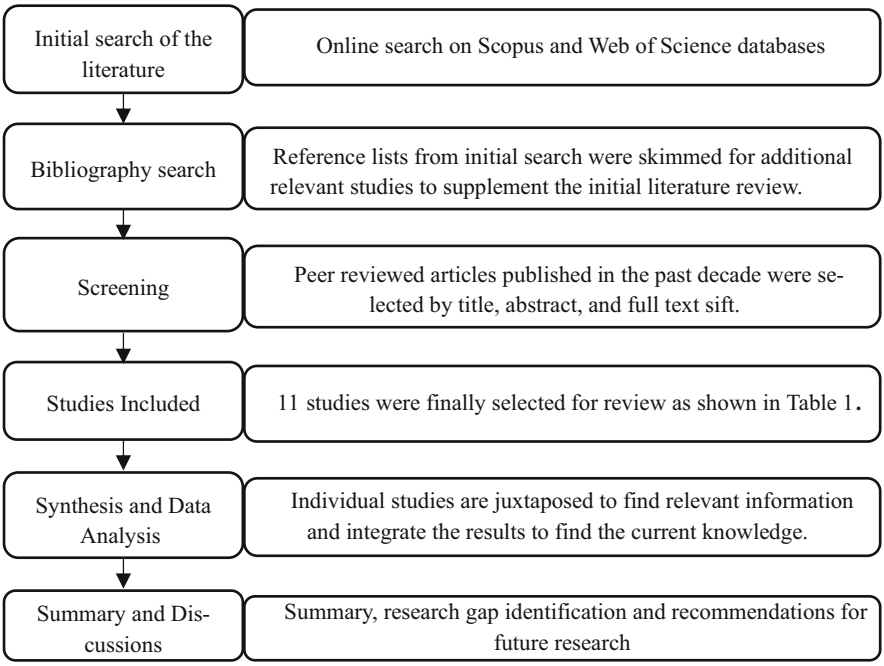

Fig. 1 Literature survey process

of building materials and enhance the energy efficiency of buildings. Considerable attention has been given in the last decades by the architecture, engineering, and construction (AEC) industry in making buildings energy efficient by moving towards renewable energy sources, which has lowered operational carbon emissions [23]. However, the share of embodied carbon emission is projected to increase from 14% to 18.5% (half of total carbon footprint) by 2050 [24].

Embodied carbon in building and construction industry comes predominantly from the energy-intensive production of cement, steel, aluminum, and insulating materials. The strategies to reduce embodied carbon include use of low-carbon materials, deign improvements and building less [25]. In addition, use of circular construction materials (construction materials with recycled, reused and repaired contents) can reduce emissions [21].

In recent years, life-cycle assessment (LCA) method has gained popularity for evaluating a product's environmental effects throughout its life cycle, aiming to increase resource-use efficiency and reduce liabilities. LCA involves identifying and quantifying environmental loads, such as energy and raw materials consumption, emissions, and waste generation, while assessing alternatives for reducing environmental impacts [26].

3.1 Life Cycle Assessment (LCA)

The idea of LCA was conceived in the 1960s in response to concerns in environmental degradation and natural resource depletion of human activities [27]. The methodology and applications have evolved in recent decades, achieving scientific consensus and adhering to established standards. LCA has become an internationally standardized method (ISO 14040:2006) to assess the direct and indirect environmental consequences of resource use along their life cycle stages. ISO defines LCA as a process of compilation and evaluation of the inputs, outputs, and the potential environmental impacts of a product system throughout its life cycle [28]. EN 15978 is an LCA standard specific to the European region, harmonized with ISO 14040, and employed for evaluating the environmental performance and potential impact of buildings and construction products. EN 15978:2011 is utilized alongside EN 15804:2019, which establishes a LCA methodology for construction products, including detailed guidelines for creating Environmental Product Declarations (EPDs).

Analyzing the environmental impacts of processes and products throughout their entire lifecycle, as per EN 15978:2011 [26], involves four stages: production, construction, use, and end of life, which are further divided into 16 substages (refer to Fig. 2). The benefits and loads stage of reuse, recovery, and recycling are separately shown outside the system boundary as an optional fifth stage in module D.

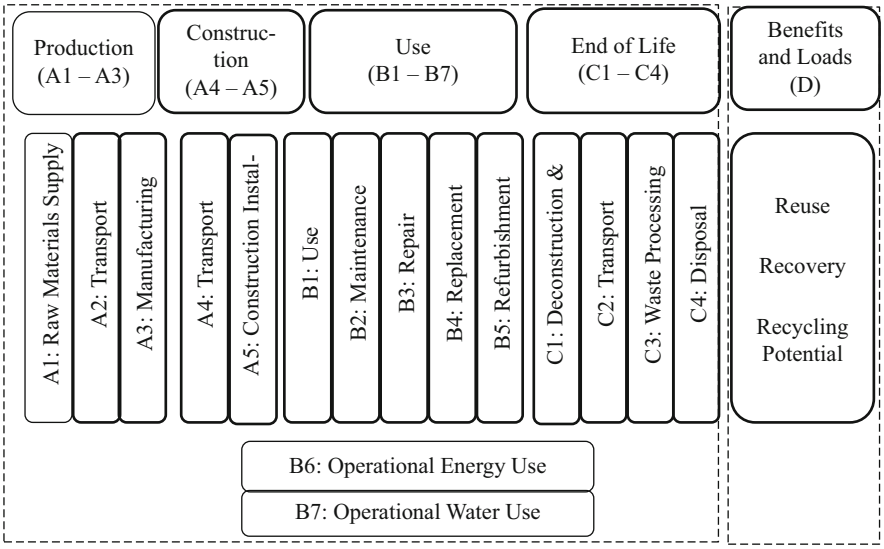

Fig. 2 Life cycle stages as per EN 15978 [26]

4 LCA Studies of TCC

This section presents the review results by addressing each stage of the LCA process, followed by a comparison of the studies. Additionally, it explores end-of-life scenarios and considerations beyond system boundaries. Table 1 outlines the studies included in this review, providing essential characteristics such as year of publication, country, scope, system boundary, and structure type. Approximately half of the studies are conducted in Europe, with the remainder distributed across Asia, North America, and Oceania.

4.1 Goal and Scope Definition

Environmental impact assessment of TCCs using the LCA approach has been conducted for building floor slabs [29–33], bridges [32, 34–36], and walls [3, 4]. The studies compared the TCC system in terms of life cycle carbon foot print with reinforced concrete [29, 30, 35, 37], prestressed concrete [35, 36], ultra-high-performance fibre reinforced cementitious composite (UHPFRC) [34], steel

Table 1 Summary of reviewed paper

Reference	Year	Country	Study scope	System boundary	Structure type
[37]	2023	Korea	CLT-concrete/ RC/ CLT	Cradle-to-gate	Floor
[29]	2014	Australia	GLT-concrete/ CLT/RC	Cradle-to-gate	Long span floor
[36]	2017	Portugal	GLT-concrete/ RC/PC	Cradle-to-grave	Bridge deck
[33]	2022	Malaysia	GLT-concrete/ light weight steel-concrete/precast hollow core concrete/cofradal	Cradle-to-grave	Floor
[31]	2021	Canada	CLT-concrete/GLT-concrete		Floor
[35]	2022	Czech Republic	Transverse prestressed wooden concrete/steel concrete composite	Cradle-to-gate	Bridge deck
[4]	2023		CLT-UHPC/ CLT/RC	Cradle to cradle	Wall
[30]	2023	Luxemburg	CLT-concrete/RC/steel concrete composite	Cradle to cradle	Floor
[34]	2021	Switzerland	Timber-UHPFRC/ RC/UHPFRC	Cradle-to-grave	Bridge deck
[3]	2018	Italy	Concrete glulam framed panel (CGFP)	Cradle to gate	Wall
[39]	2017	Italy	Concrete CLT framed panel (CGFP)	Cradle-to-gate	Wall

concrete composite (SCC) [30, 33], hollow core precast concrete slab [33], cofradal slab [33], and cross-laminated timber [4, 29, 37]. The TCC systems studied included CLT-Concrete, GLT-Concrete and CLT-UHPFRC.

Few studies have conducted a cradle-to-cradle LCA [4, 30], while majority of the studies conducted either a cradle-to-gate or cradle-to-grave LCA. The cradle-to-cradle assessment scope examines total environmental impact of a product from extraction of raw materials to reusing, repurposing or recycling into a new product at the end of its life so that the product never gets wasted and it is kept in the economic loop.

4.2 Life Cycle Inventory

A diverse range of databases was employed by the reviewed literatures, reflecting the regional specificity of certain databases [30, 31] and the absence of environmental profiles for materials such as UHPFRC & CLT [34] in some databases. Most of the cases adopted the generic Ecoinvent database followed by environmental product declaration (EPD), KBOB, GaBi, ÖKOBAUDAT and Athena. According to [31], the carbon intensity of CLT on Athena showed an exaggerated value compared with EPD values from major regional CLT producers in Canada which affected final LCA outcomes. Due to the absence of CLT environmental profile in databases [37], used GLT profile as a substitute for CLT, which may have an influence on the final result. According to [38], the comparison of five common LCI databases showed that the greenhouse gas emission values are different for the same wood product across the databases, which indicates that the use of appropriate database is necessary.

4.3 Life Cycle Impact Assessment

Global warming potential (GWP) and life cycle energy were the most evaluated environmental impact indicators on the reviewed papers. Other indicators such as Ozone layer depletion (ODP), acidification potential (AP) and eutrophication potential (EP), Photochemical oxidation (POCP) and abiotic depletion (ADP) are also identified in some of the studies as shown in Table 2.

4.4 Interpretation

The most comprehensive LCAs of TCCs to date were conducted by [4, 30]. In [4], modules A1–3, B4, C1–4, and D were considered, while [30] focused on A1–3, B1, C1–4, and D, as indicated in Table 3. However, none of the studies encompassed all

modules. The emphasis across the studies was on the product stage (A1–A39), suggesting that more comprehensive data are available for this stage compared to others.

4.5 Comparison of Studies

Comparing research cases is challenging due to differences in structure type, system boundary, database, location, and functional unit. The GWP of selected studies where the studies have a likely similar functional unit, system boundary, and life span are given in Fig. 3. According to [37], TCCs emitted 50–70% less CO_2 for increasing span length compared with RC slabs. The study analyzed the effect of carbon storage in timber and found that TCC slabs can reduce CO_2 emissions by 77% due to the carbon storage potential of timber.

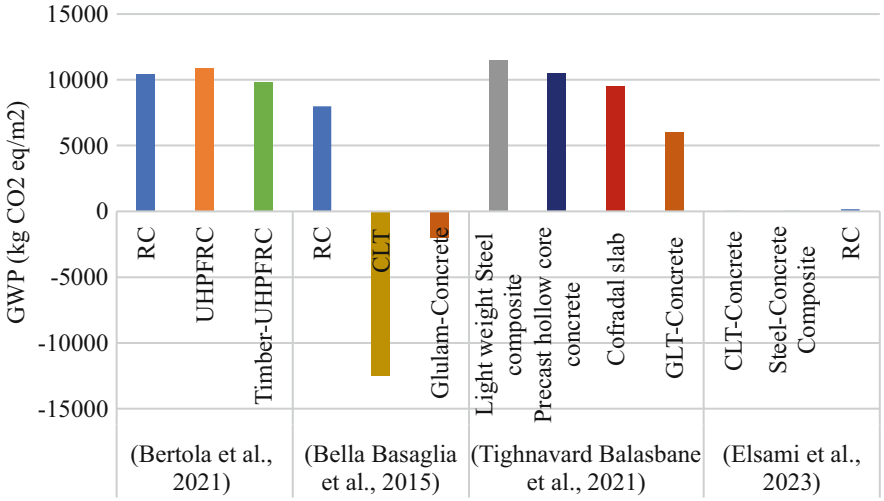

Fig. 3 Global warming potential comparison

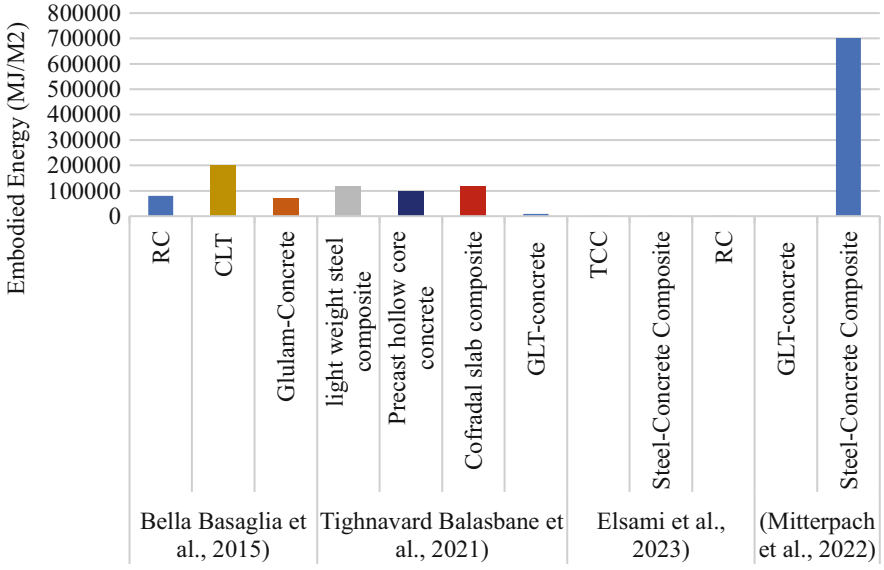

Fig. 4 Embodied energy comparison

Another study [35], compared the environmental impact of a TCC bridge with a steel–concrete bridge. The findings revealed that the TCC bridge exhibited 28% lower GWP and 30% lower nonrenewable energy consumption compared to the steel-concrete bridge. The comparison of embodied energy consumption among the selected studies is provided in Fig. 4.

4.5.1 End of Life Scenarios and Considerations for Benefits and Loads Beyond the System Boundary

Comprehensive cradle-to-grave analysis requires information about material disposal impacts which occurs for several decades. In recent decades, the popularity of TCCs has grown; however, estimating the disposal impacts (C4) has proven unattainable due to insufficient information on the demolition and disposal of TCC structures. Data on the GWP of the disposal process for Ultra-High Performance Fiber-Reinforced Concrete (UHPFRC) were not available in databases, as the material has been used only recently in TCC structures [4, 34]. For CLT members, incineration is considered as end of life scenario in module C3 and the benefit of thermal energy recovered is accounted in module D [4].

The study by [30] analyzed three end-of-life scenarios for CLT in CLT-concrete floor systems. The first scenario involves full energy recovery through wood incineration to recover heat energy. The second scenario, widely adopted in Europe, allocates approximately one-third of wood products for disposal, recycling, and energy production, respectively. The third scenario considers the full reusability of CLT panels after their service life, assuming easily demountable shear connections are used. The cradle-to-grave analysis revealed that the third scenario exhibits approximately 25% and 15% lower GWP compared to scenarios 1 and 2, respectively. Furthermore, an analysis of the benefits and loads (Module D) of the three scenarios demonstrated that the potential GWP benefits of scenario 3 are twice as high as those of scenarios 1 and 2.

5 Summary and Conclusion

This study conducted a literature review on the environmental impacts of TCCs utilizing the LCA methodology. The results unveiled significant environmental advantages of TCCs compared to conventional structural systems. These benefits are particularly notable when accounting for the carbon storage potential of timber in TCCs and further enhanced by implementing an end-of-life scenario allowing for the deconstruction and reconstruction of timber and concrete elements.

Variations in assessment outcomes have been noted in the literature, attributed to differences in LCA methodologies, varying goal and scope definitions, diverse data sources, and regional disparities. This underscores the need for a standardized and globally recognized LCA methodology to accurately evaluate the environmental impacts of TCCs.

Moreover, it has been observed that the selection of end-of-life scenarios significantly influences the outcome of the LCA. Specifically, the environmental impact of TCCs can be substantially reduced when designed for deconstruction and the reuse of timber and concrete elements, highlighting the necessity for further research on easily demountable and reconstruct able TCC shear connection systems.

Future research endeavors should aim to further explore the environmental impacts of TCCs, given the current insufficiency in both the quantity and depth of existing studies. It is recommended to conduct more comprehensive investigations using a cradle-to-grave approach, which includes assessing the carbon sequestration potential of wood and considering the impact of different end-of-life scenarios. This holistic approach will enable decision-makers to access comprehensive data when considering TCCs as an environmentally beneficial structural system.

1 Introduction

Typical roads are designed with a relatively impermeable top layer, for example, stone mastic asphalt. Water that accumulates on top of this type of asphalt, due to snow melt or rain events, either evaporates or runs off from the surface into a collection system. It is possible some amount of water is absorbed into the asphalt and underlying pavement layers, particularly if there is a crack or other such damage in the road.

However, another type of asphalt design exists and has been used in various locations (for example, the Netherlands) that is more porous than typical asphalt with the purpose of allowing water to infiltrate the road. This accomplishes several objectives: one is to handle stormwater directly 'on the spot' and thus minimize the need for construction of a rainfall runoff collection system alongside the road. Another objective is to minimize water splash that occurs when vehicles drive over wet asphalt. A third objective is minimizing noise that is created when vehicle tires

drive over asphalt; however, this current study focuses on the simulation of water infiltration through porous asphalt and not on the application of a noise model.

Modelling of the physical process of water infiltration through porous asphalt is similar to other porous media applications, and a wealth of knowledge already exists about this domain. Fluid flow through porous media is typically categorized as either saturated or unsaturated, and can also involve more than one phase (i.e. liquid and gas) and more than one component (i.e. hydrocarbon, CO_2 and water in an oil reservoir). While the underlying physics is relatively well understood, computational advances have allowed engineers and researchers to focus on applying multi-physics models and using high-performance computing to simulate fluid behaviour at smaller and smaller scales. That is, the porous media is modelled at a scale where individual aggregates or grains, air voids and other components of the media are resolved locally in space, rather than representing the media as a homogenized material with effective parameters such as void content (or porosity).

In order to perform this 'pore-scale' modelling and simulation, the precise distribution of materials in the media must be resolved spatially. To do this, one can take a digital image of the media with a high-resolution camera, an X-ray computed tomography (CT) scanner, or other similar apparatuses, depending on the resolution desired. This current study focuses on the use of X-ray CT scanning to acquire images of a porous asphalt sample, and the steps that follow after image acquisition, in particular: image processing, construction of a three-dimensional (3D) digital representation of the sample and fluid flow simulation applied to the sample. The objectives are to: (1) demonstrate the image processing workflow and compare it to other similar studies, (2) simulate saturated permeability in the sample and (3) study how coarsening of the digital sample affects both the computational cost of the simulations and the results of the simulated permeability.

The paper is outlined as follows: first, the general physics of saturated fluid flow through porous media is presented, second, the simulator used to solve the general physics is briefly described, third, the porous asphalt sample and the imaging details are described, forth, results of the simulations are presented considering various spatial coarsening levels in the sample, and lastly, the results are discussed in the context of how the workflow of imaging and simulation can provide relevant information about porous asphalt in a way that is computationally practical.

2 Method

2.1 Materials and 3DXRCT Scanning

A 10-cm high, 6-cm diameter, cylindrical porous asphalt sample was created in the lab by the Norwegian Public Road Authority (Statens Vegvesen), as part of a previous research work. Findings from investigations done on this sample, as well as other field-cut samples, are found in [1] and [2]. In [2], details of the sample used in this current study (called sample 'A') were presented, as well as details of the

3DXRCT scanning work that was conducted at Norwegian Geotechnical Institute (NGI) to produce the 7.5 GB dataset of grayscale values representing the physical 3D sample, and the details of an algorithm developed to detect the top-to-bottom connected air voids. This algorithm was written in MATLAB programming language, and is available on an online public repository; see link given in [2].

2.2 Fluid Flow Simulation

The fundamental physics of the fluid flow problem is represented by the Navier-Stokes equations. However, for flow that is steady and sufficiently slow, the NSE reduces to the Stokes equation. In this work, the lattice Boltzmann (LB) equation is used to approximate a solution to the Stokes equation, and the open-source software PALABOS is used to do this [3]. PALABOS stands for Parallel Lattice Boltzmann Solver and is ideal for handling a relatively large dataset because of its parallel computing capabilities. Simulations of this work were run using up to four processors.

The output of the lattice Boltzmann simulations are pore-scale fluid velocities, that is, the velocity of water at each spatially resolved point through the 3D porous asphalt sample. These velocities can be visualized in order to gain a better understanding of the infiltration behaviour; however, an important quantity that can be computed from these velocities is the sample's permeability. This is done by taking an average of the pore-space velocities to get the Darcy velocity, and then by using this Darcy velocity along with the applied pressure gradient in the simulation to calculate the saturated permeability from the Darcy equation.

Permeability results from the LB simulations are given in lattice units. The conversion from lattice units (k_{LB}) to physical units (k_{phy}) is according to the following relationship:

$$k_{\mathrm{phy}} = k_{\mathrm{LB}} \left(\Delta x_{\mathrm{phy}}\right)^2 \tag{1}$$

where Δx_{phy} is the voxel size in meters. The physical permeability calculated by this relationship is in units of meters squared, and this value can be expressed in Darcy, where 1 Darcy is equivalent to approximately 10^{-12} m^2. It can also be expressed as a saturated hydraulic conductivity in meters per second:

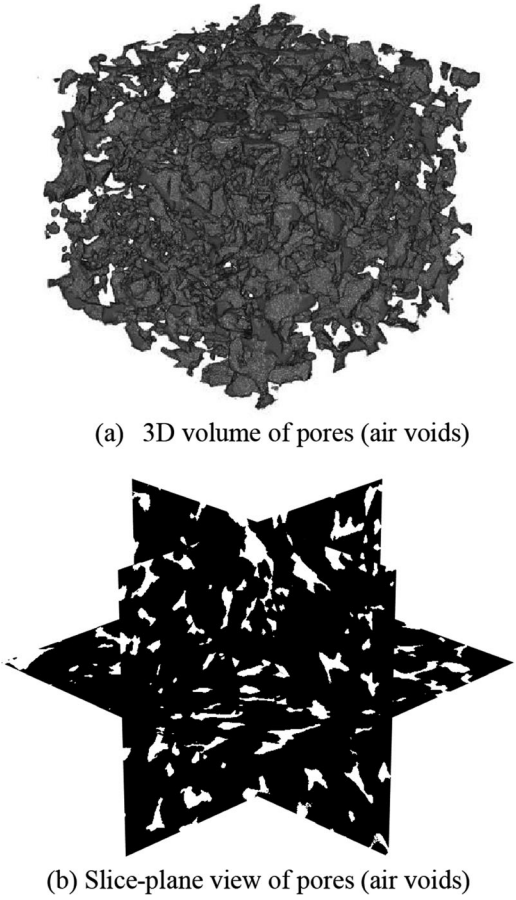
$$K = \frac{\rho g}{\mu} k \tag{2}$$

where μ is the fluid viscosity in pascals-seconds, ρ is fluid density in kilograms per meter cubed and g is gravitational acceleration in meters per second squared. The fluid viscosity and density are assumed to be 0.001 Pa-s and 1000 kg/m^3, respectively, in all cases.

Other interesting quantities that can be computed from the pore-scale fluid velocities include tortuosity. However, knowledge of the saturated permeability of the porous asphalt is considered more important, since it plays a role in further fluid flow modelling efforts, particularly for unsaturated flow.

2.3 Spatial Coarsening

The full dataset consisted of $2000^3 = 8 \times 10^9$ voxels, and after removing some of the voxels outside the region of interest (ROI), the dataset consists of $1543 \times 1544 \times 901 = 2.15 \times 10^9$ voxels (including the empty voxels surrounding the cylindrical sample that was imaged as a rectangular volume), and 1.87×10^6 voxels of the cylindrical ROI. And even though the pores or air voids take up 16.14% of the cylindrical ROI (and the connected pores take up 12.30% of the cylindrical ROI), it is still quite computationally costly to run a fluid flow simulation on a lattice grid made up of 1.87×10^6 fluid-solid nodes. The lattice grid is rectangular, so the dataset is further reduced by cropping the sides. This is finally our rectangular ROI of the porous asphalt sample. In order to reduce the computational cost, we investigate the effect of spatial coarsening. That is, we coarsen the rectangular ROI in the *x*-, *y*- and *z*-directions by the same degree of coarsening and run simulations on each coarsened case. We then compare the simulated velocity field and simulated permeability.



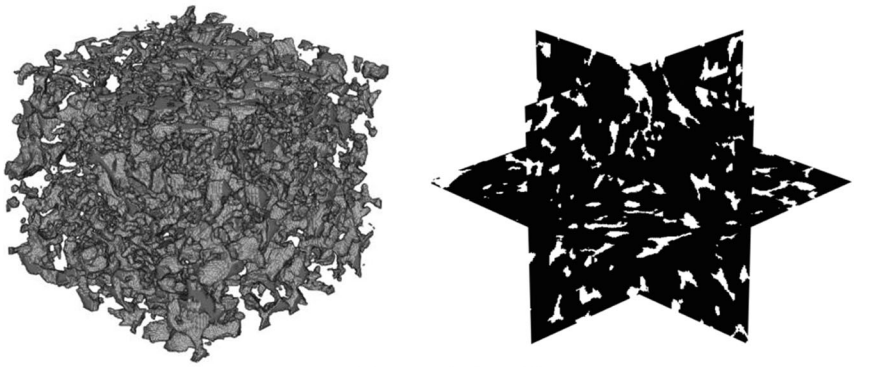
3 Results

3.1 Uncoarsened Digital Model

The rectangular ROI is shown in Fig. 1. The vertical distribution of porosity is shown in Fig. 5, the line is labelled as CL = 1, which means the coarsening level of 1, that is, no coarsening applied. In this porosity distribution, the total porosity fluctuates around the average of 13.54%. The top-to-bottom connected porosity fluctuates around an average slightly less than the total porosity, and is always (slightly) less than the total porosity in each *XY* plane slice.

3.2 Coarsened Cases

The structure of the pore space (both total and top-to-bottom connected) is visualized in Figs. 2, 3 and 4 for a coarsening level of 5, 10 and 25, respectively. Also visualized in these figures are the velocities magnitudes, given in lattice units, to show any dominant infiltration pathways through the sample.



(a) 3D volume of pores (air voids)

(b) Slice-plane view of pores (air voids)

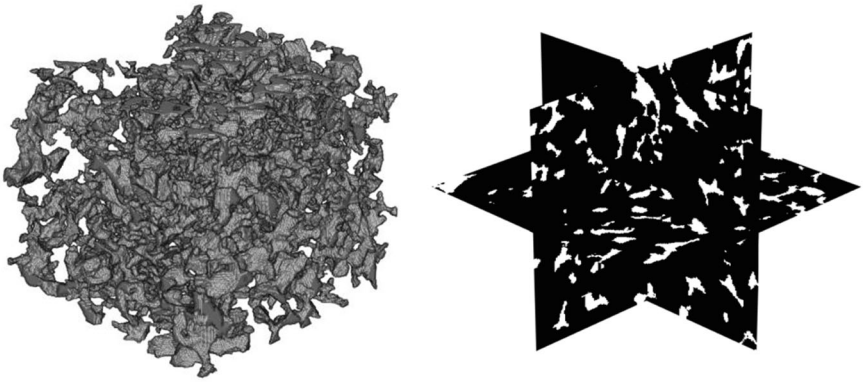


Fig. 1 The uncoarsened dataset. In (**a**), the grey colour represents pores or air voids that are found within the porous asphalt sample. In (**b**), the pores or air voids are represented by the white colour, and both the solids and the space outside the ROI are black

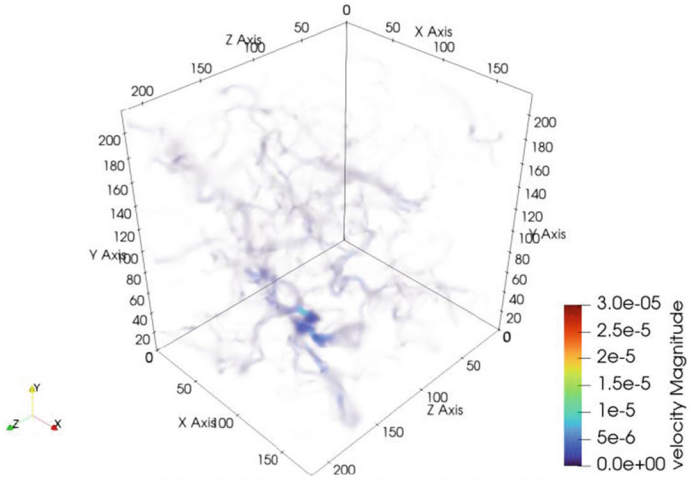
Results of the spatial coarsening and simulations are shown in Table 1. Details of the uncoarsened case are shown in the table for reference; however, a simulation was not conducted on this uncoarsened case due to the high computational cost of simulating on a lattice grid comprised of over 1 billion nodes. It is possible a simulation could be run using a more powerful computer with more than four available cores but this has not been investigated further in this present study.



The difference between these coarsened cases is shown in Fig. 5. Coarsening did not have a significant effect on the total pore space in the sample, and the fluctuation in the vertical direction was relatively similar in all cases. But coarsening had a significant effect on the top-to-bottom connected pore space in the sample, presumably because removing some of the micropores that keep the pore space well connected resulted in more isolated 'pockets' or isolated 'pathways' in the pore space. This is particularly evident in Fig. 4b, where much of the pore space has been removed as it does not connect to the one remaining top-to-bottom pore branch.

(a) Total air voids

CL	Voxel size (cm)	(*Nx, Ny, Nz*)	# Voxels (× 10^6)	Porosity		Simulated *k*			Simulated *K*
				Total	Connected	LB units	Physical units (m^2)	Physical units (Darcy)	Physical units (m/s)
1	0.0063	(1089, 1089, 901)	1068.5	0.1354		–	–	–	
5	0.0313	(218, 218, 181)	8.60	0.1356	0.1266	0.00625122	6.1×10^{-10}	621	6.0×10^{-3}
10	0.0626	(109, 109, 91)	1.08	0.1359	0.1113	0.00182735	7.2×10^{-10}	726	7.0×10^{-3}
25	0.1566	(44, 44, 37)	0.072	0.1362	0.0170	0.000199997	4.9×10^{-10}	497	4.8×10^{-3}

"CL" refers to spatial coarsening level, where 1 means uncoarsened
"–" means simulation not conducted

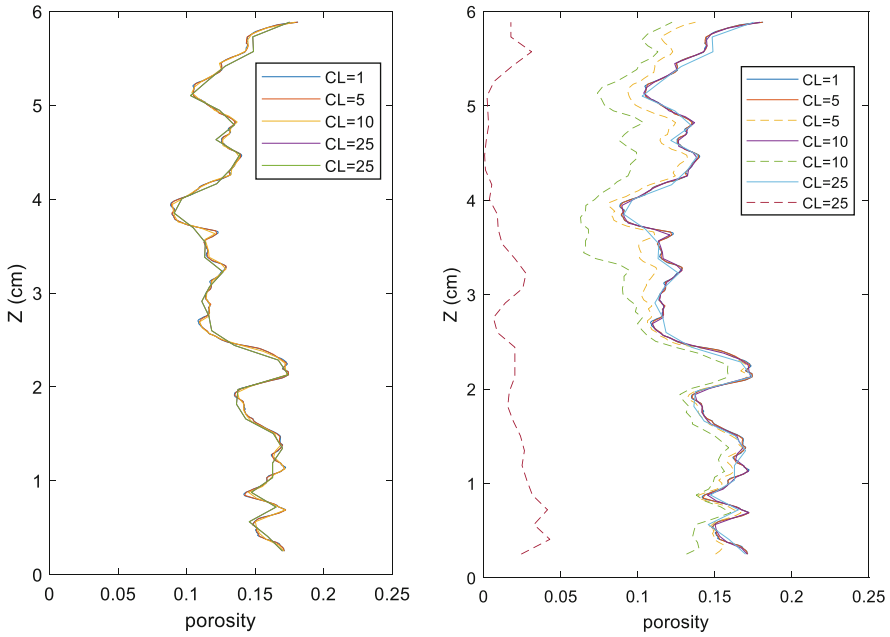

Fig. 5 Distribution of porosity in vertical direction for various cases of spatial coarsening. (**a**) Only shows total porosity. (**b**) Showing both total porosity (solid-coloured lines) and top-to-bottom connected porosity (dashed coloured lines). 'CL' in legend refers to coarsening level

The simulated permeabilities of the coarsened cases are all high (between 500 and 700 Darcy), and it is noted that gravel can have a permeability of up to 10^5 Darcy. It is interesting to note that there is not an observable trend between porosity and permeability between these three coarsened cases. This could be related to an issue with convergence of the simulation, and it was noted during this work that some pore throats present in the geometries were not properly discretized in space with the lattice mesh. This issue can be solved by refining these pore throats with more lattice nodes; however, this increases the computational cost of the simulations. While it is important to achieve convergence in the solution, we leave this issue for a future work and note that results in the present work are intended for visualization of the flow paths rather than accurate representation of the velocity magnitude. Permeability values are expected to change as grid refinement is done to for convergence purposes; however, it is possible the values will not change by many orders of magnitude.

4 Conclusions

This work helps visualize the fluid flow pathways through a sample of porous asphalt, and shows how spatial coarsening can be used to speed up simulation work while still resulting in a permeability of around 400–700 Darcy. The permeability should be viewed as demonstrative since it was noted that simulation results had not converged appropriately due to narrow pore throats present in the geometry, and that refinement of the lattice mesh is required; however, this was left for future work.

Other future work includes studying other coarsening approaches, and studying the influence of the ROI's volume on simulated permeability. That is, the size of the representative element volume (REV) for this porous asphalt sample should be assessed, even though this work assumed a rectangular ROI measuring 6.82 cm × 6.82 cm × 5.64 cm was sufficient.

1 Introduction

The use of computed tomography (CT) imaging has become increasingly popular in studying pavement structures, offering detailed insights into their complex microstructural properties. The imaging technique allows for a non-destructive examination of asphalt's pore structures, such as porosity, a key factor affecting the material's performance and durability. However, CT imaging also comes with its challenges, including high costs and time-intensive processes, especially when large datasets are required for comprehensive analysis.

Accurate methods for statistical reconstruction of the three-dimensional (3D) pore structures from limited sample images have been explored to tackle these challenges. Generative adversarial networks (GANs) [1] have emerged as a promising alternative, offering a more efficient and flexible approach to augmenting the available dataset for pavement structure studies. It has the potential to synthesise high-fidelity

asphalt microstructures from a limited set of real CT images. This technique not only mitigates the constraints associated with traditional CT imaging but also introduces new potentials based on the development of deep learning techniques.

Porosity distribution is a crucial parameter that significantly influences the mechanical behaviour and longevity of pavement materials. The vertical distribution of the porosity of asphalt materials can be of a certain pattern based on the conditions of the asphalt materials, which are crucial because it influences the material's durability, permeability and overall performance under traffic and environmental conditions.

In this work, we aim to develop a controllable technique that allows us to generate microstructures with user-defined porosity profiles. This can potentially allow the creation of large amount of diverse, realistic asphalt microstructures that can be used for further simulations and analyses. With this technique, we can generate microstructures in a more flexible manner so that a more targeted investigation into how porosity distribution impacts the overall performance of pavement systems.

2 Related Works

Generative Adversarial Networks (GANs) is a class of generative models originally introduced by Goodfellow et al. in 2014 [1]. GANs typically consist of two neural networks, the generator and the discriminator, which are trained simultaneously through adversarial processes. Since its introduction, different variants have been proposed to enhance its capability and performance. Deep convolutional GANs (DCGAN) [2] apply convolutional neural networks within the GAN framework, leading to more stable training and better quality of the generated images. Self-Attention Generative Adversarial Network (SAGAN) [3] incorporates a self-attention mechanism into a GAN architecture, which improves the performance significantly for long-range dependency image generation tasks. Since then, GANs have been used to successfully generate various data, such as images, text, videos, etc.

Mosser et al. [4] applied GAN to reconstruct 3D microstructure of a granular porous structure. SliceGAN [5] resolves the dimensionality incompatibility between two-dimensional (2D) training images and 3D generated volumes so that it can generate 3D volumes from 2D images, which are more accessible and of better resolution and quality. However, SliceGAN holds limited capabilities in handling the heterogeneity of the microstructures.

Conditional GAN (GAN) [6] extends the GAN framework by introducing class labels (categorical conditions), which can be used to condition the discriminator and generator so that the single generator can generate images of various categories. However, this method does not work for continuous scalar conditions, which is the case for many porous structure-related properties. Continuous conditional GAN (CCGAN) [7, 8] addresses challenges in conditioning on continuous scalar labels

by reformulating empirical cGAN losses and introducing a novel method for integrating regression labels with the generator and discriminator. This approach effectively overcomes limitations associated with traditional cGANs when dealing with continuous scalar conditions. CCGAN has served as the foundation for our research. In this study, porosity has been explored as the scalar condition, so that we can generate porous structure for specified porosity. Furthermore, like [9], the latent space interpolation technique is used to synthesise 3D microstructure volume based on the trained CCGAN.

3 Methods

3.1 Dataset and Preprocessing

In the study, we use micro-CT images of Porous Asphalt (PA) sample (detailed in [10]) as our training dataset. This lab-crafted sample is designed with sufficiently high porosity to allow surface water to permeate the material, facilitating drainage on roads. The original dataset features a dimension of 2000^3 and a resolution of 62.6 μm. It is of cylindrical core shape. To be used for deep learning training, using the processing technique from [10], a region of interest was extracted, noise filtered, and the pore space segmented. The resulting processed image is shown in Fig. 1. For efficient training samples, we further cropped it to a square within the core sample, yielding a 3D data sample with dimensions of $1000 \times 1000 \times 901$.

To effectively train the CCGAN model used in this study, a substantial number of real samples are needed. To compile the necessary training samples, we randomly selected 32,000 image patches from the dataset. To capture enough reprehensive pore structure, while maintaining a small enough image size that can be used for training the CCGAN, we down-sampled the patches by a factor of four to get a patch of size 128×128. This process is shown in Fig. 1.

To understand the porosity distribution among these samples, we plotted their porosity values in a histogram, as shown in Fig. 2. GAN models aim to approximate the real data's distribution through a high-dimensional probability function, with a particular emphasis on capturing the likelihood of various porosity levels within the dataset in this study. The success of a GAN model is closely tied to how well this distribution is represented in its training set. It is therefore crucial to have a dataset that is both diverse and balanced enough to cover the range of the observed porosity values. As a result, the model is expected to perform well within the porosity value range that is adequately represented. As depicted in Fig. 2, the 5th and 95th percentiles of the training samples' porosity values fall within the [0.07, 0.19] range, which also represents the focus of the experiments conducted in this study.

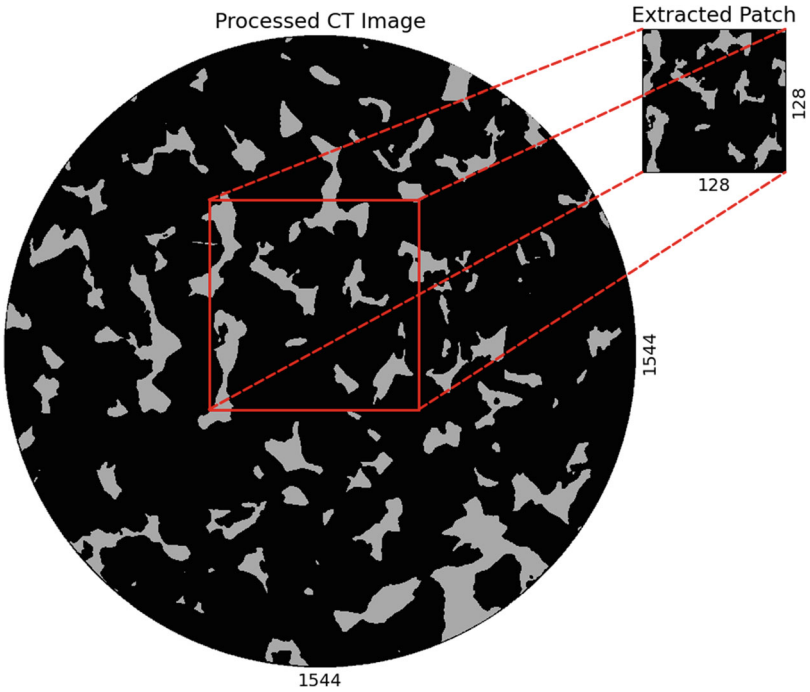

Fig. 1 An example of a slice of asphalt CT image and an extracted patch from the dataset. The patches are down-sampled by a factor of four

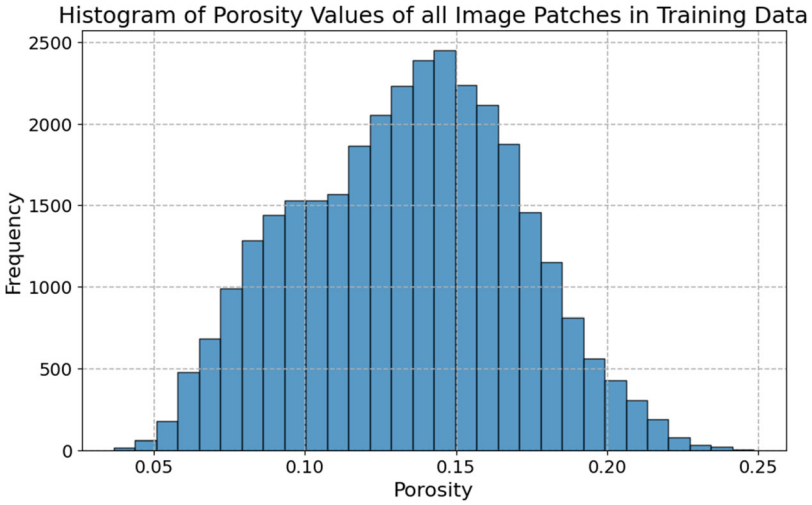

Fig. 2 Distribution of porosity values of the 32,000 image patches used in the training data

3.2 *Network Architecture and Training Parameters*

Figure 3 shows the overall workflow and architecture of the neural network structure used. In a typical GAN, the network structure consists of a generator and a discriminator. CCGAN extends the structure of a GAN by introducing a regression label to condition the training of both the generator and discriminator. In this work, the porosity of the porous structure is used as the regression label. The generator takes both a random noise vector (latent space) and the porosity label as inputs. The discriminator receives both real and generated data, along with the porosity label, and is trained to determine whether the data is real or fake, considering the input porosity. During training, the generator aims to generate data that the discriminator cannot distinguish from real data, given the input porosities. At the same time, the discriminator learns to better distinguish between real and generated data with given porosities.

Training GANs with high-resolution images enhances the quality and detail of generated images, enabling the model to capture more complex features. However, training GANs with higher resolution images demands more training data, computational resources and memory. It also increases the complexity of the learning process, potentially destabilising the balance between the discriminator and the generator. To manage these challenges, we limit our training images to a resolution of 128×128.

In microstructure generation, accurately identifying the phase of each pixel is crucial. In this study, we incorporate image segmentation directly into the neural network model. Our approach involves one-hot encoding of the training images to designate each phase with distinct channels, setting pixels to 1 where a phase exists and 0 elsewhere. By using a SoftMax activation function, we transform the output into a probability distribution for each phase. By using an argmax function we can easily get the segmented image from the output, with clearly defined phases for each pixel.

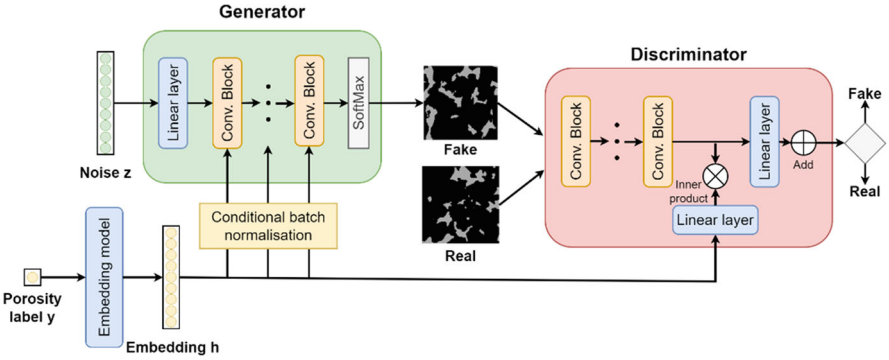

Fig. 3 Overview of deep learning architecture used. The architecture is primarily based on SAGAN architecture but with some modifications for our purpose, such as using a SoftMax activation function in the generator. The porosity is used as the regression label into the generator and discriminator using the improved label input method developed in CCGAN [8]

3.3 Latent Space Interpolation

Once the generator is trained, it can produce 2D microstructures or slices that follow a specified porosity. To use this 2D generator to produce 3D volumes, latent space interpolation [9] is used to generate correlated 2D microstructure slices. These slices can then be stacked to synthesise a cohesive 3D microstructure. For simplicity, we use a linear interpolation, given by the expression

$$f_{z_1,z_2}(\lambda) = (1-\lambda)z_1 + \lambda z_2 \tag{1}$$

The relative weight of the two latent vectors is thus controlled with the parameter λ. Here we set the parameter λ using the following equation

$$\lambda = \frac{i}{N} \qquad i = 0, 1, 2, \ldots, N-1 \tag{2}$$

where N is a control over how much we want the microstructure to change between the slices. To generate more images than N, we can perform this procedure in several cycles, where after each N steps we sample a new random latent vector. Using this approach, we can generate an arbitrary number of unique images.

4 Results

4.1 Generating 2D Slices with Controllable Porosity

After training the generator using the real sample images, along with their corresponding porosity labels, it can produce new, unique 2D images with given porosity values. Figure 4 displays a side-by-side comparison of real images against images generated by the model, using the porosity labels from their real counterparts. This qualitative comparison reveals that the structure of the generated images bears a close resemblance to that of the real images, demonstrating the generator's proficiency in replicating 2D slices.

4.2 Determining the Optimal Number of Steps for the Interpolation Method

The latent interpolation technique used in our work is a method to make our generated 2D slices into a cohesive 3D volume. Our goal is to create a 3D volume with material properties that match our dataset. For CT images of microstructures, the individual 2D images are usually highly correlated with their neighbouring slices. The degree of correlation depends on the size of the structures in the material

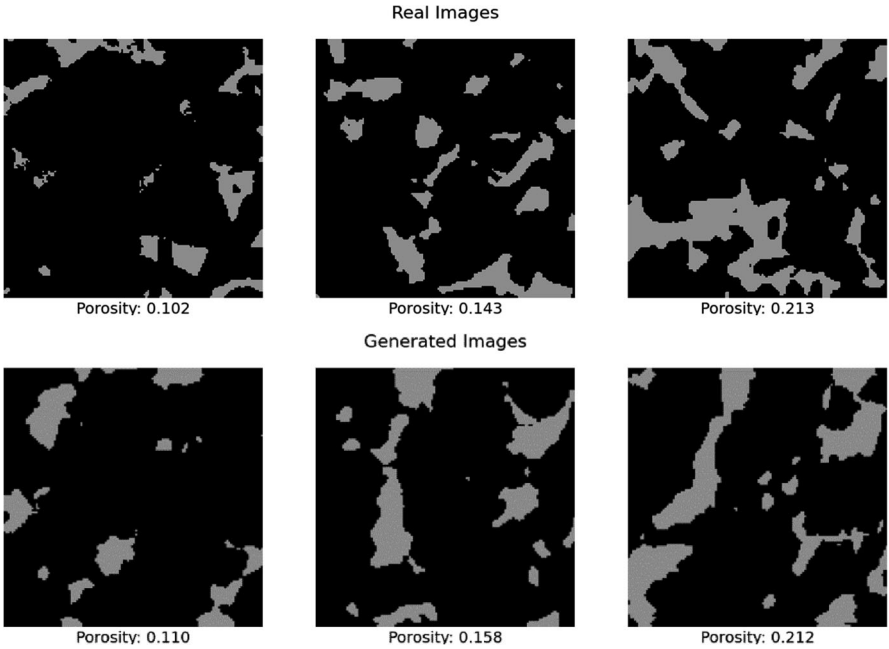

Fig. 4 Comparison between real images from the dataset, and generated images, using the porosity values of the real images as input labels

and the distance between the 2D images. For our generator, we can use the number of interpolation steps N, to control how many images we want to generate before they are independent of each other. This gives us an explicit method to control the correlation properties of our generated 3D volume.

To get the best match between the real dataset and our generated volume, we calculated the mean correlation value between an image and its neighbouring images, shown with the blue line in Fig. 5. This was done for the full volume of size $1000 \times 1000 \times 901$, where neighbours up to 100 images away were considered. Using the measured porosity profile from the real dataset as an input to our generator, we generated corresponding 3D volumes of shape $128 \times 128 \times 901$ for varying values of N. To find the best match to our dataset, the value of N with the minimal root mean square error (RMSE) between the correlation curve of the real dataset and our generated volume was selected, which was found to be 55. Figure 5 shows the correlation curve for varying values of N, where we can see that our optimal value closely matches the correlation behaviour of the real dataset.

4.3 Generating 3D Microstructures

The vertical distribution of porosity in asphalt materials significantly influences their structural integrity, filtration capabilities and overall performance. This study

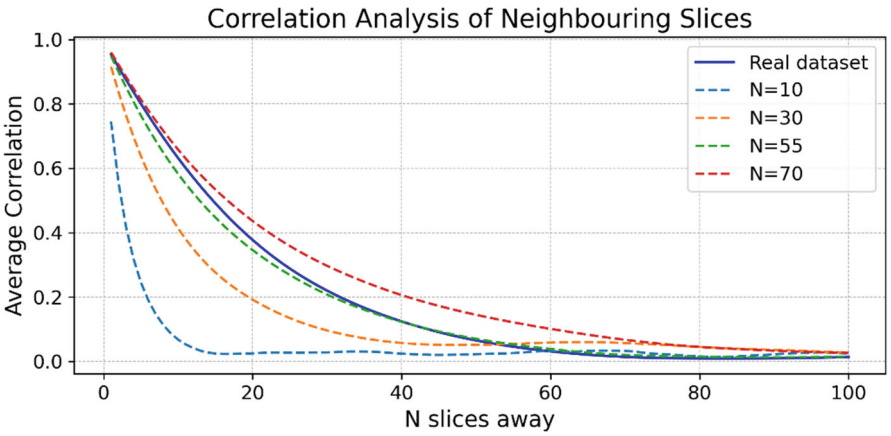

Fig. 5 Analysis of the correlation between neighbouring slices for the dataset. This is used to determine the parameter N for the number of slices in the z direction to sample before they should be independent of each other

focuses on generating asphalt microstructures that accurately capture the specific vertical porosity distribution.

In Fig. 6, the right panel illustrates the porosity profile of the actual dataset in the vertical direction, represented by the blue line. Utilising this profile as a reference and input, we aim to generate 3D microstructures that replicate this specific porosity distribution. The left panel of Fig. 6 displays three slices from the generated 3D microstructures, indicating that our generator indeed generates 2D microstructures to match the input porosity accurately. An orange dashed line in the right panel of Fig. 6 depicts the vertical porosity profile of the generated 3D microstructures. A comparison between the blue and orange dashed lines reveals similar porosity profiles, although deviations are observed.

Utilising the same generator, instead of generating a vertical porosity profile from a real dataset, we generated 3D microstructures based on a user-defined linear porosity profile, shown in Fig. 7. The vertical porosity profile of the resulting 3D microstructure demonstrates a general linear trend, while with noticeable deviations from the specified porosity profile. This observation demonstrates the capability of the current method to generate asphalt microstructures based on custom porosity profiles, which can be challenging with real samples. This approach could potentially set new ways in asphalt material design and optimisation.

A significant advantage of the deep learning-based generation technique is its efficiency: once the generator is trained, it can reconstruct 3D microstructures very quickly. In this study, generating a 3D microstructure with dimensions $128 \times 128 \times 901$ requires only 0.7 s using an NVIDIA 3090 RTX Ti GPU. This efficiency suggests the feasibility of producing numerous realisations of 3D microstructures, each with identical or varied porosity profiles.

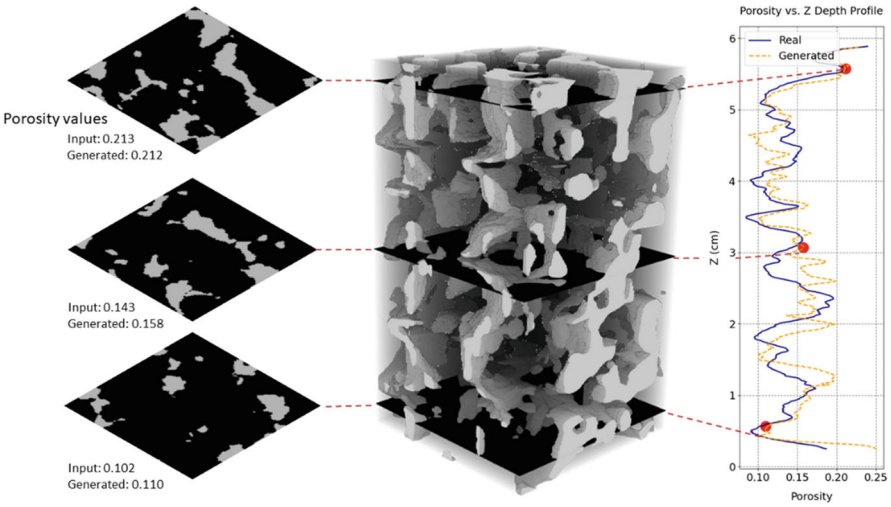

Fig. 6 Visualisation of generated 3D volume from real porosity profile: Left: Three selected slices from the volume. Middle: 3D rendering of the generated porous volume. Right: A comparison of the porosity profile extracted from the dataset (blue line), which was used as input to the generator, and the calculated porosity profile from the generated volume (orange dashed line)

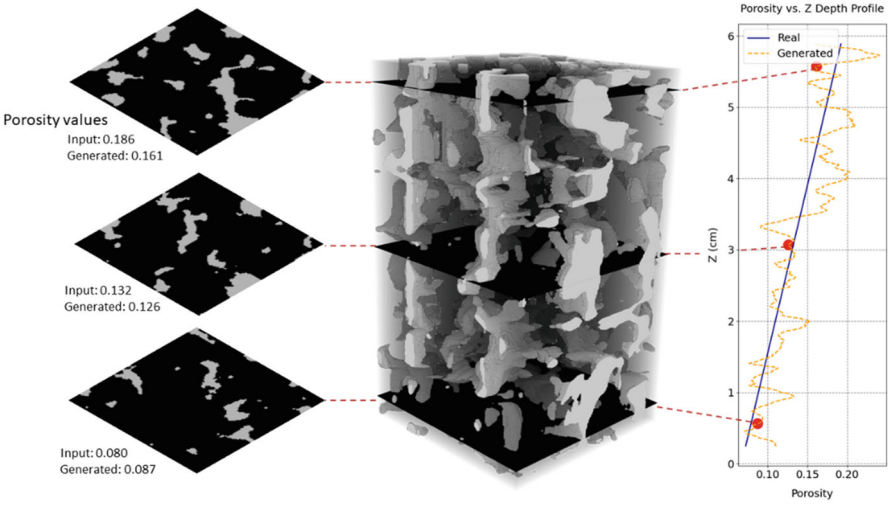

Fig. 7 Visualisation of generated 3D volume from linearly increasing porosity profile: Left: Three selected slices from the volume. Middle: 3D rendering of the generated porous volume. Right: A comparison of the defined linearly increasing porosity profile (blue line), which was used as input to the generator, and the calculated porosity profile from the generated volume (orange dashed line)

4.4 Evaluating the Properties of the Generator

In Figs. 6 and 7, we can see that the generated porosity profile has a similar profile to the real data but has some fluctuations. To evaluate the degree of fluctuations and average behaviour, 50 volumes were generated for a given porosity profile. The porosity of the generated volumes was calculated, and the mean and standard deviation calculated across the 50 volumes. Figure 8 shows the result for a user-defined linearly increasing porosity profile and a porosity profile extracted from the real dataset. The results indicate that the average porosity profile follows the specified input porosity profiles but with a significant variation. For the linear porosity profile, we can see that the generator consistently generates higher values for low porosities and lower values for higher porosities. This regression to the mean is likely a result of low and high porosity values not being well represented in our dataset.

Figure 9 shows a comparison of the material properties—porosity, surface area and effective diffusivity—between the real dataset and generated volumes. The

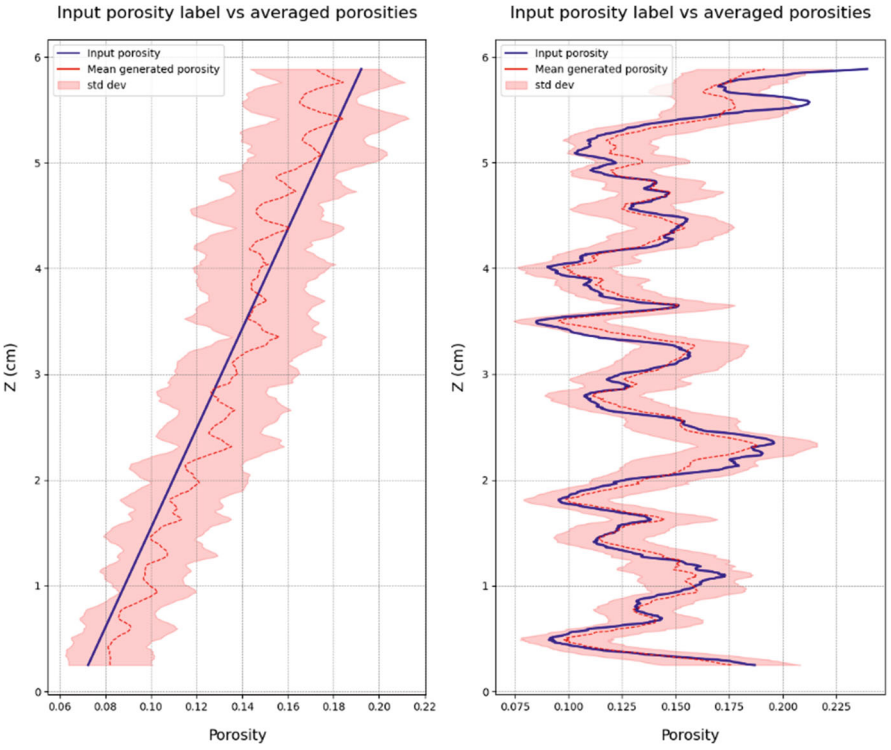

Fig. 8 Comparing the input porosity label to the averaged porosity profiles of 50 different generated microstructures. Left: For linearly increasing porosity values. Right: For a porosity profile extracted from the real dataset

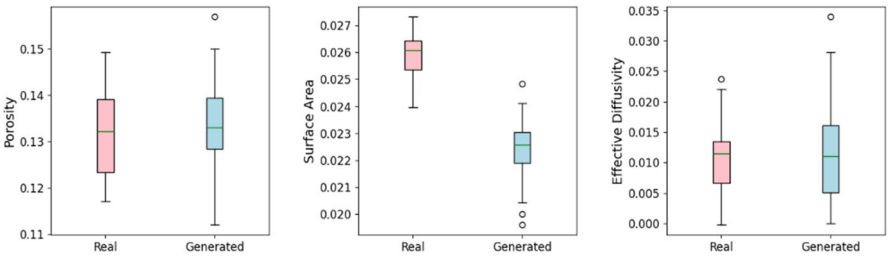

Fig. 9 Comparison of the material properties porosity, surface area and effective diffusivity, between the real dataset and generated volumes. The boxes extend from the first quartile (Q1) to the third quartile (Q3), with the central green line indicating the median. With whiskers extending 1.5 times beyond the interquartile range (IQR), (Q1 − 1.5 IQR below and Q3 + 1.5 IQR above). Outliers are indicated as circles

metrics have been calculated with TauFactor [11]. There is a close match between the median porosity of the real and generated data. However, the generated data have a narrower distribution, except for some outliers. The surface area of the generated volumes has a small consistent bias toward lower values. The effective diffusivity is a metric related to the flow transport of the material, which is determined by the 3D material structure. This is a metric that describes the emergent 3D behaviour of the volume. In the comparison, there is a close match between the median values of the real and generated data, demonstrating that the generator can create representative 3D volumes.

5 Conclusion

This study introduces a framework that incorporates Continuous Conditional Generative Adversarial Networks (CCGAN) and latent space interpolation techniques for the controllable generation of microstructures with specified vertical porosity profiles. The ability to fine-tune the generation of 3D microstructures provides a flexible and controllable approach that could potentially pave a new path for asphalt material design and optimisation. We believe the approach used in this work can potentially be extended to generate microstructures based on other properties.

Within the framework, by using the presented CCGAN model, we can generate 2D microstructures that closely resemble real samples, guided by specified porosity labels. Latent space interpolation technique is shown to be effective in assembling the 2D microstructure slices into cohesive 3D volumes. However, we have observed deviations in the porosity profile of the generated 3D microstructures compared to the input porosity profile. Exploring the possibility of combining our controllable generation technique with a 3D-aware training approach offers a promising direction for future research.

Acknowledgement We acknowledge Rebecca Allen from OsloMet for providing the asphalt CT images (detailed in [10]). These images, derived from an asphalt sample prepared by the Norwegian Public Roads Administration (Statens Vegvesen), were produced using micro-CT by the Norwegian Geotechnical Institute (NGI) to support thesis work at OsloMet. We also thank the authors of [7, 8] and [11] for publishing their developed source code, which are used in this work.

1 Introduction

Buildings can act against air pollution through photocatalysis [1], which also attributes self-cleaning and antimicrobial effects to surfaces [2], mainly benefiting façades in urban environments. Photocatalysis involves electron transfers from the valence to the conduction band of semiconductors under irradiation, the reaching of

electron–hole pairs to the particles' surface, and their reaction with air, forming reactive species to mineralize pollutants [3].

Several photocatalysts exist, like titanium dioxide (TiO_2), zinc oxide (ZnO), and iron (III) oxide (Fe_2O_3) [4]. Their conventional production with physical and chemical methods is environmentally unfriendly, involving toxic chemicals (stabilizing and reducing agents, chemical solvents), being costly and time consuming [5]. The large bandgap energy of well-established photocatalysts, like TiO_2, limits their photoactivation to ultraviolet (UV) radiation [6], and their efficiency may be further harmed by the high recombination between photoinduced electrons and holes [7]. Moreover, there are concerns about nanomaterials' ecotoxicity and long-term impacts on human health [8].

The green synthesis of nanoparticles is valuable for biological and environmental applications [5] since converting waste into functional substances should be encouraged [9] to pursue a circular economy and fight climate change. Blue economy accounts for efforts promoting the use of marine resources in search of sustainability [10]. So, marine algae have been employed in the green synthesis of nanoparticles due to their fast harvesting, renewability, low toxicity, and simple handling [11]. Products like mollusk shells derive from aquaculture, and their large availability, combined with the usual landfill or seawater disposal, pollutes the environment [12], demanding novel usages.

This research dived into the green synthesis of photocatalysts based on sea resources through a comprehensive literature review in several research fields, seeking resilience and climate mitigation. The goals were to answer whether marine bio-photocatalysts are already embraced by the construction sector and identify experimental starting points for their use in building envelopes, fostering preservation and better air quality.

2 Methods and Overview

For the primary question, "How to synthesize (and evaluate) an effective bio-photocatalyst produced with marine resources following a green route?", the proposed query string was: "(bio* OR natur* OR green OR waste OR sustainab* OR organic) AND (synthes* OR produc* OR compos* OR fabric*) AND (fish OR shell OR *algae OR marine OR maritime OR sea*) AND (photocatal* OR photoact*)". The survey was broad to inquire if any result concerned buildings or, if not, to identify potential experimental approaches. The title, abstract, and keywords of journal papers in English from Scopus were searched, including documents from the beginning of 2020 up to February 2024. Filtering rounds began with the titles, followed by abstracts and full-text analysis. The selected full papers explicitly described the extraction of raw marine materials; experiments using purchased chitosan, alginate, or algae powder, for instance, were discarded. Literature reviews were disqualified in the final selection.

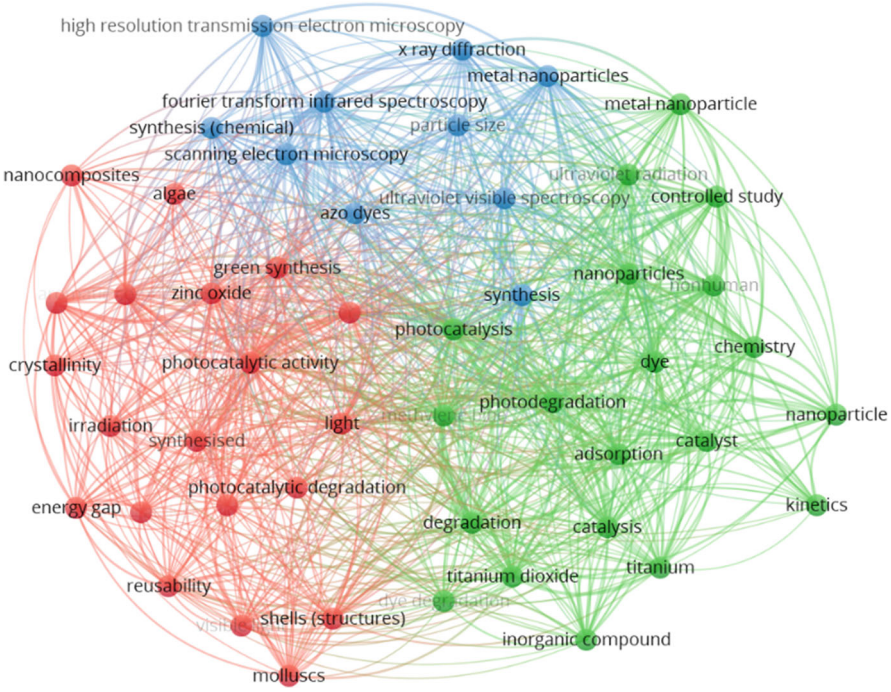

Fig. 1 Network visualization of all keywords from the 64 selected papers (VOSviewer v1.6.18: co-occurrence analysis, full counting method, five minimum keyword occurrences)

In total, 1894 papers were initially retrieved. Title and abstract analysis led to the selection of 186 documents, of which 122 were discarded after full paper reading. So, the final sample had 64 papers, whose keywords network is depicted in Fig. 1, from VOSviewer v1.6.18. Green synthesis is within the three main clusters, and shells, mollusks, and algae connect with photocatalysis. Photoactivity inherent aspects, like energy gap, kinetics, and reusability, as well as characterization techniques, are also shown in Fig. 1.

At least 68.8% of the papers had wastewater or water treatment as a primary goal [4, 7, 9, 11–51]. Meanwhile, 20.3% usually referred to more than one photocatalysis application [52–64] despite typically testing dyes and organic molecule degradation. Around 6.2% of the studies focused on medicine or human health [65–68] and 4.7% on indoor air purification [69–71], the closest topic to buildings but not related to façades.

Algae were used to synthesize photocatalysts in 42.2% of the papers, including seaweed [11, 17, 30, 31, 34, 38, 41, 47, 48, 51–55, 58, 64, 66, 68] and microalgae [15, 28, 29, 36, 37, 43, 45, 49, 57]. Different shell types were studied in 37.5% of the articles, comprising abalones [39, 70, 71], clams [7, 27, 39], crabs [42], crawfishes [20], mussels [12, 18, 26, 32, 39, 50, 56, 69], oysters [13, 19, 21, 23, 39], scallops [4, 39, 61], snails [62], shrimps [40], and seashells in general [9, 14]. The remaining

documents addressed other sea species: one for bacteria [44], marine oyster extract [60], sand [59], sponge [24], and tunicates [46]; two for fungi [25, 35]; and three for fish waste (bones [16, 22] or scales [63]) and plants [33, 65, 67]. So, algae and shells were the most used bio-sources.

Three papers referred to the application of bio-photocatalysts, mentioning tetraethylorthosilicate encapsulation [38], thin films of chitosan (from crab shells) with polyvinylidene chloride [42], and cellulose hydrogels with extraction from tunicates [46]. None of the selected documents addressed environmental impacts with life cycle assessments. Safat et al. [60] tested cytotoxicity against fibroblast cells, Sundar et al. [65] and Rajivgandhi et al. [67] against MCF-7 cells, and Lavanya et al. [66] against breast human hepatoma (Huh-7) cells. However, no article presented ecotoxicity assessments.

3 Characterization and Photocatalytic Evaluation Methods

X-ray diffraction (XRD) and UV-Vis or UV-Vis/NIR spectroscopy were the most frequent tests to characterize novel photocatalysts. XRD provided mineralogical compositions and, in addition, crystallographic data, such as crystalline sizes, using the Scherrer formula [29, 35]. Bandgaps were determined from spectroscopy results with Tauc plots [7, 9]. Surface compositions and valence states were measured with X-ray photoelectron spectroscopy (XPS) [56], and Fourier-transform infrared spectroscopy (FTIR) complemented chemical analysis by examining functional groups [4].

Microscopy techniques, like scanning electron microscope (SEM), field emission scanning electron microscopy (FE-SEM), transmission electron microscopy (TEM), and high-resolution transmission electron microscopy (HRTEM), were shown in most papers, combined or not with energy dispersive spectrometer (EDX/EDS). Thermogravimetric analysis (TGA) and particle size/specific surface area also characterized the photocatalysts, including N_2 adsorption–desorption isotherms [20]. Electron–hole separation, charge transfer, and migration [22] were analyzed with photoluminescence spectra (PL), and free radical and hole scavenging experiments were common to investigate photochemical-produced charges [9]. Several papers modeled kinetics and detailed photocatalytic mechanisms. Although not so frequent, other characterization tests, such as Raman measurements [11] and zeta potential [4], were also carried out.

Most studies performed dye degradation to evaluate photoactivity. Dyes such as rhodamine B (RhB) [18, 26, 30], methylene blue (MB) [19, 55, 56], methyl orange [40, 44, 65], and congo red [11, 16, 34] were considered reference pollutants. In some cases, antibiotics were degraded by the photocatalysts in aqueous solution, including amoxicillin [4], enrofloxacin [20], procaine penicillin [21], sulfadiazine [56], and tetracycline [36], further than phenols [33], and herbicides like glyphosate [23]. For testing, the marine-based photocatalysts were mixed in a solution with the compound to be degraded and kept in the dark for variable times (30 min [9, 24, 53,

55, 66], 1 h [26], 2 h [27], etc.), until reaching adsorption–desorption equilibrium [50], and under stirring to achieve good dispersion [55]. Then, the prepared suspensions were exposed to light sources, generally under continuous agitation [20]: mainly visible light [17, 31, 51, 61, 65], sunlight [19, 21, 24, 52, 53], led light [36, 49, 54, 59], xenon [18, 20, 23, 55, 57] and UV lamps [4, 22, 29, 30] were used. At given intervals (3 min [11], 10 min [66], 30 min [53], etc.), aliquots from the solutions were removed for UV-Vis or UV-Vis/NIR spectroscopy. Supernatants were usually collected and centrifuged for sampling [9].

Some studies, like Saikia et al. [11] and Serrà et al. [36], evaluated the total organic carbon (TOC) of the reactions before and after pollutants' degradation. Serrà et al. [36] also performed liquid chromatography-mass spectroscopy (LC–MS) to identify intermediate products during tetracycline photodegradation. Reusability tests were typically achieved by submitting the synthesized photocatalysts to several consecutive degradation runs, like three [7], four [65], five [11], six [4], or ten [36]. Generally, the catalysts were regenerated with filtering [40] or centrifugation, washing, and drying [9, 14, 52].

For indoor air purification, formaldehyde and toluene were studied [69–71]. The photocatalysts were coated on quartz glass, and the tests were run by turning on light sources in reactors with injected gas volumes [69–71] after a period in the dark (1 h [69], 2 h [71]). Qiu et al. [69] measured carbon dioxide (CO_2) generation in time and formaldehyde degradation with a gas detector of photoacoustic spectrometer. Wang et al. [70] and Wang et al. [71] used a photoacoustic infrared multigas monitor.

4 Synthesis and Behavior of Marine-Based Photocatalysts

Three main groups were identified regarding the objectives behind employing marine materials to synthesize photocatalysts. The sea species were mainly used as carriers or supports for well-known photocatalysts, as catalysts without combining additional photoactive materials, or as reducing and capping agents.

Since nano-scaled particles tend to agglomerate, using carriers with adsorption abilities and hydrophilic surfaces to support photocatalysts may reduce their aggregation [72]. Employing sea materials to face environmental pollution can represent the "control of waste by waste," being potentially upgraded by trace metal elements in their composition, such as ZnO and TiO_2, and by their contribution to higher availability of active sites [39] for pollutant degradation and surface area for adsorption [12].

Wang et al. [39] studied powders from seashells calcined at 300 °C for 5 h and 500 °C for 2 h to support TiO_2 with a sol–gel process; Rabie et al. [51] supported nano-ZnO and Co-ZnO in algae of the *Sargassum* species using microwave irradiation; and Cai et al. [18] used a solvothermal method to prepare powders of mussel shells calcined at 900 °C for 3 h to support yttrium-doped Bi_2MoO_6. Wang et al. [39] observed that calcined abalone shell supports increased the concentration of O vacancies, enhancing charge separation on the TiO_2 surface and, therefore, its

photoactivity, reaching even better results than commercial P25 nanoparticles in a 23.4% catalyst concentration. Rabie et al. [51] verified around 58% and 75% of enhancement in the photocatalytic performance of ZnO/algae and Co-ZnO/algae composites compared with pure ZnO; in fact, 2.45 eV and 2.32 eV were the calculated bandgaps for the composites, lower than the usual values for ZnO and Co-ZnO. Regarding the photocatalytic mechanism, Cai et al. [18] indicated that O_2^- and h^+ represented the primary active species, with a crucial role of ·OH. On stability and reusability, after four cycles, Cai et al. [18] observed a decrease from 99.7% of RhB degradation to 83.3%, probably due to a loss of catalyst during centrifugation and by the adsorption of intermediates onto the catalyst surface.

For a Bi_2WO_6/calcined mussel shell composite, Li et al. [12] measured 52.3% TOC removal after 150 min of reaction, suggesting a gradual mineralization of RhB. In the presence of a SiO_2-doped photocatalyst derived from a waste mussel shell, Wang et al. [50] got mineralization rates of 33.5% and 16.5% for MB and RhB solutions; so the dyes were decomposed and only partially mineralized under visible light. Zhang et al. [23] studied glyphosate degradation kinetics by cerium (Ce) and nitrogen (N) co-doped TiO_2 nano-photocatalysts loaded on modified oyster shell powders with the Langmuir–Hinshelwood mechanism, reporting an apparent first-order model over 120 min. The glyphosate degradation rate by the composite with 0.5% Ce doping molar ratio (0.5%-CeNT@Oys), with a 2.91 eV bandgap, was 8 times higher than pure TiO_2 (3.20 eV), indicating the synergy of adsorption and photocatalysis under xenon light [23].

Koladia et al. [14] compared the formal quantum efficiency (FQE) of photocatalysts synthesized by combining CaO from seashells and powdered molybdenum disulfide (MoS_2) in different mass proportions (1:3, 2:3, 9:11, 1:1, and 3:1) with pure CaO, MoS_2, and TiO_2. In this case, the FQE illustrated the photonic efficiency concerning industrial effluent treatment, dividing the reaction rate by the photon flux. The photocatalyst 45-CaMo (9:11) had the highest FQE, 0.32%, compared to 0.24% from TiO_2, 0.13% from pure CaO, and 0.02% from pure MoS_2 [14]. Bhole et al. [9] also reported the FQEs for MB molecules treated by incident photons, considering photocatalysts produced from seashell-derived CaO and synthesized Fe_2O_3 powder (rust); the highest FQE was 0.27% for the mixture with 10% Fe_2O_3 and 90% CaO.

Considering the photocatalysts produced without additional doping, Eddy et al. [13, 19, 21] and Qu et al. [27] focused on oyster and clam shells, respectively. Eddy et al. [13, 19, 21] applied the sol–gel method, counting on hydrochloric acid (HCl) and sodium hydroxide (NaOH) solutions and calcination to convert calcium carbonate ($CaCO_3$) into calcium oxide (CaO) nanoparticles; Qu et al. [27] also used HCl and calcination in the synthesis. Compared to pure photolysis of crystal violet dye, using CaO nanoparticles enhanced photodegradation from 3.9% to 98% under sunlight; higher degradation was observed with increasing contact times and catalyst dosages [13]. Eddy et al. [21] got an average bandgap of 4.42 eV for CaO nanoparticles calcined up to 850 °C, while Qu et al. [27] found 2.64 eV for calcination at 1000 °C, which led to 99.7% and 90.8% MB and congo red

degradation by adsorption-photodegradation mechanisms, respectively, compared to 25.9% and 70.55% removal rates in the dark.

Campalani et al. [63] produced carbon dots from fish scales with a hydrothermal treatment, while Prosad Moulick [16] obtained hydroxyapatite by calcinating fish bones at 900 °C for 2 h. With 0.08 g fish bone catalyst and a 10.0 ppm congo red solution, nearly 82% of degradation was achieved within 3 h [16]. Carbon dots from fish scales had 3 eV of bandgap, converting 56.6% methyl viologen, with better photoelectron transfer than N-doped carbon dots [63]. Lastly, with dead marine microalgae *Scenedesmus quadricauda*, Wu et al. [37] got estrogen photodegradation under visible light.

Finally, several papers used marine materials (mostly algae) as reducing or capping agents. For instance, Maduraimuthu [53] prepared a seaweed extract from *Ulva lactuca* and added it to silver nitrate ($AgNO_3$) solution to form Ag nanoparticles. Indeed, phytochemicals like proteins, saponins, and quinines may reduce Ag^+ ions, further preventing aggregation and providing stability [53]. Wang et al. [17] produced an aqueous extract with *Solieria tenuis*, added with a chloroauric acid ($HAuCL_4$) solution to synthesize Au nanoparticles; phycoerythrin from the seaweed improved catalytic ability. Lavanya et al. [66], who synthesized silver nanoparticles using *Halimeda macroloba* seaweed extract, observed binding energy peaks at 367.5 eV and 373.8 eV with XPS, showing that Ag (0) was dominant and Ag (I) was completely reduced.

Azeem et al. [34] used 1.0 mmol of radical scavengers to study the reaction mechanism of macroalgae-based Ag nanoparticles under visible light. Butanol and ethylene diamine tetra-acetic acid sodium affected the photoactivity significantly, indicating the decisive roles of ·OH and h^+ on MB degradation, respectively, since hydrogen peroxide (H_2O_2) and superoxide dismutase had low effects, $\cdot O_2^-$ had a minor participation in the results [34]. Saikia et al. [11] applied ammonium oxalate, isopropyl alcohol, and 1,4-benzoquinone as scavengers for h^+, ·OH, and $\cdot O_2^-$, respectively, separately mixing them with congo red solution under sunlight; the radicals' role was $h^+ < \cdot OH < \cdot O_2^-$, with quenching of the $\cdot O_2^-$ reducing degradation from 85.4% to 21.7% [11].

Regarding indoor air purification to tackle sick-house pollution [69] and incomplete photocatalytic degradation [70, 71], none of the papers worked with building materials or surface applications. However, concerning the $TiO_2/C/CaCO_3$ heterojunctions produced with an 11.8% mass fraction of mussel shell extract by Qiu et al. [69], formaldehyde was wholly degraded in 80 min under light, while the pure TiO_2 only led to a slight degradation. Wang et al. [70] explained, for the ternary $TiO_2/C/MnO_2$ with abalone shells, that electrons could be transferred from the conduction band of the TiO_2 and MnO_2 to carbon (C) promoting electron–hole separation and, thereby, the lifespan of charge carriers; carbon materials enhanced visible light absorption. In Wang et al. [71], pure TiO_2 had a bandgap energy of 3.3 eV, decreased from 3.1 eV to 2.9 eV by adding 0.2–0.8 g of insoluble matrix proteins from abalone shell waste.

5 Conclusions

This chapter reviewed marine-based photocatalysts inquiring about their presence in construction. Wastewater treatment was the main reason for bio-photocatalyst synthesis, while indoor air pollution was the closest topic concerning buildings. Algae, shells, fish waste, and other sea species have been studied, and titanium, zinc, and silver were the metals most combined with the bio-sources. Photoactivity was usually evaluated through the degradation of contaminants in solution.

Building envelopes coated with photocatalysts benefit from depolluting, antimicrobial, and self-cleaning effects, and green synthesis could further enhance these advantages. The availability of sea waste and underused resources has yet to be explored within construction since no retrieved study has applied marine-based photocatalysts to buildings and their façades. Experimental gaps in bio-photocatalysis should be fulfilled, envisioning buildings' resilience to climate change and their adaptability to requirements, mainly regarding air quality, sustained by toxicity and life cycle assessments.

1 Introduction

Concrete, the most widely manufactured solid material in the world, contributes significantly to global warming due to the high embodied energy of Ordinary Portland Cement (OPC). The production of OPC contributes approximately 5–7% towards global annual CO_2 emissions [1]. Compared to OPC, Supplementary Cementitious Materials (SCMs) such as fly-ash and slag have miniscule levels of embodied energy in terms of carbon dioxide equivalent (CO_2-e) [2]. However, replacement of OPC with fly-ash and slag alone is not sufficient for reduction of global CO_2 emissions stemming from the construction industry. Reinforced Concrete (RC) structures around the world in coastal environments are susceptible to abrupt and unwanted repair and maintenance due to damage induced by corrosion of

the embedded reinforcement. RC structures present in chloride-laden conditions often approach serviceability and durability limit states, that is, cracking and spalling of the concrete cover in a more rapid manner. In countries such as Bangladesh, the absence of performance-based standards for RC structures exposed to harsh marine conditions often lead to premature patchworks for continued functionality [3]. Such patchworks not only escalate the life-cycle costs of the RC structure in consideration but also exacerbate the structures lifetime CO_2 emissions due to additional use of OPC.

The service lives of RC structures exposed to chloride-induced corrosion can be assumed to consist of two separate phases, these are the corrosion initiation (T_i) and the crack propagation (T_{cr}) phases [4]. The initiation phase, T_i, represents the time required for chloride ions to reach the level of the embedded reinforcement, causing depassivation of the protective layer around the reinforcement, thereby initiating corrosion. The second phase, T_{cr}, represents the time taken for the rust products of corrosion to accumulate and cause the concrete cover to crack and spall, thus reaching the serviceability limit state. After this point, routine patchworks are required to replace the deteriorated original concrete in order for the continued functionality of the structure. Hence, the lifetime CO_2 emissions for an RC structure exposed to chloride-induced corrosion shall correspond to the initial CO_2 emission caused by the construction of the structure and the incremental CO_2 emissions caused by continuous patchwork operations [5]. Suitable corrosion management strategies should be employed in order to delay the time to repair in RC structures and lessen the number of patchworks required within the prescribed service life. One of these strategies is to set back the corrosion initiation time by use of Supplementary Cementitious Materials (fly-ash, slag), subsequently reducing the number of repair cycles [6]. Additionally, concrete cover can be utilized as an energy-efficient strategy in reducing lifetime CO_2 emissions. Previous studies [7] have demonstrated that concrete cover is a simple and cost-effective tool for reducing the number of patchworks required in a structures service life, provided the cover thickness is within a feasible limit.

In this study, the effectiveness of OPC replacement by SCMs such as fly-ash and slag combined with different concrete covers in reducing the lifetime CO_2 emissions of a typical coastal structure has been assessed within a prescribed service life of 50 years. A time-dependent probabilistic analysis using the Monte Carlo Simulation approach has been conducted for both the initiation and the propagation phases, considering the relevant limit states and corresponding failure criteria. Patchwork is applied when the failure probability exceeds a certain threshold value for the serviceability limit state and is continued routinely. The CO_2 emissions over the service life of the structure is determined for the different binder and cover alternatives by considering the emission factor (CO_2-e) for OPC only. The outcomes of the limited study performed can be used as a stepping stone in establishing performance-based local guidelines for extending service lives and reducing the carbon footprint of RC structures, advancing towards a NetZero future.

2 Experimental Program

2.1 Materials Used

The materials used for producing the concrete mixes in this study were Ordinary Portland Cement (OPC) or CEM-I and different replacements of fly-ash and slag as SCMs. Class F fly-ash and blast furnace slag obtained from local sources were used. The specific gravity and unit weight of CEM-I used were 3.15 and 1440 kg/m^3, respectively. The aggregates used in this study were locally available 19 mm downgraded crushed stone chips as coarse aggregates and local "Sylhet Sand" as fine aggregates with fineness modulus of 2.82.

2.2 Concrete Mix Design

The proportions for concrete mix designs were determined using the ACI Mix Design Manual [8]. The target slump was chosen to be 75–100 mm and the w/b ratio used was 0.40, corresponding to a specified design strength of 35 MPa. Three different mixes were produced by replacing CEM-I with fly-ash and slag. One mix with 35% fly-ash replacement, one with 40% slag replacement, and one control mix with CEM-I only and no SCM replacement. Cylindrical samples of 100 × 200 mm dimensions were cast for different tests. A summary of the mix design details is provided in Table 1, where FA and S represent fly-ash and slag, respectively.

3 Conducted Tests

3.1 Compressive Strength Test

Since the compressive strengths of the different concrete mixes were used as a target parameter, it was evaluated as per the specifications of ASTM C39 [9]. After curing

Table 1 Mix design details for the mixes cast in this study (per m^3 of concrete)

Mix ID	Proportion of SCMs	CEM-I (kg)	Fly-ash (kg)	Slag (kg)	Course Aggregate (kg)	Fine Aggregate (kg)
W/B ratio: 0.40						
C1	CEM-I (100%)	513	–	–	1001	630
35F	CEM-I (65%) + FA (35%)	333	180	–	1001	615
40S	CEM-I (60%) + S (40%)	308	–	205	1001	622

the standard cylindrical specimens in lime water, the strengths were measured at 28 and 180 days. The C1 and 40S mixes achieved the design strength of 35 MPa in 28 days, while the 35F mixed achieved it in the later ages.

3.2 Non-steady State Rapid Migration Test

The chloride diffusion coefficient (D_{rcm}) indicates the resistance of the different concrete mixes to degradation by ingress of chloride ions. Additionally, the D_{rcm} serves as an input parameter in modelling the corrosion initiation phase, representing unique concrete mixes. The Rapid Migration Test (RMT) was conducted as per the specifications of Nordtest Method NT BUILD 492 [10]. After submergence of the concrete cylinders in the curing pond for 180 days, they were taken out and sawn into disk specimens of dimensions 100 × 50 mm. The disks were sawn from the middle portion of the concrete cylinder. After vacuum saturation in a saturated Ca $(OH)_2$ solution, the cylinders were kept submerged in the solution for 24 hours. An electrical potential was then applied to the disk specimens for a certain duration, forcing chloride ions to migrate into the concrete as described in the standard [10]. After the test duration, the specimens were split into two, and a silver nitrate solution was sprayed on the inside of the specimen, resulting in the formation of a white precipitate representing the depth of chloride ion penetration. The chloride diffusion coefficient (D_{rcm}) was obtained by determining the average depth of chloride ion penetration, applied voltage, temperature of the anolyte and the length of the specimen as per the standard [10].

3.3 Electrical Resistivity Test

The surface resistivity values of the concrete mixes were assessed using the Wenner Four-Probe [11] method as per the specifications of AASHTO T 358-15 [12]. The commercially available Proseq Resipod was used for measuring the surface resistivity. This involves the application of an electrical current through two outer probes, while the resulting voltage difference is measured through the inner electrodes. The cylindrical specimens were kept in submergence up until the testing age at 180 days. Multiple correction factors have been applied to the surface resistivity readings, which are factors for specimen geometry, temperature, and degree of saturation. The application of these factors has been discussed in previous studies [13] and not described in details for this chapter.

4 Service Life Prediction

The service life of an RC structure subjected to chloride-induced corrosion can be divided into two phases; these are the initiation (T_i) and the crack propagation (T_{cr}) phases as described previously. The serviceability limit state is assumed to be reached when the concrete cover cracks, after which continued service of the RC structure requires routine maintenance works.

The initiation phase can be defined as the time required for chloride ions to reach the level of the reinforcement, causing the depassivation of the alkaline protective layer. The diffusion of chloride ions through concrete can be approximated using Fick's Second law of diffusion. Corrosion is assumed to initiate when the chloride concentration at the reinforcement level exceeds a critical concentration, known as the threshold chloride content (C_{th}). According to fib Bulletin 34 [14] model code for service life design, the chloride concentration ($C_{x,t}$) at a certain depth 'x_c' at the corrosion initiation time 'T_i' can be expressed by:

$$C(x,t) = C_o + (C_{s,\Delta x} - C_o) \cdot \left[1 - \operatorname{erf} \frac{x_c - \Delta x}{2 \cdot \sqrt{K_e \cdot K_t \cdot D_{rcm(t_o)} \cdot \left(\frac{t_o}{T_i}\right)^m \cdot T_i}} \right] \tag{1}$$

$$K_e = \exp\left[b_e \left(\frac{1}{T_{ref}} - \frac{1}{T_{real}} \right) \right] \tag{2}$$

The parameters associated with Eqs. (1) and (2) for modelling the corrosion initiation period in tidal, splash and spray zones (exposure class XS3) [14] are presented in Table 2. The probabilistic failure curves for the initiation period are based on the parameters described in Table 2 and the experimental D_{rcm} values presented in Table 4. The variable covers considered for the probabilistic modelling are 37.5, 50, and 62.5 mm, which is denoted by 'x_c' in Table 2.

The model used for predicting the time for first corrosion induced crack to occur is based on the assumption of a perfectly perfect plastic behaviour of concrete. The accumulation of rust products on the porous zone surrounding the reinforcement puts pressure on the concrete cover, eventually causing the cover to crack. Thus, the propagation period (T_{cr}) can be expressed as [18]:

$$T_{cr} = \frac{\rho_s z F \left(\frac{2 x_c f_{ct} k}{D} + \delta_o \right)}{M(\alpha_v - 1) i_{corr}} \tag{3}$$

In Eq. (3), the corrosion rate 'i_{corr}' has been predicted using the model suggested by Pour-Ghaz et al. [19], which establishes independent correlations among the corrosion rate of steel, ambient temperature, kinetic parameters, concrete resistivity and limiting current density. The experimental resistivity measurements were

Table 2 Parameters used for modelling the corrosion initiation period

Description	Notation of Parameter	Distribution (Mean (μ), Standard deviation (σ))
Threshold chloride concentration (wt-%/binder) [15]	C_{th}	Beta (0.60, 0.15); l.b: 0.20, u.b: 2.0
Initial chloride concentration (wt-%/binder) [15]	C_o	0
Surface chloride concentration (wt-%/binder) [15]	$C_{s,\Delta x}$	LN (3, 1.35)

incorporated into this model for prediction of the corrosion rate 'i_{corr}'. In Eq. (3), 'k' is the hole flexibility and can be expressed as [18]:

$$k = \frac{\left(\frac{1+\nu+(D+2\delta_o)^2}{2x_c(x_c+D+2\delta_o)}\right)(D+2\delta_o)(1+\varphi_c)}{2E_c} \tag{4}$$

The descriptions of the different parameters used for the prediction of the propagation period using Eqs. (3) and (4) are provided in Table 3.

Cracks form in the concrete cover at the end of the propagation period. In order to resume functional service of the RC structure, routine patchwork is applied by replacing the cracked concrete cover with new concrete. Thus, the total time to cracking can be expressed as:

$$T_L = T_i + T_{cr} \tag{5}$$

Due to the nature of the models used and the stochastic variables involved, the time to corrosion initiation and cracking for an RC structure is modelled using a probabilistic approach. In this study, the Monte Carlo Simulation was conducted for 100,000 iterations, and the time-dependent failure probability for both the initiation

Table 3 Parameters used for modelling the crack propagation period

Description	Notation of Parameter	Distribution (Mean (μ), Standard deviation (σ))
Elastic modulus of concrete (MPa) [20]	E_c	N(4733$\sqrt{(f_c)}$, 0.12 μ)
Tensile strength of concrete (MPa) [20]	f_{ct}	N (0.6227$\sqrt{(f_c)}$, 0.20 μ)
Poisson's ratio of concrete [18]	ν	0.20
Creep coefficient of concrete [18]	φ_c	2.35
Rebar diameter (mm)	D	10
Mass density of steel (gm/m^3)	ρ_s	7,850,000
Relative volume ratio [21]	α_v	Beta (3.01, 0.8097); l.b: 1.695, u,b: 6.3)
Porous zone thickness (m) [21]	δ_o	U (l.b: 5E-06, u.b: 12E-05, 0.53 μ)

f_c 28-day compressive strength of concrete determined from standard tests, *U* Uniform distribution

and the propagation phases was modelled by evaluating the failure criteria. The T_i and T_{cr} have been determined by adopting a target failure probability or reliability criteria. In this study, the probability of failure is taken to be 10% and 6.7%, corresponding to reliability index of 1.28 and 1.5, as suggested by fib 34 [14] and DuraCrete [22] for the criteria of corrosion initiation and cracking of concrete cover, respectively. After the application of routine patchwork, it is assumed that crack appears once again after the duration of the crack propagation period. Thus, the number of repair cycles required could be assumed by considering a design service life of 50 years and determining the T_i and T_{cr} from the probabilistic analysis.

5 Estimation of Embodied CO_2

For determination of the embodied CO_2 and the impact of the different types of binders considered on emissions, the following equation has been used:

$$E = \sum M \times \mathrm{EF} \tag{6}$$

where 'E' is the total embodied greenhouse gas emissions (in tons CO_2-e) for all the building materials, considering the lifecycle of the concrete from cradle to grave, 'M' is the amount of building materials (in tons) and 'EF' is the CO_2 emission factor for concrete. For this study, the emission factor for CEM-I was considered as 0.913 t CO_2/t [23]. In comparison to CEM-I, fly-ash and slag have comparatively low values of the emission factor at 0.027 t CO_2/t [3] and 0.022 t CO_2/t [23], respectively. Thus, for the blended mixes 35F and 40S, only the emission factors for CEM-I were considered.

For the calculation of the total amount of materials used, a typical bridge section constructed in the coastal region of Bangladesh has been considered (Fig. 1). In the

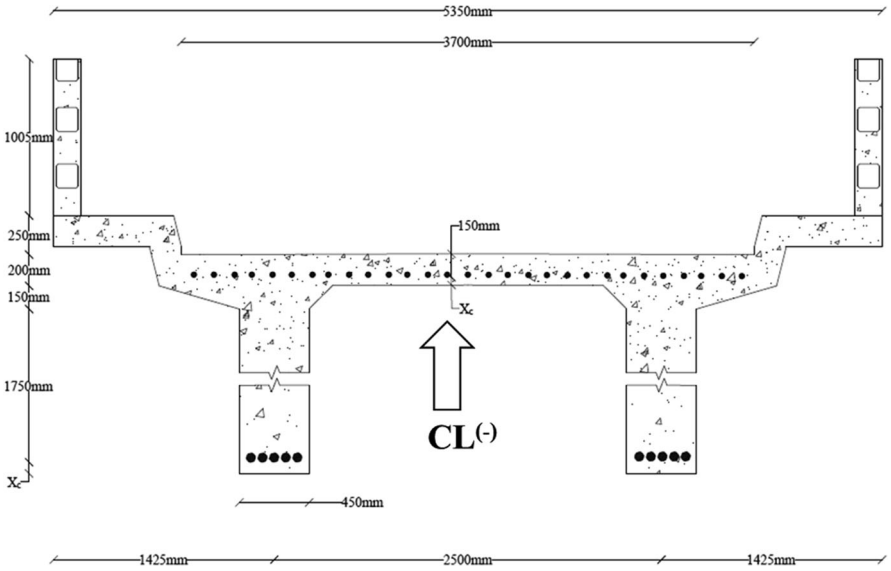

Fig. 1 Typical section of a bridge deck considered as a case study

figure, the parameter 'X_c' represents the variable covers considered in this study for analysis. After calculating the number of patchworks required in the 50-year design service life of the RC structure, the total number of materials used was calculated per metre of the bridge span. The concrete required for construction was determined from the bridge dimensions, and the concrete required for patchworks was calculated by assuming that 10% of the area exposed to chlorides require concrete replacement at each interval. It is assumed that the concrete required for maintenance works is of the same quality as that of the original structure.

6 Results and Discussion

6.1 Probabilistic Service Life Analysis

The principles of the probabilistic analysis conducted have been described previously in this article. The time-dependent failure probabilities have been computed considering the exposure class XS3 (tidal, splash and spray zones) in the coastal region of Cox's Bazar, Bangladesh. The concrete covers considered are 37.5, 50, and 62.5 mm, respectively. The summary of the probabilistic calculus for all the alternatives considered is presented in Table 4, along with the experimental Chloride Diffusion Coefficient (D_{rcm}) and Electrical Resistivity values. Figures 2 and 3 display a sample of the computed probabilistic curves for cover thickness of

Table 4 Summary of the probabilistic analysis for all the alternatives considered

Mix ID	Chloride Diffusion Coefficient ($\times 10^{-12}$ m^2/s)	Electrical Resistivity (kΩ·cm)	37.5 mm cover		50 mm cover		62.5 mm cover	
			T_i (years)	T_L (years)[a]	T_i (years)	T_L (years)[a]	T_i (years)	T_L (years)[a]
C1	4.73	11.12	0.3	1.6	1.5	3.8	2.9	6.2
35F	1.79	29.19	2.4	8.2	16.7	24.1	52	62.5
40S	1.97	22.60	1.1	6.4	5.5	12.3	14.3	23.4

[a] $T_L = T_i + T_{cr}$

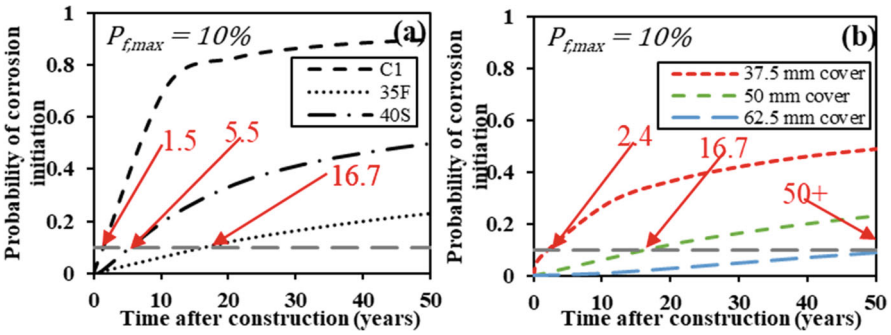

Fig. 2 Probabilities of corrosion initiation with time for (**a**) Different binder types considering 50 mm cover and (**b**) 35F mix considering different cover thicknesses

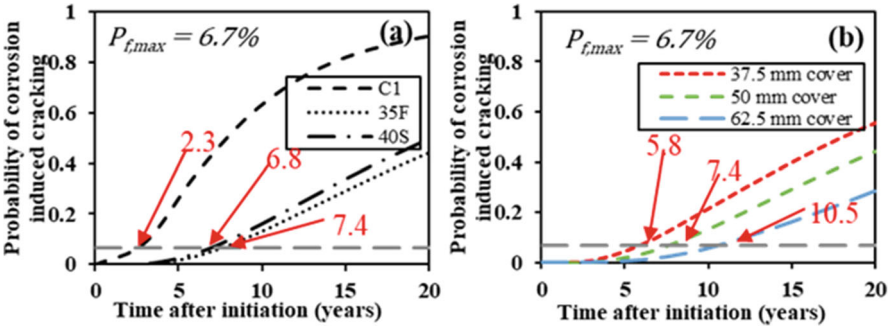

Fig. 3 Probabilities of crack initiation with time for (**a**) Different binder types considering 50 mm cover and (**b**) 35F mix considering different cover thicknesses

50 mm (Figs. 2a and 3a) and the 35F (Figs. 2b and 3b) mix for the initiation and the propagation phases, respectively.

From Figs. 2, 3, and Table 4, it is clear that blended mixes perform substantially better than the C1 mix in terms of both T_i and T_{cr}. As it can be seen from Figs. 2a and 3a, for a cover of 50 mm in case of C1 mix, corrosion initiates only 1.5 years after construction and the first crack appears only 2.3 years after initiation. Whereas, for the 35F mix, the initiation time is greatly extended to 16.7 years (Fig. 2b) and the

time to first-cracking is also increased to 7.4 years (Fig. 3b). It is also evident that the slag mix 40S perform substantially better than the C1 mix as well, in terms of both T_i and T_{cr}. The pozzolanic activity of fly-ash causes long-term pore refinement due to the formation of secondary Calcium Silicate Hydrate (C-S-H) gel, resulting in a denser microstructure and thus delaying the onset of corrosion [24]. For the 40S mix, the C-S-H formation occurs earlier, resulting in an inferior late-age pore refinement compared to fly-ash [25]. The differences in the microstructure tortuosity impact the corrosion rate in steel as well since the electrical resistivity is affected. Thus, the crack propagation period is longer for 35F and 40S mixes than that for C1 mix.

Along with the incorporation of SCMs, increasing cover thickness can significantly enhance the T_i and T_{cr} for the mixes considered. From Fig. 2b, it is evident that increasing the cover thickness from 37.5 to 62.5 mm extends T_i from only 2.4 years to 52 years for the 35F mix. This can be observed for all other mixes as well (Table 4). However, for C1 mix, even 62.5 mm cover results in corrosion initiating within 3 years only. The crack propagation time is considerably extended by increasing cover as well. Larger cover will require more force to initiate cracking and hence, requiring accumulation of more corrosion products, thus lengthening the time to first cracking. From Fig. 3b, the crack propagation time increases from almost 6 years to 10.5 years for 35F mix by increasing the cover thickness from 37.5 to 62.5 mm.

6.2 Repair Cycles and Embodied CO_2

The number of patchworks required in the 50-year design service life of the structure is calculated. It is assumed that after the appearance of the first crack in the concrete cover, patchwork will be applied where the cracked cover will be replaced by concrete of original quality. The next patchwork will be required after the duration of the crack propagation period of that particular binder type. The total embodied CO_2 in the 50-year service life of the structure is calculated using Eq. (6) for all the different alternatives considered.

Figure 4 presents the results of this analysis. From the figure, it can be seen that the total CO_2-e emissions for each particular binder type directly corresponds to the number of repair-work required in the structure's service life. The number of patchworks required decreases with increasing cover for all binder types. However, for the C1 mix, even at 62.5 mm cover, the required number of repair intervals is 11, whereas at 62.5 mm cover, the 35F mix requires no patchworks at all in the 50-year period. The 35F mix performs most satisfactorily, requiring the least number of repairs for each cover considered.

The embodied CO_2-e emissions vary mostly with respect to cement replacement. Since, C1 has a high embodied energy, the binder with no replacement results in the highest CO_2 emission of about 2800 kg CO_2-e, whereas the mixes with 35% and 40% binder replacement result in almost 1400 kg CO_2-e emissions for 37.5 mm cover. Additionally, increasing concrete cover results in fewer patchworks and

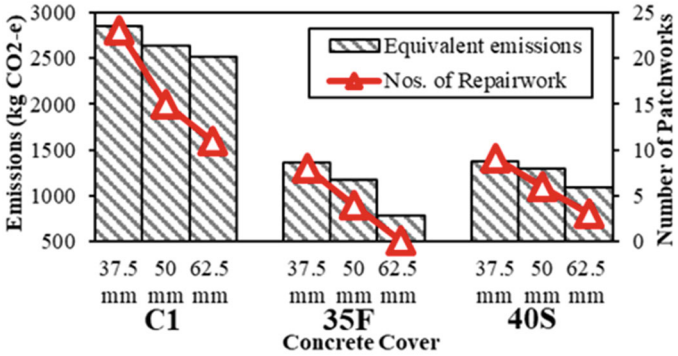

Fig. 4 Total CO_2 emissions per metre length of the bridge and number of repair-works required considering 50-year design service life

consequentially, lower CO_2-e emissions. This is evident from Fig. 4 as well. For all the mixes, increasing concrete cover results in considerable decrease in CO_2-e emissions. The reduction is more prominent for the blended mixes. For C1, increasing concrete cover from 37.5 to 62.5 mm results in a nearly 14% decrease in CO_2-e emissions. The same decrease is around 43% for the 35F mix. Considering a combination of binder replacement and increased cover, the embodied CO_2-e emissions are seen to decrease from 2800 kg CO_2-e (C1, 37.5 mm) to only 790 kg CO_2-e (35F, 62.5 mm). This clearly signifies the importance of optimally combining SCMs as cement replacement with cover design for RC structures under chloride exposure in achieving the NetZero target.

7 Conclusions

In this limited study performed, a probabilistic performance-based approach is utilized for assessing the service life of ordinary and blended concrete mixes and their CO_2-e emission potential in harsh, marine exposures. Based on the time-variant failure probabilities, the total time to cracking for combinations of different binder and cover alternatives could be estimated. The analysis showed that the SCM blended mixes significantly lengthened the time to first-cracking for RC structures, and increment in cover thickness reduced the number of repair intervals within a 50-year design service life. The embodied CO_2-e emissions determined from this analysis highlight the significance of incorporating SCMs into blended mixes, combined with sufficient cover thickness for reducing the carbon footprint of the rapidly growing construction industry, particularly in extreme exposures. The framework hereby presented could be used to evaluate the carbon footprint and environmental impact of new, emerging binder types as well.

1 Introduction

The economic and social development of many countries hinges significantly on a well-established transportation network. Within this network, bridges emerge as pivotal and complex structures, fostering fast and effective transportation and enhancing connectivity between different regions and nations [1–3]. Nevertheless, a noteworthy percentage of these bridges face diverse forms of deterioration, encompassing fatigue, erosion, acid assaults on concrete components, carbonation, and the corrosive impact of chloride on steel elements [4–6].

The corrosion process affecting structural steel is an electrochemical phenomenon that requires the concurrent presence of both moisture and oxygen [7]. In the context of steel reinforcement, the alkalinity inherent in concrete prompts the embedded reinforcing bar to display characteristics similar to stainless steel. This

corrosion-resistant state endures until chloride ions, sourced from substances like seawater or roadway deicers, accumulate on the surface of the reinforcing bar in significant concentration. Upon reaching this critical level, the steel initiates the corrosion process, giving rise to the expansion of rust that has the potential to compromise the surrounding concrete [8, 9]. Corrosion of steel elements can reduce structural integrity, decrease load-bearing capacity, increase maintenance costs, and reduce the service life of bridges [10]. Evaluating the condition of bridges is crucial because it allows for the timely detection of corrosion-related issues, ensuring proactive measures to address the detrimental effects and safeguard the structural integrity and safety of the infrastructure [11, 12].

The most common way to check a bridge's condition is through visual inspection, where qualified inspectors assess the structure based on what they see [13]. This approach is generally cost-effective, as it typically does not require tests or cause disruptions to traffic. However, its reliance on expert opinions introduces potential limitations due to subjectivity [14]. In contemporary practices, integrating various technologies like structural health monitoring or unmanned aerial vehicles into the inspection process proves beneficial in identifying hidden critical elements and defects [15–17]. Despite their effectiveness, these technologies are not universally available and cannot entirely replace expert assessments. Visual inspection findings remain valuable in supporting the planning of maintenance and rehabilitation efforts [18].

Various computer-aided bridge management systems have been developed to support timely decision-making for scheduling maintenance, repair, and rehabilitation activities [19, 20]. Brutus is an online bridge management system developed by the Norwegian Public Roads Administration (NPRA) for the maintenance of bridges in Norway [21]. Simple inspections and main inspections are planned within the system, and all data from visual inspections are recorded in individual panels provided for each bridge, including information such as construction year, structural system, and material type.

This study aims to assess the corrosion risk of bridges in Oslo, Norway, based on visual inspection data provided in the Brutus system during 2023. An overview of the case studies, including their material type, construction year, length, and structural system type, is provided. The inspection methodology and risk assessment approach provided by the NPRA are presented. Finally, the corrosion risk of the bridges is assessed, and the bridges are categorized into three different damage states.

2 Overview of the Case Studies

This study focuses on the condition assessment of 337 bridges for which the Oslo municipality is responsible for preservation and maintenance. The investigation results reveal that over half of these bridges were constructed during the period from 1950 to 1999, primarily driven by population growth, economic expansion, and

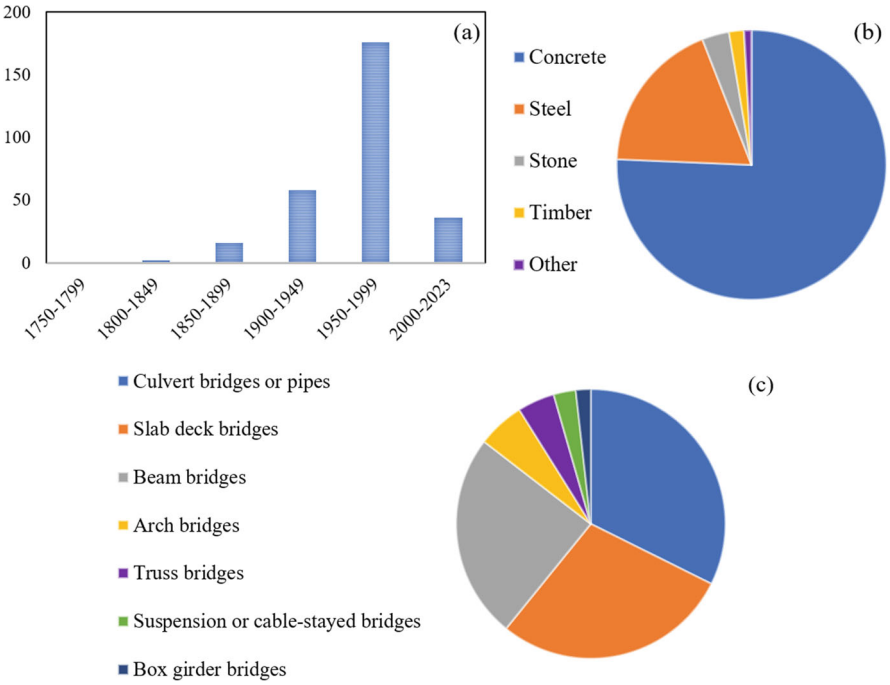

Fig. 1 Categorization of the bridges by (**a**) year of construction, (**b**) construction material, and (**c**) type of structural system

advancements in transportation infrastructure as illustrated in Fig. 1a. Analysis of bridge materials indicates that concrete is the predominant construction material, accounting for more than 75% of the bridges, followed by steel as the second most common material as shown in Fig. 1b. The bridge bearing systems are categorized into seven types: culvert bridges or pipes, slab deck bridges, beam bridges, box girder bridges, arch bridges, truss bridges, and suspension or cable-stayed bridges [21]. The evaluations indicate that culvert bridges or pipes, plate bridges, and beam bridges are the most frequently used structural systems among the bridges under investigation as shown in Fig. 1c.

3 Risk Assessment Methodology

The condition assessment was done based on the Norwegian standard for inspection of bridges [22]. Simple and main visual inspections should be conducted annually and every 5 years, respectively based on [22]. Simple inspection involves visually examining elements above water without using access equipment, often requiring observation from a distance on larger bridges. During the main inspection, the entire bridge is visually inspected to ensure all elements are functioning correctly

Table 1 Degree of R- and NR-corrosion damages and qualitative description. (Adapted from [22])

	Qualitative description of the damage level	
DoD	R-corrosion	NR-corrosion
1	Steel surface is generally without rust	Steel surface is generally without rust
2	Steel surface has started to rust and loosen	Steel surface has started to rust and loosen.
3	Steel surface where the scale layer has rusted away or can be scraped off. Some visible rust pits	Steel surface is rusted away or can be scraped off. Visible rust pits are not formed
4	Steel surface where the scale layer has rusted away. Visible rust pits have largely formed	Steel surface is rusted away. Visible rust pits have largely formed

Table 2 FDIs, the corresponding risk levels, and qualitative descriptions. (Adapted from [22])

FDI	Risk level	Qualitative description
1 or 2 or 4	Low	The corrosion risk is negligible however for a longer than expected service life, and serious consideration should be given
6 or 9	Moderate	The corrosion risk is not negligible. Special inspections or tests should be planned and done to avoid propagation of the corrosion and avoid increasing the maintenance costs. Maintenance usually occurs in this phase.
12 or 16	High	The bridge condition has degraded to poor, and the restoration costs may become prohibitive. In some special situation, the structural components should be replaced, if possible, after specialists' evaluation.

[22]. Representative areas of large, uniform surfaces such as steel and concrete are chosen for closer examination to detect expected damage. Four degrees of damage (DoD) were assumed and the corresponding qualitative description for each of them are presented in Table 1. Negligible differences can be found between the description of the R- and NR-corrosion types for all damage degrees. Nevertheless, a more specific description of R-corrosion damage should be presented to distinguish these two damage types. For instance, the loss of bond between reinforcement and concrete is a potential indicator that can be added to the description.

The consequences of the damages were categorized into four main groups which are damages that can affect the load-bearing system, traffic safety, maintenance cost, and environment or aesthetics [22]. Furthermore, the grade of the consequences is rated from 1, when no analysis or measurement is required to 4, when the engineers or the owners should be contacted. In this chapter, the final damage index (FDI) was calculated as the DoD multiplied by the degree of damage consequence. Note that the difference between the DoD and the degree of damage consequence would be less than 2. The possible FDI and the corresponding qualitative description for each risk level are shown in Table 2.

4 Results and Discussion

The findings of the visual inspection of bridges in 2023 were graded and FDI was calculated for different components of each bridge which is subjected to corrosion damage. In total, 193 bridges suffer corrosion damages in such a way that 154 and 87 bridges are subjected to the R-corrosion and NR-corrosion damages. Most corrosion damages lead to increased maintenance costs and the second most repeated consequences would be the environment or aesthetics. Figure 2 shows the risk level of bridge elements that were categorized as low, moderate, and high levels, subjected to corrosion damages.

The majority of bridge elements exhibit low R-corrosion based on Fig. 2a, with only three elements identified as having a high level of corrosion risk, necessitating imminent rehabilitation or replacement. Among these, concrete slabs, which serve as the primary load-bearing system in slab deck bridges, are particularly susceptible to R-corrosion risk. The findings highlight that 39 bridge elements pose a moderate corrosion risk, indicating the need for maintenance to prevent corrosion propagation to larger areas or other elements. Figure 3a and b illustrate a bridge slab with high R-corrosion risk level and Fig. 3c shows a column with moderate R-corrosion risk level. To prevent R-corrosion, it's important to use high-quality concrete mixes with corrosion-inhibiting admixtures, ensure proper concrete placement techniques and effective curing, apply surface coatings or membranes for additional protection, consider implementing cathodic protection systems for existing structures, and conduct regular inspections and proactive maintenance to address corrosion issues promptly [23–26].

Most bridge elements exhibit a low NR-corrosion risk based on Fig. 2b, while five elements have been identified as being at a high level of corrosion risk, necessitating rehabilitation or replacement of components soon. Notably, the railing stands out as the bridge element with the highest NR-corrosion rate among other bridge components. Consequently, stricter regulations regarding the material

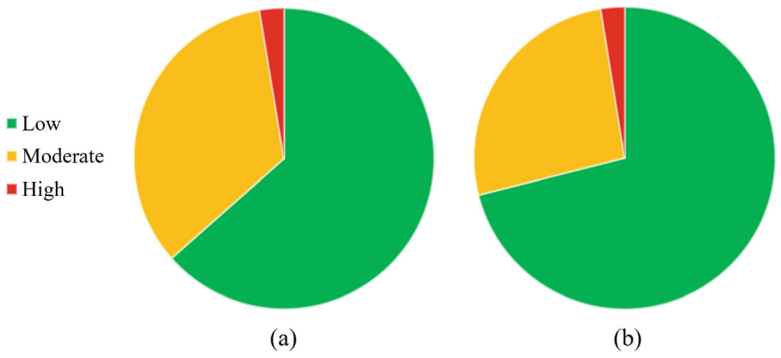

Fig. 2 Risk level of investigated bridge elements subjected to the (**a**) R-corrosion and (**b**) NR-corrosion damages

Fig. 3 (**a**) A bridge plate with a high risk of R-corrosion damage, (**b**) a close-up view of corroded reinforcement in the element, highlighting the extent of corrosion, and (**c**) a bridge column with medium risk of R-corrosion damage

selection for this component should be considered to reduce maintenance costs and mitigate the risk of collapses. Additionally, the results indicate that 52 bridge elements are at a moderate corrosion risk and require maintenance. Figure 4a illustrates a beam with a high NR-corrosion risk level and Fig. 4b shows a bridge railing with moderate NR-corrosion risk level. To combat the NR-corrosion in bridges, engineers can employ corrosion-resistant materials, routine maintenance, protective coatings, proper drainage, and moisture-minimizing design features [27–29]. Innovative solutions like electrochemical protection systems and environmental controls further bolster preventive efforts [30, 31].

5 Conclusion

Bridges suffer from various forms of deterioration, including corrosion of steel elements. The assessment of corrosion risk in bridges based on visual inspection data offers valuable insights into maintenance needs and underscores the importance

Fig. 4 (**a**) A steel beam with a high level of NR-corrosion damage and (**b**) railing of a bridge with a medium level of NR-corrosion damage

of proactive measures to preserve infrastructure integrity. The risk of reinforcement corrosion (R-corrosion) and non-reinforcement corrosion (NR-corrosion) in various elements of 337 bridges, for which the Oslo municipality is responsible for maintenance, has been assessed through visual inspection. Visual inspections of bridges led to the grading and calculation of the final damage index (FDI) for various components affected by corrosion. The main findings of this study are as follows:

- The investigation highlights that a significant portion of the bridges were constructed between 1950 and 1999 due to factors such as population growth, economic expansion, and advancements in transportation infrastructure.
- Concrete emerges as the predominant construction material, with over 75% of the bridges, followed by steel.
- Culvert bridges, slab deck bridges, and beam bridges are among the most commonly used structural systems.

- The visual inspection unveiled corrosion damage in 193 of the surveyed bridges, with 154 bridge elements showing signs of R-corrosion and 87 bridge elements affected by NR-corrosion. Moreover, most corrosion damages of the studied bridges lead to increased maintenance costs.
- Most bridge elements show low R-corrosion risk, with only three elements requiring urgent rehabilitation or replacement due to high corrosion levels. Concrete slabs, integral to slab deck bridges, are notably prone to R-corrosion risk.
- Similarly, most bridge elements exhibit low NR-corrosion risk, although five elements require prompt attention for rehabilitation or replacement. Remarkably, among bridge components, railings display the highest NR-corrosion rate.

1 Introduction

To reach the reduction goals of CO_2 in new reinforced concrete (RC) structures, their carbon emissions must be considered throughout their entire life cycle. Since RC structures are designed to last for decades, the carbon emissions produced during their operation phase are relevant [1]. This is critical for structures exposed to aggressive environments, such as chloride contamination, given the elevated risk of reinforcement corrosion. Corrosion-induced degradation leads to considerable repairs, increasing the total CO_2 footprint of the structure [2].

The new generation of the Eurocode for reinforced concrete structures introduces the lab-performance concept in the design rules for durability [3]. In the new approach, the dimensioning of the concrete elements is based on the actual resistance of the concrete mix design against aggressive environments. This is achieved through the introduction of the Exposure Resistance Classes (ERC). The ERC

M. Kioumarsi, B. Shafei (eds.), *The 1st International Conference on Net-Zero Built Environment*, Lecture Notes in Civil Engineering 237,
https://doi.org/10.1007/978-3-031-69626-8_58

classifies the concrete into predefined categories concerning its resistance against corrosion induced by carbonation, chlorides, and damage caused by freeze/thaw attacks. The new durability rules offer advantages by simplifying the evaluation of current (and future) eco-efficient binder systems. Therefore, the lab-performance approach paves the way for durable and more sustainable reinforced concrete structures.

This work proposes a dimensioning concept that integrates lab-performance concept and sustainability assessment. The framework enables the design optimization of reinforced concrete elements in view of durability, environmental footprint, and budget. The framework applicability is demonstrated through a case study.

2 Methods

2.1 Dimensioning Concept for Sustainable and Durable Structures

The framework extends the lab-performance design concept described by the new Eurocode 2 [3]. The design process is divided into five steps.

1. *Definition of the Exposure Classes and Design Service Life*
   The exposure class (EC) is assigned according to the environmental exposure conditions that leads to the element degradation as per [4]. The design service life is 50 years for current buildings and 100 years for civil engineering structures such as bridges or tunnels [3].
2. *Determination of the Exposure Resistance Class (ERC) and Minimum Concrete Cover*
   Concrete is classified in exposure resistance classes (ERC) against deterioration in the form of corrosion induced by carbonation (XRC) and corrosion induced by chlorides (XRDS). The classification into the resistance class is based on the performance test results under predefined conditions described in [3]. The lab-performance defines the ERC and the minimum concrete cover based on the EC and the design service life. Since the ERC and the minimum concrete cover are dependent on each other, two approaches shall be considered to define both parameters. The first approach defines a minimum concrete cover on basis of structural performance that is the preference for the lowest cover possible. The second approach determines a desired ERC considering the materials availability, costs, or other relevant considerations.
3. *Structural Design*
   The Eurocode presents the procedures for designing reinforced concrete elements. The design must consider the concrete mix design's minimum concrete cover and mechanical properties, as defined in the previous step. The design provides the amount of steel reinforcement required for the environmental assessment and cost analysis.

4. *Environmental Assessment and Costs*

   The next step is to determine the total costs and environmental impacts associated with the design alternative of the reinforced concrete element over the design life. The environmental impacts are estimated using the life cycle assessment (LCA) as per [5]. The analysis must define the life phases to be considered in the LCA and LCC. The assessment should cover at least the raw material production, installation, and operational phase. The evaluation of costs and environmental impacts are linked to a functional unit covering a specified temporal frame. Some examples of functional units are fractions of elements (m^2), individual elements, or the whole structure with a specific service life.

5. *Selection of the Most Sustainable Alternative*

   To select the design with the most balanced performance in relation to the environmental footprint and costs, a multi-criteria decision-making technique is employed. The goal of the multi-criteria technique is to assess the several alternatives through a composite indicator that represents the results of the environmental impacts and costs. A comprehensive selection of state-of-the-art techniques can be found in [6].

   The construction of the individual indicators consists of two main steps: Normalisation and weighting. Normalisation is the conversion of the unit of the impact indicator (e.g. kg-CO_2) into a standardised, dimensionless unit that enables a direct comparison between the various impact indicators. Methods for standardising indicators can be found in [7]. Weighting is the process that quantifies the preferences of stakeholders in relation to the various indicators and thus enables aggregation between them.

The final part of the evaluation process comprises the evaluation of uncertainty. The sources of uncertainty are divided into parameter uncertainty, model uncertainty and scenario uncertainty [8].

3 Case Study

The application of the dimensioning concept presented in Sect. 2.1 is demonstrated for a structure exposed to chloride-induced corrosion. The case study compromises a column in an underground parking garage exposed to chloride contamination. Figure 1 shows the column's cross-section.

The case study is inspired by an existing structure. After 14 years of service, the columns were repaired due to chloride contamination. Therefore, the elements did not achieve the designed service life of 50 years as recommended by the current standards for similar structures.

Step one: Definition of the Exposure Classes and Design Service Life.

Mud and snow contaminated with salt are carried by the cars to the underground parking lot, thus contaminating the structure with chlorides. Besides, the concrete

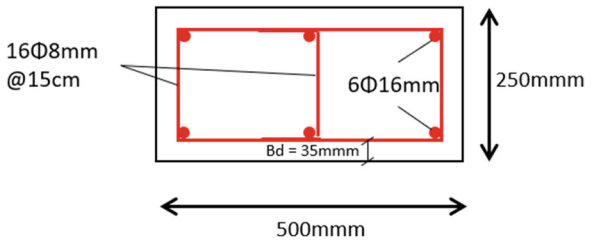

Fig. 1 Column cross-section taken from the original design

Table 1 Considered concrete mix design along with their Exposure Resistance Classes and corresponding minimum concrete cover after [3]

Mix design	Binder	w/b [−]	XRDS	XRC	C_{min} [a] [mm]	C_{min} [a] [mm]	C_{min} [mm]
Concrete A	CEM II/B-S 42,5 R	0.40	XRDS 3	XRC 1	55	10	55
Concrete B	CEM III/A 32,5 N	0.50	XRDS 4	XRC 5	60	30	60
Concrete C	CEM III/A 42,5 N	0.42	XRDS 1.5	XRC 2	40	15	40
Concrete D	CEM III/A 42,5 N	0.50	XRDS 4	XRC 4	60	25	60
Concrete E	CEM III/B 42,5 L-LH/HS/NA	0.40	XRDS 0.5	XRC 3	30	20	30

[a] C_{min} based on the RC for chlorides and carbonation, respectively

bears a risk of carbonation due to the carbon dioxide in the atmosphere and coming from the vehicles. Due to the intermittent moisture brought by the cars, it can be assumed that the element faces cyclic contact with water. Given the environmental conditions, the element risks reinforcement corrosion due to chloride contamination and concrete carbonation. Thus, the exposure classes XD3 and XC4 are assigned. For current buildings, the design service life is 50 years.

Step two: Determination of the Exposure Resistance Class (ERC) and minimum concrete cover

The Exposure Resistance Class (ERC) and minimum concrete cover are defined following the approach's structural performance and material availability. The first approach aims to achieve the best structural performance by choosing the smallest possible concrete cover. Considering a service life of 50 years, the minimum concrete cover for exposure classes XD3 and XC4 are 30 and 10 mm, respectively. Thus, the smallest possible concrete cover is 30 mm. Consequently, the required ERCs are XRDS 0.5 and XRC 5. The concrete mix 'E' in Table 1 meets both criteria.

The second approach defines the Exposure Resistance Classes based on the materials availability. This study considers study 5 concrete mix designs, which were characterized within the framework of the DAUPERF Project. Table 1 contains the considered concrete mixes, along with their Exposure Class Resistance and their corresponding minimum concrete cover. Table 1 shows that the ERC for chlorides (XRDS) dominates the assignment of the minimum concrete covers. In the next steps, the concrete mixes are exclusively referenced based on their XRDS classification.

Table 2 Considered concrete mix design along with their Exposure Resistance Classes and corresponding nominal concrete cover

Mix design	ERC	C_{min} [mm]	C_{nom} [mm]
Beton A	XRDS 3	55	65
Beton B	XRDS 4	70	80
Beton C	XRDS 1.5	45	55
Beton D	XRDS 4	70	80
Beton E	XRDS 0.5	30	40

Step Three: Structural design

The reinforced concrete column is designed following the European Normative for reinforced concrete elements (EN 1992-1). First, the nominal concrete cover C_{nom} must be determined. The nominal concrete cover is defined as the minimum concrete cover C_{min} plus allowance in design to account for deviation ΔC_{dev}. Assuming a tolerance class 1, the allowable deviation ΔC_{dev} is 10 mm [3]. Table 2 presents the C_{nom} in connection with the considered concrete mix designs in step 2 (see Table 1).

The design goal is to conserve the original cross-section while meeting the specified nominal concrete cover. For this purpose, the longitudinal steel is moved towards the element centre, and the reinforcement ratios are adjusted accordingly. However, this is constrained by the minimum clearance between the steel bars stated in the standards [9]. For this reason, the nominal concrete 80 mm is not plausible; thus, alternatives with concretes B and D (XRDS 4) are suppressed in the analysis. Therefore, only the Exposure Resistance Classes with XRDS 3 and below are feasible for the case study. This indicates that the element geometry also limits the selection of the ERC.

Figure 2 plots the resulting cross-sections of the feasible alternatives, along with their corresponding column interaction diagram. The interaction diagram also contains the results of the original design.

Step four: Environmental Assessment and Costs

The system boundaries of the environmental and cost assessment are the raw material production, transport, and installation. The operation phase is not considered since all designs are expected to meet the service life without repair. Additionally, it is assumed that the decommissioning and disposal of the element have the same environmental impacts and costs since the designs have the same volume of reinforced concrete. Thus, the end-of-life phase is not considered in this example.

The economic assessment takes into account the direct and indirect costs. The directs include the materials required for the concrete mixes (binder, aggregates, and admixtures), steel reinforcement, and workforce. The workforce includes the staff for setting the formwork, reinforcing steel placement, concreting, and curing, whose costs are computed after [10]. The indirect costs include external service costs, risk costs, administration, and profit, which are assumed to be the same as the direct costs. Since the alternatives will meet the design service life, no repair actions are considered within the life cycle.

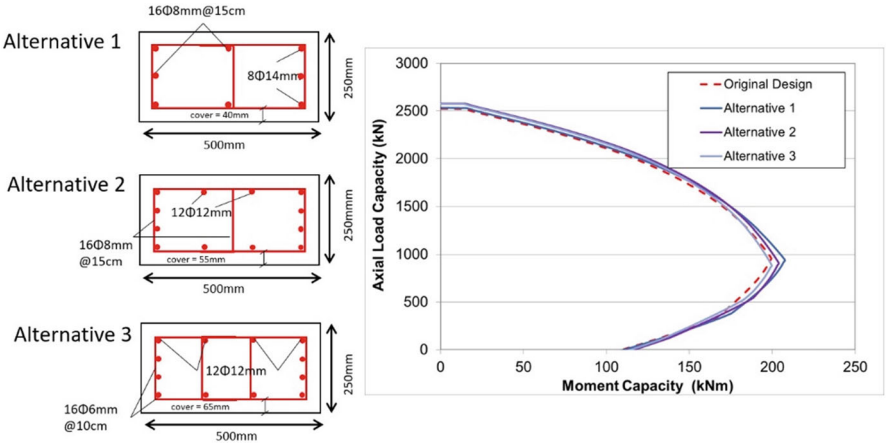

Fig. 2 Reinforcement detailing for the three alternatives (left). Iteration diagram of the columns (right)

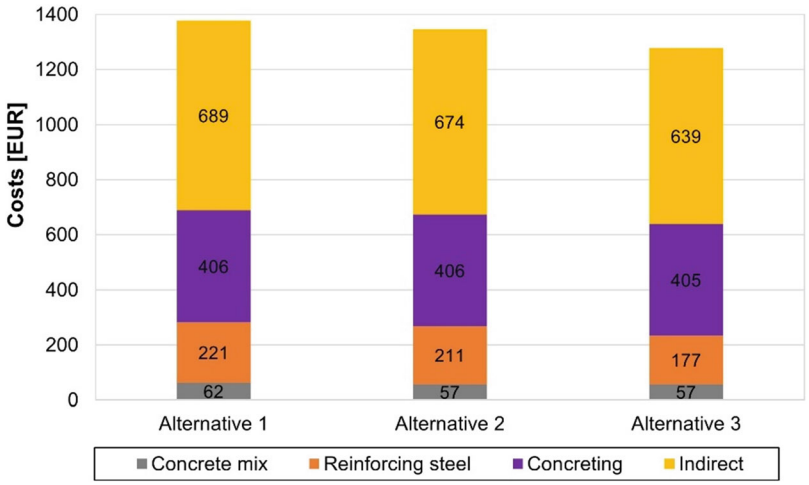

Fig. 3 Distribution of the construction cost for one column

Figure 3 provides the total costs of the column across the considered design alternatives. The results show that the ERC selection influences the elements total cost. The changes in the reinforcement ratios drive the cost differences. The best ERC (i.e. XRDS 0.5) allows the minimal nominal cover, leading to a more efficient reinforcement ratio and thus leading to the lowest total costs. It is worth mentioning that the concrete mix has the lowest contribution to the total costs of the element. The indirect and labour costs bear most of the total costs in the element.

The LCA includes the construction of the new column with dimensions of 250 × 500 × 2500 mm^3. Figure 4 shows the system boundaries. The construction of the elements includes the production of concrete and reinforcing steel. The concrete production includes the transport of cement, aggregates, and admixtures from the production site to the mixing plant. The transport of reinforcing steel to the construction site is also included. All transport distances are assumed to be 50 km. The concrete pumping and compaction processes are also modelled. The environmental data of the materials were taken from the Environmental Product Declarations (EPD) of the IBU [11]. The installation and transport processes and their impacts were taken from the Ecoinvent database [10]. The global warming potential (GWP) in kg-CO_2 eq is used in the project as the impact category for the LCA.

Figure 5 shows the GWP results across the considered design alternatives. Analog to the trend found in the total costs, the selection of the best ERC impacts the Global Warming Potential of the element. The higher ERC (i.e. XRDS 0.5) significantly reduces the CO_2 emissions to −38% compared with the lowest ERC (i.e. XRDS 3). The reduction in CO_2 emissions is attributed to the binder employed in the concrete mix since the binder is the main contributor to the element GWP. The

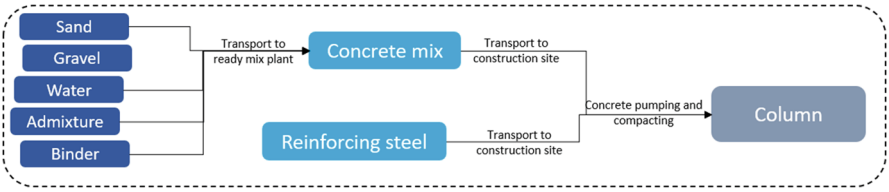

Fig. 4 System boundary of the column construction

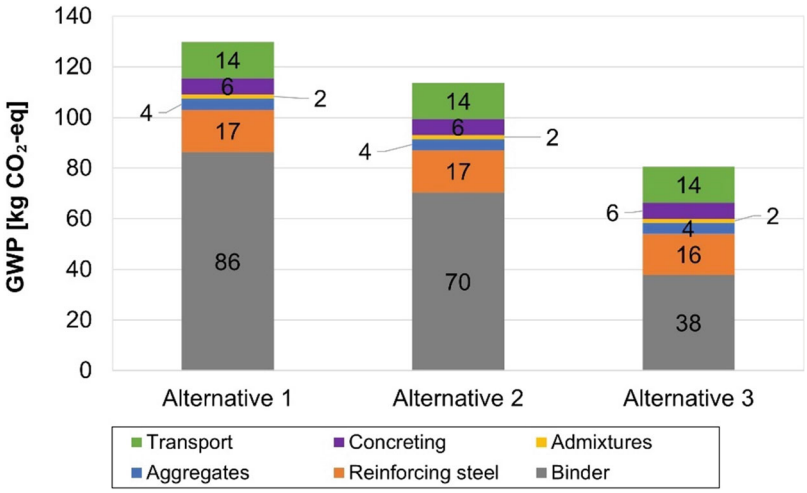

Fig. 5 Global Warming Potential of the column construction

binders account for up to 67% of total CO_2 emissions. The concrete mix design in alternative 3 (XRDS 0.5) contains a low-clinker binder (CEM III/B), whose emissions are −60% less than the binder in alternative 1 (XRDS 3), i.e. CEM II/B-S. Besides the binder, the production of steel reinforcement and transportation of materials significantly affect the GWP emissions.

Step five: Selection of the Most Sustainable Alternative

A multi-criteria assessment is necessary to select the alternative with the most balanced performance regarding total costs and GWP. In the case example, the decision is trivial since alternative 3 has the lowest costs and emissions; it is thus the most sustainable alternative. However, the multi-dimensional assessment is performed to compare the obtained results with reduction goals and planed budget.

The normalization technique is now modified to the "Distance to a reference," as per [7]. The approaches compare the indicator results to a reference value or objective (see Eqs. 1 and 2). This could be a target to be reached in each time frame; for example, the reduction goal of emissions is 65% by 2030 as per [VDZ]. The resulting indicators behave as key performance indicators, thus indicating the relative achievement of the reduction goals. The multi-criteria method for evaluating the results is simple weight aggregation (SAW). The scheme assumes equal weights for the costs and environmental ($W_{costs} = W_{CO2} = 0.5$), see Eq. 3.

$$I_{\text{Costs}-i} = \frac{\text{Cost}_{\text{ref}} - \text{Cost}_i}{\text{Cost}_{\text{budget}}} \tag{1}$$

$$I_{\text{CO2}-i} = \frac{\text{GWP}_{\text{ref}} - \text{GWP}_i}{\text{GWP}_{\text{reduction}}} \tag{2}$$

$$I_{\text{Sustainability}-i} = W_{\text{costs}} * I_{\text{Costs}-i} + W_{\text{CO2}} * I_{\text{CO2}-i} \tag{3}$$

Based on the actual structure, the reference GWP emissions per column is 152 kg-eq. According to [12], the aimed GWP reduces this value by 65%, thus leading to a GWP reduction of 53 kg-eq per column. Based on the case study information, the reference total cost per column is 2207 EUR, which includes construction and repair. The goal is to suppress the repair costs (830 EUR).

Table 3 presents the results of the sustainability score considering the reduction goals and budget. The sustainability indicator designates alternative 3 as the most sustainable design. The alternative 3 yields 98% of the cost reductions, thus being almost in line with the planned budget. Although this alternative delivers significant reduction, these are still below from the reduction goal. Alternative 3 reaches 72% of the reduction targets for the CO_2 emissions.

Table 3 Sustainability scores of the design variants

Alternative	ERC	I_{Costs}	I_{CO2}	$I_{\text{Sustainability}}$
Alternative 1	XRDS 3	0.89	0.22	0.55
Alternative 2	XRDS 1.5	0.92	0.38	0.65
Alternative 3	XRDS 0.5	0.98	0.72	0.85

4 Conclusions and Outlook

This research extended the lab-performance design concept for reinforced concrete structures, consigned in the new generation of EUROCODE, to include the essential aspect of sustainability. The applicability of the proposed dimensioning concept is demonstrated through an application example, a reinforced concrete column exposed to chlorides. The case study is inspired by an actual structure. The following conclusions are drawn from the results of this study.

The dimensioning concept successfully integrates the lab-performance concept, economic costs, and environmental impacts in the design of durable and sustainable reinforced concrete elements. The proposed framework simultaneously considers the environmental footprint and costs by employing and applying multi-criteria decision methods, thus facilitating the selection of the most balanced alternative given the environmental burdens and costs.

The Exposure Resistance Class (ERC) selection leads to more cost-efficient and environmentally friendly results. The optimal ERC (i.e. XRDS 0.5) permits the reduction of the minimal concrete cover, hence achieving a more efficient reinforcement ratio. Given the reduced reinforcing steel amount, the total costs are reduced. Furthermore, the ERC significantly influences the emissions of the element. However, the reduction in emissions is mainly attributed to the binder used in the concrete mix design. Therefore, the selection of the binder system needs to be carefully assessed to obtain the aimed reduction in emissions.

In this study, only two dimensions were considered to assess sustainability: the environment and the economy. Future studies must consider the social aspects by using relevant indicators for the impact on civil infrastructure. Furthermore, the assessment of the environmental dimension only contemplates emissions. Other relevant impacts need to be included for a more comprehensive study, such as energy demand, water consumption, and waste generation. Additionally, the dimensioning concept can extend the system boundaries up to the end of life. Accounting possible impacts and costs linked to refurbishing, recycling, and disposal. In this way, the concept of circular economy can be integrated into the design of reinforced concrete elements. Finally, the multi-criteria decision process must be constructed with a panel of technical experts, academics, and stakeholders. The weighting scheme and aggregation techniques must be selected according to the project objectives and shareholders' preferences.

Funding Note and Acknowledgment This work was supported by the German Committee for Reinforced Concrete (DAfStb) under the grant number V 519. The authors gratefully acknowledge the financial support. Furthermore, the authors would like to thank the Engineering Consultancy Schiessl-Gehlen-Sodeikat[12] for providing the documented case study.

1 Introduction

Concrete repair and rehabilitation are vital disciplines in structural and civil engineering, given the age of concrete infrastructure and the need to extend its service life. Most concrete repair projects entail removing and replacing the defective concrete with a repair mortar or bonded overlay. Proprietary repair materials are often used for repairs of this kind. Marketed as 'high-performance', these materials tend to have very high compressive strength exceeding 40 MPa and give the illusion that they are more crack-resistant [1].

Compressive strength is one of the main parameters for the structural design of concrete structures. It serves as a quality control and conformity assessment of concrete during construction [2]. However, an undue emphasis has been placed on

strength and not enough on durability when it comes to repair materials. When Vaysburd et al. reviewed 120 North American repair projects, not one project prescribed a compressive strength in the region of 20 MPa [1], nor did any prescribe a limitation on shrinkage. It is of no surprise then that when Tilly [3] investigated the performance of 130 patch repairs, only 50% were found to be intact after 5 years of service and that incorrect repair design and material selection were two of the reasons for these failures. A more recent study by [4], who interviewed Clients, Contractors and Engineers, found that 90% of the respondents had listed cracking as the primary damage in concrete structures. While poor quality of work was listed as one of the primary reasons for cracking, the respondents also listed the concrete specs to be higher than required, making the concrete more brittle.

There are standards and guidelines to aid designers and contractors in selecting and specifying material performance requirements for concrete repairs, like the EN 1504 series [5]. However, the values specified in these standards are often viewed as arbitrary, allowing materials to be tailored to meet these requirements but not the repair needs on-site [6]. Furthermore, since these tailored materials are often proprietary, their composition and cement contents are unknown.

The cement and concrete industry is one of the largest contributors to greenhouse gas (GHG) emissions [7]. Various steps have been taken to reduce the GHG emissions associated with the industry, which include optimising cement production processes, carbon capturing, replacing clinker contents with supplementary cementitious materials, and using alternative fuels [8, 9]. Another alternative is to reduce the cement contents in the mortar or concrete mix by increasing the water/cement ratio. Such an approach would inevitably lower the material's compressive strength and influence the structural design of a new concrete structure. Olsson et al. [10] considered compressive strength and the quantity of steel to optimise the structural design of reinforced concrete columns and slabs and found a potential to reduce GHG emissions by 18–25%.

This paper investigates the negative impact of high-strength mortars in concrete repair. It presents recommendations for reducing this negative impact by amending the compressive strength requirement in repair materials. A summary of compressive strength and elastic modulus requirements for concrete repair, prescribed by European and American codes, is first presented. Five proprietary cementitious mortars available in South Africa that comply with the compressive strength requirements of these standards are then presented. Their cement contents are then estimated using an existing compressive strength prediction model for mortar based on Abrams' generalisation law. In addition, two mortars of known composition and strength were considered to validate the model, one of which illustrates how prescribing a lower strength can reduce the cement contents of a mortar. Previous studies on the structural contribution of cementitious materials and the correlation between compressive strength and cracking in repair materials are then discussed. The paper then concludes with recommendations on prescribing material requirements for a more durable repair, which could inherently reduce GHG emissions.

2 Standards and Guidelines on Repair Materials

The ACI 546.3R and EN 1504-3 are the most prominent documents on material selection for concrete repair. The ACI 546.3R provides guidelines for selecting materials for concrete repair, including the material types available and their characteristics and suitability to various repair applications. The EN1504-3 does not give any background on the material types available. Instead, the standard lists the performance characteristics required, how to assess these characteristics and what the requirement is for a particular repair application. While both documents follow different approaches, they both prescribe performance criteria. Table 1 shows the criteria for compressive strength and elastic modulus.

The classes listed under EN 1504-3 refer to the repair method, which is non-structural (Class R1 and R2) and structural (Class R3 and R4). As for ACI 546.3R, the criteria listed only apply to Portland-cement (PC) based materials.

Except for the elastic modulus value prescribed by ACI 546.3R, all the criteria listed in Table 1 are prescribed a minimum value with no upper limit. While this approach seems beneficial, some have criticised these limits as arbitrary, with Wood commenting that this approach by EN 1504 has led to products being tailored to meet the CE requirements and not those on-site [6]. Furthermore, the approach of prescribing minimum performance criteria has unknowingly led to the large-scale production of commercial repair mortars, which may meet the minimum criteria but are over-designed in terms of compressive strength and have excessively high amounts of cement.

3 Predicting the Cement Contents of Repair Mortars in South Africa

A total of five commercially available cementitious repair mortars in South Africa were considered in this study, as well as a repair mortar (RM) designed in the lab and a low-strength mortar taken from [12] (Mix 25). The information available in the commercial repair mortar datasheets is provided in Table 2, and the mixed design of

Table 1 Performance requirements of repair materials for concrete repair

Property	EN 1504-3 [5]	ACI 546.3R [11] (PC based only)
Compressive strength (MPa)	Class R1: ≥ 10 Class R2: ≥ 15 Class R3: ≥ 25 Class R4: ≥ 45	Similar to substrate but ≥ 28
Elastic modulus (GPa)	Class R1 & R2: No requirement Class R3: ≥ 15 Class R4: ≥ 20	E (repair) $\approx$ E (substrate)

Table 2 Datasheet information on commercial cementitious repair mortars in South Africa

Mortar ID	Compressive strength (MPa)	Water consumption (kg)	Yield (L)
1	49	3.825	13.7
2	58	2.7	12.5
3	45	3.05	10
4	55	3.3	12
5	55	3.3	12

Table 3 Mix design of repair mortars

Material	Unit	RM	Mix 25 [12]
CEM II 42.5 A-L	kg/m^3	500	323
Water	kg/m^3	210	297
Dune sand	kg/m^3	730	747
Greywacke crusher sand	kg/m^3	820	843
Compressive strength	MPa	55	15

the two repair mortars is provided in Table 3. It is also worth noting that only three of the five commercial repair mortars provided drying shrinkage data.

The datasheets of these commercial products described these mortars as suitable for structural repair applications, with all the 28-day compressive strength values (σ_{C28}) meeting the EN 1504-3 strength requirements for Class R4 materials in Table 1. Since these repair mortars are proprietary, their constituents are not included, meaning their cement contents are publicly unknown. However, appropriate compressive strength prediction models can help estimate these cement contents. One suitable model is that developed by Abrams [13], which only requires the water/cement (w/c) ratio and is defined as:

$$\sigma_{C28} = A/B^{w/c} \tag{1}$$

The coefficients A and B are constants for a material tested at a particular age under certain conditions. Although the model was initially developed for concrete mixes, Rao [14] also found Abrams' generalisation law applicable to mortars. Several mortar mixes with differing cement/sand ratios were considered in this study, each of which had incremental water/cement ratios ranging from 0.3 to 0.65. The cement used in this study was 43-grade Portland cement, conforming to IS: 8112-1989.

The study revealed the water/cement ratio as the single largest factor influencing the mortars' compressive strength. These findings were also reported by [15], whose extensive study on various mortar mixes found the water/cement ratios' influence on strength to be unaffected by the type and grading of the fine aggregate. The more generalised form proposed by Rao is provided in Eq. 2 and applicable to low- and high-strength mortars with a water/cement ratio greater than 0.40.

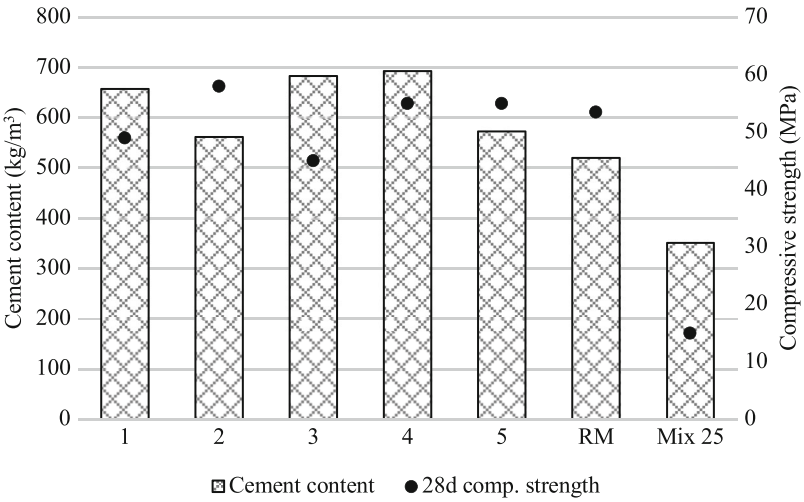

Fig. 1 Cement content results of the repair mortars considered and their compressive strength

$$\sigma_{C28} = 11.3\ (w/c)^{-1.713} \tag{2}$$

The cement content of each mortar was determined using its compressive strength and water content values in Table 2. Equation 2 and the compressive strength yield the water/cement ratio, allowing the mortars' cement content to be estimated using its water content. The cement contents of repair mortars RM and mix 25 were also estimated and compared to those in Table 3 to validate the model. The estimated cement contents and compressive strength of each mortar considered are presented in Fig. 1. While the cement content results of mortars RM and Mix 25 are over-predicted, the difference is only 4% and 8% of the actual value in Table 3, respectively. Rao [14] reported similar variations, commenting that the model was suitable for practical design purposes and was also deemed suitable for the purposes of this study.

As illustrated in Fig. 1, the model results showed the cement content in all five commercial repair mortars to be above 550 kg/m^3 and higher than mortar RM. Mortar 4 had the highest cement content of nearly 700 kg/m^3, which was 33% more than mortar RM. The cement content estimated in Mix 25 was below 350 kg/m^3 and 1.4–2 times lower than the other mortars considered. While it can be argued that mortar Mix 25 is not a structural repair mortar due to its low compressive strength, the definition of what constitutes a structural repair needs to be considered and if these high-strength repair materials meet this requirement.

4 The Contribution of Cementitious Materials in Structural Repair

The ACI Committee 364 [16] defines a repair as structural when it can carry the applied load. This requirement has led to the misconception that if the cementitious repair material has a high compressive strength, the repair will structurally contribute to the member's load-carrying capacity. While this notion may be partly true in the short term, since the elastic modulus of cementitious materials is closely tied to their compressive strength, it does not consider the long-term effects of shrinkage and creep in the repair.

Naharaghi et al. [17, 18] explored these effects by developing an analytical model for unreinforced repaired axial members loaded in compression. Based on Hooke's law and Euler–Bernoulli beam theory, the model considers the applied load, elastic modulus of the concrete substrate and repair material and shrinkage and creep characteristics of the repair material. Creep and shrinkage in the substrate concrete were ignored as the model assumes the repairs to be done on aged concrete members where such time-dependent deformations have already ensued. The model computes the stresses in the concrete substrate and repair material for a defined period that is discretised into days.

The study presented a square column repaired with a commercially available high-strength cementitious grout bulked with 9 mm Greywacke stone. Figure 2 depicts the column dimension and extent of repair, which was 20% of the column's cross-sectional area. Experimental work was undertaken to determine the material characteristics of the repair grout, which are presented in Table 4. Due to the cementitious grout containing stone aggregate, its cement content could not be predicted using Rao's model. A temperature and relative humidity of 22 ± 1 °C

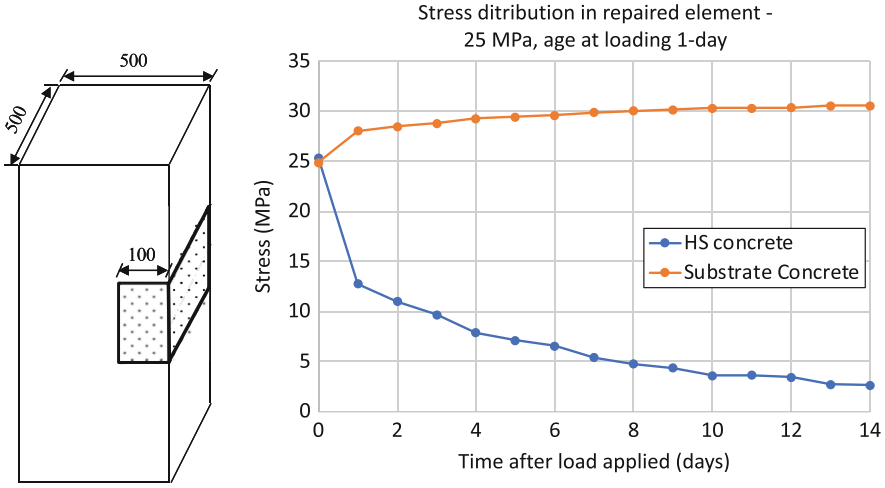

Fig. 2 Repair geometry and stress outputs from analytical model over time [17]

Table 4 Cementitious grout properties from testing and considered in the analytical problem

Age (Day)	Compressive strength (MPa)	Elastic modulus (GPa)
1	42	25.5
28	77	28.5

and 55 ± 5% were used for shrinkage and creep testing, which started the day after the samples were cast. After 90 days, the shrinkage and creep micro-strains were 340 μ-ε and 120 μ-ε/MPa.

The properties of the substrate concrete were assumed to have a compressive strength and elastic modulus of 50 MPa and 25 GPa, respectively. All loads were presumed to have been removed before the column was repaired, and the repair duration was assumed to be 1 day long. This short period allowed the assumption that only elastic strain was recovered in the substrate. Following the one-day repair period, an axial compressive load of 25 MPa was applied and maintained.

The stress results from the model in Fig. 2 show that despite equivalent load sharing between the repair and substrate on the day of loading, due to the similarities in elastic moduli, the stress in the repair begins to rapidly decline, with approximately 50% of its load contribution being lost after 1 day. This drop in load contribution was owed to the repair materials' shrinkage and creep development. Consequently, this reduction of stress in the repair increased the load contribution of the substrate. The increase in stress in the substrate was not as significant as the repair, though, since the substrate's cross-section was four times larger than the repair. The model showed that stress transfer from the repair to the substrate began to stagnate after 14 days of loading, with the repair only taking 10% of its original load contribution. Thus, despite the high strength of the repair concrete, its ability to structurally contribute became redundant after a short period.

The result above begs the question of whether cementitious materials can carry any significant load in the long term and whether high-strength repair materials are always necessary.

5 Compressive Strength and Cracking Tendency in Repair Materials

A crucial comment raised by the ACI Committee 364 [16] is that, while a structural repair needs to contribute to the load, it must also protect the underlying concrete and reinforcing steel from deterioration and corrosion. Repair material cracking is one of the biggest concerns in repair as this enables easy access of deleterious agents into the repaired structure. From a structural perspective, cracking can also reduce the bond strength between the repair material and substrate, preventing any stress transfer between the substrate and repair. One of the leading causes of cracking is restrained shrinkage of the repair material.

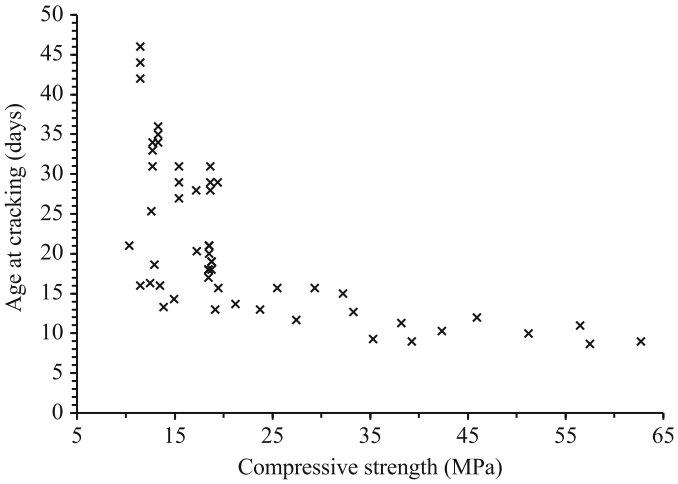

Fig. 3 Age at cracking versus compressive strength at 28 days [19]

A study by Beushausen and Arito [19] found a strong correlation between compressive strength and shrinkage cracking tendency in mortars. This study examined the age of cracking for 40 different repair mortar mixes. These mortar mixes contained various cement types, chemical admixtures, water/binder ratios, water contents and aggregate combinations, with 28-day compressive strengths ranging between 10 and 60 MPa. The cracking age was determined using the ASTM C1581 [20] restrained shrinkage test method, commonly known as the ring test, and enables a relative comparison of the repair materials' susceptibility to crack under restrained shrinkage conditions.

The compressive strength and age of cracking results are illustrated in Fig. 3. As shown, the higher strength mortars cracked at earlier ages than those with lower strength, a trend also found in [21]. Despite the scatter in results, the study suggested an inverse relationship exists between the compressive strength and cracking age in the mortars. It was also noted that increasing the 28-day strength beyond 35 MPa did not significantly change the cracking age in this study, labelling this value as the 'cracking threshold'.

The reason for this occurrence was owed to the fact that an increase in compressive strength is generally complemented by an increase in elastic modulus and a drop in tensile relaxation. These changes would create higher stresses under restrained shrink-age conditions should other factors be held constant, thus increasing the material's susceptibility to crack, a reasoning also noted by [1]. Furthermore, since the elastic modulus of a cementitious material is influenced by the stiffness of its paste phase, which is dependent on its porosity and water/cement ratio [22], it could be posited that increasing the water/cement ratio can improve the materials crack resistance.

6 Recommendations

The current approach of prescribing minimum strength criteria of repair materials for structural repair can be viewed as more detrimental than beneficial. Not only do the studies above suggest that cementitious materials with high compressive strength carry virtually no axial compressive load in the long term, but they can increase the material's susceptibility to crack. Wire meshing and shear dowel reinforcement can be included with the overlay to address the risk of cracking and debonding from the substrate. Still, this approach is not very common in practice and is also viewed as counterintuitive since this would only increase the total amount of embodied carbon in the repair with no added benefit to structural performance. The compressive strength prediction model, discussed in Sect. 3, also illustrates that these high-strength repair mortars can have 40–100% more cement than one with much lower strength. Conversely, a low-strength mortar with better crack resistance can potentially perform the same as one with high strength in a structural repair scenario.

It must be emphasised that this does not mean low-strength materials should be prescribed for all structural repair scenarios and that high-strength materials should never be considered. Instead, the requirements of each repair scenario must be carefully considered, and the repair material must be designed to meet such requirements without automatically specifying compressive strength as the primary or sole performance criterion. Repair standards and guidelines are essential here as they serve as the conduit between research and industry by accepting and applying research findings, like those above, and broadcasting them to engineers and practitioners in concrete repair. Thus, updating existing codes is the most logical step to addressing the issues of premature failure in concrete patch repairs.

One simplistic approach to remedy the concerns above is to revisit the compressive strength requirement and prescribe an upper bound limit. While this suggestion does not guarantee the repair material will have a lower cement content, given that the variability in GHG emissions for producing cementitious materials increases with strength (see [10]), it does ensure a more crack-resistant material and durable repair.

A more sophisticated option would be to include guidelines of what parameters influence the repair materials' susceptibility to crack, an example of which is provided in Table 5. The benefit of this table is that it enables the designer to consider both the material properties and composition when designing a repair. Inspection of this table also reveals that most of the parameters discussed in this study, like compressive strength, elastic modulus and cement content, are significant factors that control the material's sensitivity to crack. It is worth highlighting that the water to cementitious materials ratio in Table 5 has a minor impact on crack sensitivity because this parameter considers cements blended with SCMs, not necessarily cements only.

In addition to including guidelines, mandatory steps toward testing the crack sensitivity of a repair material should also be considered. While the EN 1504-3 does prescribe a restrained shrinkage test method [23] to evaluate such a characteristic, the

Table 5 Parameters influencing the crack sensitivity of cementitious repair materials [24]

Parameter	Effect		
	Major	Moderate	Minor
Drying shrinkage	x		
Modulus of elasticity	x		
Creep		x

Accelerating admixtures	x		
Plasticisers		x	
Silica fume	x		
Fly ash		x	
Slag		x	
Water content	x		
Slump (within typical ranges)			x

test is impractical as it requires a specific reference concrete substrate to be cast 6 months prior to testing and its surface prepared to a specified roughness index, after which the repair material is only then applied and tested. A more straightforward approach would be to consider a free and restrained shrinkage test, like the ring test [20], as these tests do not require a concrete substrate and are easier to conduct.

7 Conclusion

This paper investigated the negative impacts of high-strength proprietary mortars in concrete repair by estimating the cement contents, its inability to contribute towards the load-bearing capacity of a repaired concrete member subjected to axial compression and its susceptibility to cracking when restrained. The compressive strength and elastic modulus requirements for concrete repair in EN 1504-3 and ACI 546.3R were summarised, where it was suggested that the prescription of arbitrary lower bound values has resulted in a surge of proprietary repair mortars that meet these requirements but not the needs of the repair.

Based on Abrams' generalisation law, a compressive strength prediction model for mortars was then presented to estimate the cement contents of five proprietary cementitious repair mortars available in South Africa. These proprietary mortars had a compressive strength of 45–55 MPa and were computed to have cement contents

of 550–700 kg/m^3. When comparing these results to one of low strength, it was revealed that lowering the compressive strength of the mortar can reduce the cement contents by as much as 50%.

Previous studies were then reviewed in the context of high-strength materials. The studies illustrated that not only do materials with high compressive strength increase the likelihood of shrinkage cracking but they are also incapable of carrying compressive axial loads in the long term due to shrinkage and creep of the repair material. Based on the model outputs and reviews, an argument was made on how lowering the compressive strength requirement in repair materials can not only reduce its cement content but can also yield a more durable repair.

Various remedies to attain a more durable, which could reduce the cement content in a repair material, were then put forward. The most simplistic was to prescribe an upper bound limit for compressive strength, while a more sophisticated option was to include material composition and property parameter guidelines that influence the repair materials' susceptibility to crack.

1 Introduction

Since its initial discovery, concrete has garnered substantial usage in construction endeavors due to its unique characteristics. Concrete's elevated compressive strength, wide availability, durability, harmonious interaction with reinforcement materials, economical cost, ready access to primary components (including aggregates, cement, and water), straightforward fabrication process, and adaptability for molding into diverse configurations render it a paramount choice across diverse construction applications [1–3]. Despite its commendable performance, concrete exhibits inherent weaknesses, notably its comparatively limited tensile strength and ductility, rendering it susceptible to cracking, and the tremendous embodied greenhouse gasses that result from its production [2–5]. Since the world is moving toward establishing large-scale and complicated structures built in a highly aggressive environment, these weaknesses have greatly concerned researchers and practitioners. Different means have been established to overcome some of these

weaknesses. For example, concrete structures are usually reinforced with steel bars to overcome the low tensile strength of concrete and its ductility. These reinforcement steel bars apparently restrict the crack width by controlling the plastic shrinkage, but they cannot stop cracks from forming. Consequently, the concrete's durability deteriorates [1, 6].

The formation of early age cracks might not jeopardize the concrete's strength, but they expose its interior, making it easier to ingress fluids and gasses [7]. With the presence of moisture, different ions, such as chloride and carbon dioxide, accelerate the carbonation of concrete, and the corrosion of steel reinforcement causes expansion. This poses a severe risk to concrete's lifespan in the long term since these accelerated processes will reduce structural durability, significantly shortening the concrete's life cycle [1, 2]. While these cracks can be reduced once detected by technical means, their formation is still expected. Manual repair methods are typically employed to mitigate the decline in long-term durability and functionality. However, conventionally, these approaches prove neither efficient nor entirely satisfactory, often exhibiting a lifespan of approximately 10–15 years [2, 4]; additionally, they are very costly [3]. Moreover, repairing cracked concrete structures can present challenges and, in some cases, may be exceedingly difficult or even deemed impossible, particularly when considering factors such as crack location, size, and the specific service requirements of the structure [1, 2, 5]. These challenges have fueled researchers for the past few decades to look for a way to make concrete repair, or "heal," without the need for this enormous amount of money, time, and effort. As a result, self-healing concrete was extensively explored.

Self-healing is a phenomenon intrinsic to the material itself, entailing the restoration and consequent performance enhancement following a prior event that had compromised the material's functionality. Self-healing, or self-repairing, concrete can automatically seal small cracks with no exterior analysis or human involvement [3]. Two distinct approaches for self-repair exist within concrete: autogenous self-healing and autonomous self-healing. Microcrack closure in concrete has been observed, wherein cracks are naturally sealed through the rehydration of unhydrated or inadequately hydrated cement particles within the affected areas [8]. This phenomenon is termed "Autogenous self-healing."

Autogenous healing is an unapparent characteristic of cementitious materials where small cracks, usually less than 0.06 mm, can autogenously heal themselves. As shown in Fig. 1, the self-healing processes can be attributed to (i) chemical causes (carbonation of calcium hydroxide and continuous hydration of cement grains), (ii) mechanical causes (cracks blockage due to the loose concrete particles and any other particles in water), and (iii) physical causes (size increase of the hydrated cement in cracks) [3, 4, 9–14].

Although this appears encouraging, the amount of self-healing products generated from the ongoing hydration of the anhydrous cementitious materials is minimal, potentially inadequate for effectively sealing the crack [15]. Despite realizing the concept of autogenous healing in concrete and its capability to seal its cracks without external activation, researchers were swayed to develop "Autonomous self-healing."

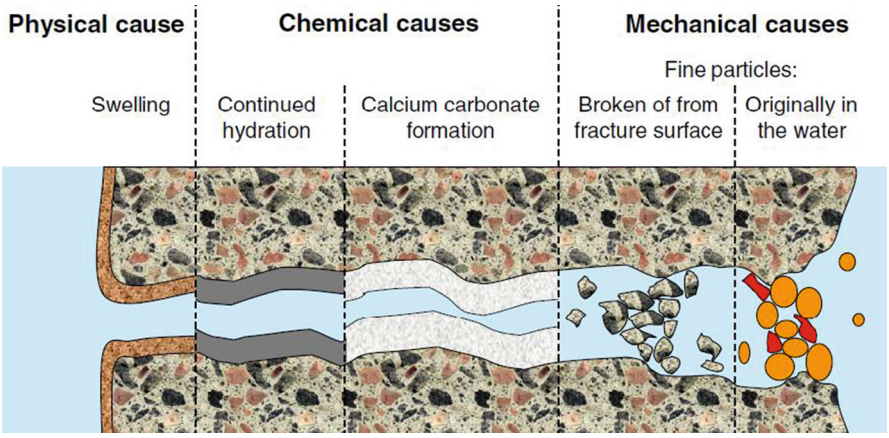

Fig. 1 Different factors contributing to autogenic self-healing in concrete [9]

This approach designs and adds engineered materials that act almost immediately when cracks happen. Researchers aimed to create a more efficient state-of-the-art mechanism than autogenous self-healing.

Unlike autogenous healing, autonomous healing employs engineered additives to accomplish self-healing. Autonomous healing also has the potential to mend larger cracks, and it has been shown to improve concrete's ability to self-heal [16]. Autonomous healing can be divided into passive and active self-healing [16, 17]. Active autonomous self-healing requires human involvement. A sensor monitors cracks until they become larger than a critical width, and then are repaired. In contrast, passive autonomous self-healing does not require any human involvement. This approach embeds functional elements in the concrete matrix, such as hollow pipes or capsules (usually brittle material). These functional elements contain the self-healing agents released once the crack reaches and breaks them [17]. Several autonomous self-healing techniques were proposed and investigated. These include electrodeposition technology, embedding shape memory alloy (SMA), capsules and vascular technologies, and microbially induced calcite precipitation using bacteria [18].

Electrodeposition technology is often used in seaport concrete structures. The electrodeposition method aims to fill cracks with insoluble inorganic compounds, such as zinc oxide (ZnO), magnesium hydroxide ($Mg(OH)_2$), calcium carbonate ($CaCO_3$), etc., precipitated from cations in seawater. These inorganic compounds form a physical barrier around rebars and cover the concrete surface. As a result, resistance against substance penetrability is increased. Electrodeposition technology takes advantage of the reinforced concrete and the surrounding aquatic environment. The healing process initiates with the application of a low-level direct electric current between a reinforcing steel bar (serving as the cathode) embedded within the concrete and an external electrode (acting as the anode) positioned in seawater to serve as an electrolyte solution (Fig. 2). Electrodeposits will occur and fill cracks in concrete and seal its surface, protecting the steel reinforcement and preventing

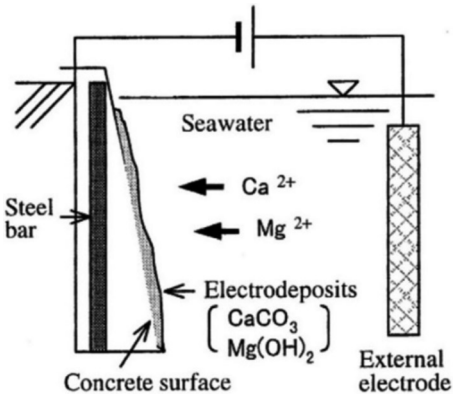

Fig. 2 An application of self-healing using electrodeposition in marine structure [21]

further corrosion. Certain conditions must be met for this technique to give the best results. These include conductive concrete, electric current, and electrolyte solution [19, 20].

Much work has been directed toward studying self-healing concrete, leading to abundant literature on the topic. This literature review aims to collect, summarize, and understand the existing research and debates relevant to electrodeposition autonomous self-healing concrete by comparing and contrasting each relevant source and critically evaluating each. Also, it aims to pinpoint where the research community is up to in self-healing concrete and highlight gaps in the existing research. The novelty of this review work is that it introduces a comprehensive review of literature that covers the self-healing field as a whole and can be used as a basis for future work.

2 Performance of Electrodeposition

Several studies have explored the potential of electrodeposition technology in promoting self-healing of concrete [19, 21–27] in addition to developing models to investigate the damage healing process [28, 29]. One of the earlier studies on electrodeposition by Ryu (2001) investigated the efficiency of the method in sealing drying shrinkage cracks in concrete specimens immersed in two electrolyte solutions (zinc sulfate ($ZnSO_4$) and magnesium chloride ($MgCl_2$)) and applying a 0.25 A/m^2 electrical charge. It was observed that after 14 days, 0.05–0.10 mm wide cracks were almost entirely sealed. The surface coating rate was 70%, irrespective of the immersion solution. The presence of electrodeposits led to achieving a coefficient of permeability less than that of the control specimen after 14 days, improving concrete's water tightness and protection against detrimental materials [24].

It should be noted that the type of the electrodeposits depends on the immersion solution; for example, depositions such as ZnO, $Mg(OH)_2$, $CaCO_3$, Copper(II) oxide (CuO), Silver (Ag), and Copper(II) sulfate ($CuSO_4$) are precipitated when the

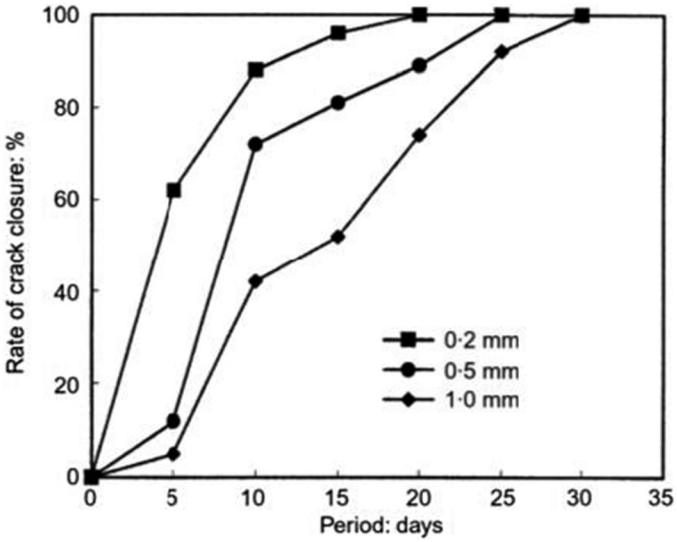

Fig. 3 Crack closure rate versus crack width [30]

immersion solutions contain $ZnSO_4$, $MgCl_2$/Magnesium nitrate ($Mg(NO_3)_2$), Ca^{2+}, Copper(II) chloride ($CuCl_2$), Silver nitrate ($AgNO_3$), and Brochantite ($Cu_4SO_4(OH)_6$), respectively, are used. Another investigation conducted by Ryu (2003) aimed to explore the potential of the electrodeposition technique for repair purposes and the formation of deposits on the surface of concrete, alongside assessing the impact of parameters such as crack width, concrete cover depth, water–cement ratio, and solution temperature. The immersion solution used in this study contained $ZnSO_4$, and the applied current was 0.5 A/m^2. Similar to his previous study, it was concluded that cracks (0.2–1 mm) were fully closed after immersion for 30 days, and the crack closure rate increased after 10 days. X-ray diffraction (XRD) results revealed that the electrodeposits formed were ZnO. A notable trend emerged, indicating an increase in crack filling depth with the increase in crack width, in contrast to the fluctuation observed in closing speed, as shown in Fig. 3 [30].

Ryu and Otsuki (2002) observed that when $ZnSO_4$ was employed as the submersion solution and a current density of 0.5 A/m^2 was administered, the electrodeposited layer formed on the surface of concrete and its thickness ranged from 0.5 to 2 mm. These electrodeposits penetrated approximately 2 mm and 8 mm deep for cracks measuring 0.2 mm and 0.6 mm in width, respectively, over a treatment duration of 56 days [21]. Conversely, Chu et al. (2014) documented crack filling depths ranging from 4.5 to 13.2 mm for reinforced concrete submerged in a $ZnSO_4$ solution, utilizing a current density four times higher than that employed by Ryu and Otsuki (2002). Consequently, electrodeposition technology enhanced mechanical strength, water tightness and permeability resistance, carbonation and corrosion resistance, and resistivity of reinforced concrete [23]. A comparison of the

findings from these two studies underscores the crucial role of current density in the successful implementation of electrodeposition and the extent of deposition achieved.

Yang et al. (2019) tried manifesting a greater current density by incorporating graphene and carbon fibers. Both types of fibers exhibit outstanding mechanical, electrical, and thermal characteristics, contributing to enhancing the physical and durability properties of concrete and augmenting the impact of electrodeposition by decreasing the concrete's resistivity. Consequently, this facilitates a higher current density on the surface of the crack [20, 31, 32]. Cracks with widths of 0.3–0.5 mm were utterly closed when the specimens were immersed in $ZnSO_4$, and a 5-voltage current was applied. Lower current densities tend to take longer, but increasing the current density without caution might increase alkalinity due to OH^- formation.

A study by Zeng et al. (2022) investigated the integration of the surfactant cetyltrimethylammonium bromide (CTAB) into an electrolyte solution to enhance the efficacy of concrete crack healing facilitated by electrodeposition. The impact of varying CTAB concentrations (0.25%, 0.50%, 1.00%, 1.50%, and 2.00%) on the healing process of concrete cracks and the long-term durability of mended mortar samples was examined. The authors noted that immediately upon connecting the circuit, air bubbles started to appear within the apparatus. Subsequently, after 20 days, the cracks of all specimens were nearly filled with white sediments, and a layer of sediment covered the specimen surfaces. XRD results implied that the sediments comprised solely of crystalline ZnO and crystalline $Mg(OH)_2$ when 0.25%, 0.5%, and 2% CTAB were added to the electrodeposition solution. Deposits observed on the sample surfaces appeared loose, irregular, and thin.

Conversely, with CTAB concentrations of 1 and 1.5%, the deposits exhibited uniform and compact distribution, forming a thick layer that filled the cracks. Irrespective of the electrolyte solution used, specimens repaired with 0.25 and 0.5% CTAB demonstrated a crack healing rate (the ratio of length of the closed crack (mm) to the initial length of the crack) of approximately 98%. However, faster healing was observed with CTAB concentrations of 1.0%, 1.5%, and 2.0%, with a crack healing rate reaching 100%. This suggests that a lower CTAB concentration may not effectively adsorb onto the surface of newly formed particles, hindering the optimal combination of Zn^{2+} and OH^- or Mg^{2+} and OH^- ions to form deposits within the cracks, thereby impeding deposit formation. Within the tested concentration range, findings revealed that the optimal CTAB concentration for maximizing the healing of concrete cracks was 1%. However, exceeding this concentration resulted in diminishing returns on the healing effectiveness. Notably, specimens repaired using an electrolyte solution containing 1% CTAB exhibited notably improved steel-mortar adhesive strength, resistance to chloride ion penetration, and corrosion resistance compared to those treated with electrodeposition alone, without CTAB [26].

Wang et al. (2022) took a different route. They examined the effect of changing the anode material on the repair efficiency of a 0.6 mm wide rust-cracked reinforced concrete and its ability to extend the service life effectively. The researchers deduced that the repaired specimens' carbonation resistance and waterproofing performance

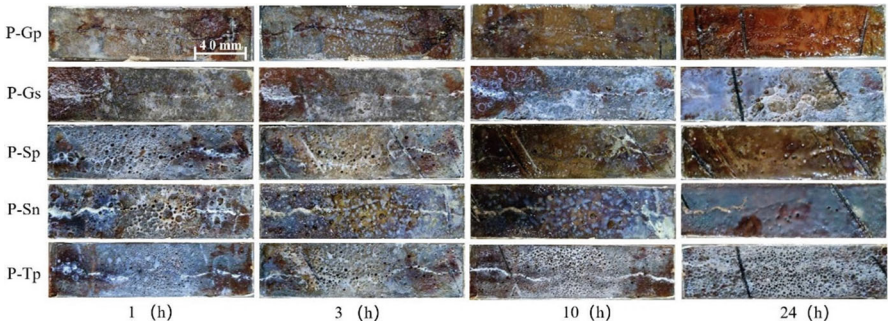

Fig. 4 Surface morphology of specimens with different anode material [33]

were enhanced irrespective of the type of material employed as an anode. However, among the various anode materials tested, including graphite plates (Gp), graphite stick (Gs), stainless plate (Sp), stainless net (Sn), and titanium plate (Tp), graphite plates exhibited marginally superior repair efficiency, as depicted in Fig. 4. The slight difference in performance was attributed to the difference in conductivity of these materials and their shape. Various tests were employed to arrive at this conclusion, encompassing mass increase assessments, epoxy resin surface thickness measurements, depth of filling evaluations, ultrasonic pulse velocity tests, water absorption analyses, and accelerated carbonation depth testing. Notably, the authors utilized a water-based cationic epoxy resin with a mole ratio of epoxy resin, diethanolamine, and glacial acetic acid set at 1:1:0.8 [33].

In another study, Wang et al. (2023) investigated the same electrophoretic deposition repair method on 0.5 mm wide rust-cracked reinforced concrete using a high-performance colloid solution containing water-based cationic epoxy resin. The research findings indicated that the approach effectively decreased water absorption and accelerated carbonation depth while improving reinforced concrete's internal compactness, unconfined compressive strength, and split tensile strength [34].

A deep dive into the various studies that investigated electrodeposition shows that plenty of parameters have a significant influence on the performance of this method, such as healing time, electrolyte solution, water/cement (W/C) ratio, current and type density, applied voltage, and anode material, and have been investigated [19, 22, 25, 27, 29, 33]. Among the several immersion solutions, including $MgCl_2$, $ZnSO_4$, $AgNO_3$, $CuCl_2$, $Mg(NO_3)_2$, $CuSO_4$, $Ca(OH)_2$, and Sodium bicarbonate ($NaHCO_3$) solutions, both $MgCl_2$ and $ZnSO_4$ were found to be the most appropriate solutions for the precipitation of deposition products [23, 25, 30]. The increase in the water-to-cement (W/C) ratio also benefits crack closure. Increasing W/C ratio increases the porosity and reduces the resistivity of concrete, which ultimately causes a higher electric current. Research conducted by Chu et al. (2017) demonstrated that pulse current yields superior healing effects compared to direct current. According to the microstructure analysis conducted by the researchers, the porous, honeycomb-like configuration structure of sediments is transformed into a uniform, dense, layered structure while maintaining the same composition when pulse current is employed

[22]. Overall, pulse current tends to result in increased ratios of weight gain, surface coating, crack closure, and greater depth of crack filling. However, further investigation is warranted to understand its effects fully.

3 Challenges and Future Prospects

While electrodeposition for promoting self-healing in concrete is a promising approach, implementing it to promote self-healing in concrete faces several challenges. These include the need to strategically place and distribute electrodes within structures to achieve uniform healing across the entire material, fine-tune electrodeposition parameters (voltage, current density, and duration) to optimize healing agent release without causing any adverse effects, and identify compatible and sustainable healing agents that are compatible with the concrete matrix and ensuring that they do not adversely affect its structural or mechanical properties. Additionally, there is a lack of long-term stability in the self-healing process, high initial cost concerns, and the need for a reliable monitoring system for real-time control. Finally, scaling up the technology for large structures, integrating it into existing construction practices, and ensuring durability under harsh environmental conditions are significant challenges.

Overcoming these obstacles requires collaborative efforts to advance the practical application of electrodeposition for self-healing concrete in the construction industry. Future research in advancing electrodeposition for self-healing concrete should prioritize the optimization of electrodeposition parameters, emphasizing comprehensive studies on voltage, current density, immersion solutions, and duration for efficient and controlled healing agent release without compromising structural integrity. It should also focus on studying the combined effect of electrodeposition and other self-healing methods, i.e., shape memory alloys. It is crucial to identify and develop sustainable healing agents compatible with concrete matrix and focus on their long-term stability. Moreover, advancements in monitoring systems, integrating innovative technologies and sensors, should be explored to provide real-time feedback on concrete conditions and the effectiveness of the healing process. Robust studies on the durability of electrodeposition systems under diverse environmental challenges, scalability for large structures, and seamless integration into existing construction practices are essential. Generally, self-healing concrete aligns with the principles of sustainable development and environmental conservation; however, self-healing technology has numerous shortcomings, spanning from material selection to assessing repair outcomes to practical engineering applications. Hence, life cycle assessments are imperative to evaluate the economic viability and comprehensive environmental implications.

The effectiveness of treatments employing electrodeposition in concrete relies on many variables, as discussed earlier, and they fall under material characteristics, wetting/pore fluid characteristics, and treatment characteristics. Attaining maximum treatment effectiveness necessitates a precise blend of factors concerning the

solution's chemistry and the intensity and nature of electrical stimulation. While lower concentrations and lesser magnitudes of electrical stimulation have demonstrated improved efficacy for specific pore/fluid compositions, identifying the optimal treatment parameters for each issue remains complex. Despite significant advancements, research and development in this area are still in their early stages.

Apart from the difficulties mentioned above, two main constraints impede the current comprehension and utilization of electrodeposition in concrete. Firstly, most existing knowledge is empirical, lacking comprehensive theoretical frameworks and simulation tools. This limited theoretical comprehension inhibits prediction accuracy and the optimization of treatments employing electric stimulation. Second, most studies rely on laboratory investigations, with limited full-scale experimental studies demonstrating technical and economic viability at scale. While laboratory experiments provide insights, many phenomena remain unclear, and field studies are scarce. Therefore, large-scale electrodeposition treatments' technical potential and economic feasibility are inadequately assessed. To bridge these knowledge gaps, it is imperative to undertake theoretical inquiries, sophisticated laboratory experiments, and comprehensive field studies. Advanced investigative methodologies like molecular dynamics, computerized tomography, and full-scale induced polarization offer potential solutions to surmount these obstacles, facilitating scientific progress in electrodeposition for concrete restoration.

Electrochemical deposition self-healing offers notable advantages in specific environments, particularly marine settings, and holds promise for reinforced concrete structures, but its applicability is not yet universal. Furthermore, the efficacy of repair is influenced by factors such as the concentration and pH of the external solution, presenting limitations in engineering applications that warrant further exploration. Despite the limited research on electrodeposition technology, with appropriate technological parameters, it is possible to enhance the properties of reinforced concrete to a certain degree, thus paving the way for the broader adoption of this method.

4 Conclusion

The exploration of electrodeposition technology for self-healing concrete presents a promising avenue for enhancing the longevity and durability of concrete structures. Despite its widespread use and advantageous properties, concrete faces weaknesses such as low tensile strength, susceptibility to cracking, and deterioration over time. These vulnerabilities have prompted extensive research efforts to develop effective concrete repair and restoration methods.

Integrating electrodeposition technology into concrete repair processes offers several benefits, including the ability to fill cracks with insoluble inorganic compounds, such as ZnO and $Mg(OH)_2$, thus forming a protective barrier against further deterioration. Studies have shown that electrodeposition can significantly improve concrete's mechanical strength, water tightness, carbonation resistance, and

corrosion resistance. However, the effectiveness of electrodeposition is influenced by various factors, including the choice of electrolyte solution, current density, immersion duration, and electrodeposition parameters.

Despite its potential, the widespread adoption of electrodeposition for self-healing concrete faces several challenges. These include the need for strategic placement of electrodes within structures, optimization of electrodeposition parameters, identification of compatible and sustainable healing agents, and development of reliable monitoring systems for real-time control. Additionally, scalability for large structures and integration into existing construction practices are significant considerations.

Moving forward, future research in electrodeposition for self-healing concrete should prioritize the optimization of parameters, comprehensive studies on voltage, current density, and immersion solutions and developing sustainable healing agents compatible with concrete matrices. Advancements in monitoring systems and integration of smart technologies should also be explored to ensure real-time feedback on concrete conditions and healing process effectiveness. Overall, while electrodeposition holds promise for enhancing the sustainability and longevity of concrete structures, further research and development are needed to overcome existing challenges and realize its full potential in the construction industry.

1 Introduction

Shrinkage in concrete structures, which can lead to significant deformation and damage, necessitates understanding its time-dependent behaviors for the structures' durability. This shrinkage is categorized into spontaneous and drying shrinkage [1]. Spontaneous shrinkage, occurring without moisture exchange with the environment, is thought to result from self-drying capillary contractions. Some researchers attribute it to internal stress within the concrete's solid framework. On the other hand, drying shrinkage, driven by water loss through evaporation, is linked to capillary actions [2]. Moreover, several shrinkage processes contribute to the overall shrinkage observed in concrete, such as autogenous shrinkage, chemical shrinkage,

carbonation shrinkage, drying shrinkage, plastic shrinkage, and thermal shrinkage [2–5]. In particular, autogenous shrinkage plays a significant role in the early behavior of high-performance concrete (HPC) and ultra-high performance concrete (UHPC) after they are cast [6–8]. These types of concrete are noted for their enhanced durability and superior mechanical characteristics compared to standard concrete, largely due to their lower water-cement ratio requirements [9]. The scarcity of water available for cement hydration leads to increased self-desiccation within the capillary pores as the relative humidity decreases, causing capillary contraction within the cement matrix [6, 10]. Autogenous shrinkage, occurring under constant temperature conditions, leads to a noticeable reduction in external volume due to these changes, which can result in cracking in the early days or weeks following casting [11–13]. Predictive models are crucial to effectively managing concrete's longevity and performance, accounting for various factors such as environmental conditions, material composition, and loading history. Despite concrete's complex microstructure making accurate modeling challenging, empirical and theoretical models have been developed and used, such as those by the Comite Euro-International du Beton and the ACI 209R-92 model in North America. These models primarily rely on experimental data but are limited in forecasting long-term shrinkage effects [14]. Recent advancements have focused on alkali-activated materials, which exhibit more complex shrinkage behaviors than traditional Portland cement, highlighting the need for innovative predictive methods [15]. The use of non-parametric approaches, particularly artificial intelligence and machine learning techniques like neural networks, has emerged as a promising avenue for accurately predicting concrete's drying shrinkage, especially in long-term scenarios involving alkali-activated materials, where research remains limited.

This research investigates the capability of both traditional and ensemble-based machine learning models to predict drying shrinkage in cementitious materials, including those enhanced with supplementary cementitious components. To facilitate this analysis, a dedicated database was compiled, incorporating data from the NU database along with findings from published studies. The paper elaborates on the theoretical foundations and methodologies employed by the models, with a subsequent evaluation of their predictive outcomes. This study specifically aims to: Assess the predictive accuracy of various machine learning models for drying shrinkage. Identify the most influential factors affecting shrinkage using SHapley Additive exPlanation (SHAP) theory. Quantitatively determine the impact of different features on the accuracy of shrinkage predictions using partial difference plots. The novelty of this research lies in its comprehensive use of SHAP values to decipher the influence of individual features in complex predictive models and its unique approach to integrating multiple types of machine learning strategies to enhance predictive accuracy. These aspects significantly contribute to the field, advancing our understanding of material behavior under drying conditions and improving predictive methodologies

2 Methodology

2.1 Database and Analysis

The required database for predicting self-compacting contractions is collected from published literature and the NU database, totaling 2889 data points extracted from 1 to 28 days. The variables used in predicting self-compacting contractions include 12 inputs comprising the water-to-cement ratio, the water-to-binder ratio, the aggregate-to-cement ratio, height, compressive strength, the volume ratio of chemical composition, the volume-to-surface ratio, temperature, initial measurement time, initial height, cement initial measurement time, water to cement ratio. Therefore, the focus is on creating a prediction model using the abovementioned variables. The data description and the variables' distribution frequency are shown in Table 1.

2.2 Shrinkage Prediction of Typical Machine Learning Model

The Random Forest (RF) technique is a type of ensemble learning used for tasks like classification and regression, leveraging the strengths of bootstrap aggregation (bagging) and the random subspace method. In this process, n bootstrap samples are created by selecting *N* instances from the training set with replacement, typically with fewer instances and features than the original dataset. Each of these samples forms the basis for a decision tree, where each node within the tree evaluates a specific attribute of the data. The progression through the branches of the tree is determined by the outcomes at each node, leading to a final classification or regression result at the leaves. The unique aspect of RF is how it aggregates the results from all individual trees, with the collective output reflecting the majority vote or average prediction across the forest. This method effectively enhances prediction accuracy and robustness by mitigating overfitting common in single decision trees:

Statistical Measures for Model Evaluation The performance of the predictive model of individual and ensemble learners is evaluated using the mentioned statistical indicators as listed below see Eqs. (1) and (2).

$$\mathrm{MAE} = \frac{1}{n}\sum_{i=1}^{n}|x_i - x| \tag{1}$$

$$\mathrm{RMSE} = \sqrt{\frac{\left(y_{\mathrm{pred}} - y_{\mathrm{ref}}\right)^2}{N}} \tag{2}$$

Table 1 Description of the database utilized in this research

	No	Unit	Min	Q25%	Mean	Median	Q75%	Max	Std	Skw

2.3 *Random Forest*

The term "Random Forest," also known as "Random Decision Forests" and "Randomized Trees," denotes an ensemble approach in machine learning that leverages multiple decision trees to tackle various regression and classification (DT) problems. Moreover, a random forest consists of a series of distinct DTs, all independent of each other. Breiman [16] illustrated that the random forest method boasts strong generalization capability. Random forests offer a flexible framework that enables the selection of task-specific objective functions and encompasses a broad range of separation function classifications and posterior models. The count of trees and their depth in a random forest are significant hyperparameters. With an increase in the number of trees, predictions may become more accurate, leading to a steady decrease in prediction error [17]. Figure 1 shows a prediction of dry shrinkage. Figure 1 demonstrates the forecast of dry shrinkage using the Random Forest method, revealing that this approach yields reasonably accurate outcomes with minimal variance between the observed and predicted values. Furthermore, the effectiveness of the model is assessed through the coefficient of determination (R^2) and statistical evaluation using the mean absolute error (MAE) and the root mean square error (RMSE). The regression analysis presented in Fig. 1 indicates the model's strong performance, as evidenced by an R^2 value of 0.89.

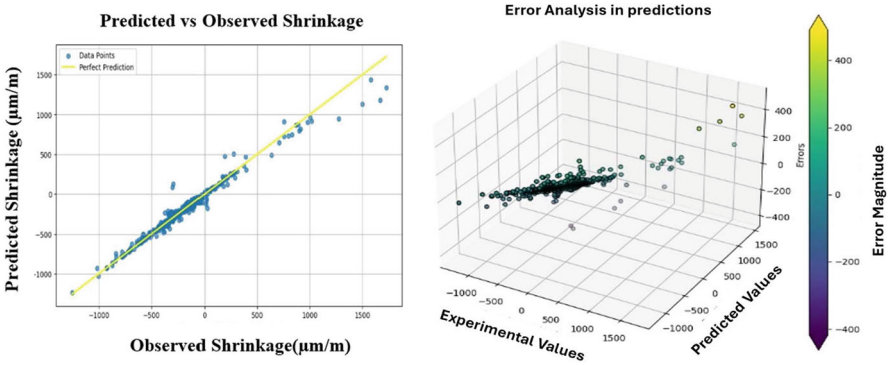

Fig. 1 Random forest; (**a**) regression analysis with the experimental and predicted result; (**b**) errors of experimental and targeted via RF

2.4 *Feature Importance Analysis Using Shapley Additive Explanations (SHAP)*

In the current study, SHAP value diagrams were utilized to examine the relative importance and impact of various features on the predictions of our advanced model. This diagram, based on concepts derived from game theory and principles of equitable distribution, allows the analyst to understand how each specific feature, individually and in relation to other features, influences the outcome of the model. In this diagram, features are ordered from top to bottom based on their net effect on the model's output. Each feature is represented by a collection of colored points indicating the positive and negative SHAP values. Red points represent higher feature values that positively impact the model's output, while blue points indicate lower feature values that may have a negative or lesser impact. The feature "H" at the top of the diagram is identified as the most impactful, while the feature "c" at the bottom has the least impact. The horizontal axis of the diagram displays the SHAP values, and the distribution of points around the zero line indicates the type of impact. Features with points leaning toward the right of the zero line have had a more positive influence on the model's output, and this influence increases as the points move further from the zero line. Conversely, points to the left of the zero line indicate a negative influence on the predictions. This information can be used to optimize models and develop more accurate decision-making strategies. By carefully analyzing the provided SHAP value diagram, it becomes apparent that features like "H" and "CCEB" are highly strategic and should be given special attention in modeling-related decisions. Ultimately, as shown in Fig. 2, this diagram allows us to move toward creating more transparent and interpretable predictive models with a deeper understanding of the impact of model features.

Fig. 2 Feature importance analysis using the Shape library in Python code

3 Conclusion

Machine learning models have increasingly shown their prowess in achieving high accuracy levels, rivaling those of neural networks as reported in existing scholarly literature. This is particularly true in the context of forecasting autogenous or drying shrinkage, where precision in prediction is critical. Among the various models explored, the Random Forest (RF) machine learning model stands out for its superior performance:

Performance Comparison: The RF model not only matched but also surpassed the accuracy of previously studied models, reaffirming the effectiveness of machine learning techniques in this domain.

Accuracy Achievements: In both training and testing phases, the RF model demonstrated high reliability, achieving a coefficient of determination (R^2) of 0.89. This indicates a strong predictive power, with 89% of the variability in shrinkage being explained by the model.

Implications: These results underscore the potential of using advanced machine learning models like the RF model for more accurate predictions of concrete behaviors, which is essential for the engineering and construction industries.

By harnessing sophisticated machine learning approaches such as the RF model, we can enhance our predictive capabilities and improve outcomes in material science applications.

1 Introduction

In recent years, the NetZero concept, that is, balancing the equilibrium between the amount of greenhouse gases (GHGs) produced and expelled from the atmosphere, has emerged as the primary framework for climate action, with countries and organizations setting ambitious targets. To limit increases in global temperatures to less than 2 °C, or even 1.5 °C, leaders worldwide committed to balancing greenhouse gas (GHG) emissions from human activities by the second half of the century under the Paris Agreement [1]. Achieving net-zero emissions involves sources and removals of GHGs that are in equilibrium, although the specifics can vary in terms of coverage, timing, and aggregation [2]. From this perspective, it is imperative to decrease CO_2 levels to halt the progression of global warming. The target of reaching NetZero within 2050 to mitigate severe climate effects rests on the

M. Kioumarsi, B. Shafei (eds.), *The 1st International Conference on Net-Zero Built Environment*, Lecture Notes in Civil Engineering 237,
https://doi.org/10.1007/978-3-031-69626-8_62

widespread implementation of technologies that don't contribute to CO_2 emissions. However, the success of this adoption significantly relies on innovating and coordinating efforts within the construction sector to optimize concrete mixtures [3].

A significant durability risk in coastal or marine environments is the corrosion of embedded reinforcement caused by chloride intrusion in reinforced concrete (RC) [4]. The movement of chloride ions within the pore solution substantially diminishes the longevity of susceptible systems [5]. Therefore, comprehending the ionic transport properties of concrete and their impact on service life is of paramount research importance for ensuring durable concrete. Traditional methods for determining chloride diffusion coefficients (D_{rcm}) typically involve destructive core extraction methods, which are costly and time-consuming and can compromise structural integrity. Alternatively, electrical resistivity measurements offer a promising, quick, and non-destructive method to evaluate ion transport in concrete, as both parameters are influenced by the same factor, that is, concrete microstructure [5]. The splash zone is typically the worst place for attacks on concrete, whereas the submerged zone is less vulnerable [6]. Unfortunately, there is a serious risk to the safety of RC structures in coastal locations in Bangladesh due to the absence of locally focused mix design regulations that prioritize primarily strengths. Consequently, restoration of deteriorated RC structures in corrosion-prone areas may demand a notably large financial allowance at later stages of their service life [7, 8]. In this view, to improve the life cycle of marine concrete structures, it is crucial to verify concrete mix designs and assess chloride-induced corrosion risks.

This research has used varying proportions of cement blends, that is, both commercially available (CEM II and CEM III) and customized (mixture of CEM I and class F fly ash/blast furnace slag), to quantitatively assess concrete durability enhancement against chloride ingression in RC structures, leading to increased service life values in saline environments. The longer it takes for corrosion-induced cracks to appear, the fewer repairs will be required during the structure's service life. This eventually results in reduced CO_2 emissions from cement production over time. In addition, the life cycle cost of a typical RC wall made of different blended mixes of the study and exposed to chloride-induced corrosion has been estimated considering 100 years of design life. This research also includes an estimation of CO_2 emissions for different binders used to compare and identify best-performing mix, prioritizing durability and repair frequency. The finding of the limited study performed would assist in recommending policies and guidelines for the local construction supply chain to reduce the carbon footprint of RC construction work exposed to salinity and eventually, contribute towards NetZero achievement.

2 Materials and Methodology

This research has utilized chloride migration coefficients of concrete mixes, determined according to the Nernst-Einstein equation [9], to evaluate the service life and likelihood of RC wall corrosion in the Life-365 software [10] exposed to severe

saline exposure. The primary focus has been on binder types, as the presence of pozzolanic characteristics in the binder directly influences the permeability of the resulting concrete, affecting the time for chloride ions to reach the embedded reinforcement. Additionally, an evaluation has been conducted to ascertain the CO_2 emissions associated with binders used in constructing and repairing RC walls.

2.1 Mix Design

This study considers five mixes to represent variation in the mix proportion of supplementary cementitious materials (SCMs) having a water-cement ratio corresponding to particular design strengths. As per the ACI Mix Design manual [11], a slump value of 75–100 mm has been considered to represent the commonly used workability of concrete mixes. The concrete mixtures incorporated single-type fine aggregate variation, which is, in this case, local sand with a Fineness Modulus (FM) of 2.5. Table 1 shows the amount of different ingredients of mixes used, where FA and S denote class F fly ash and slag, respectively. The numerical values, that is, 30FA means 30% fly ash, 20FA means 20% fly ash, and 30S means 30% slag.

The tests were performed on laboratory-cast cylindrical concrete specimens prepared using commonly used and available stone aggregate, with gradation limited to the 19 mm downgraded particle size. The water-binder ratio (w/b) has also been kept constant at 0.39, corresponding to a design strength of 35 MPa. The main types of binders used were CEM I, CEM II-B, and CEM III-A, and two blended mixes having different proportions of class F fly ash and slag mixed with CEM I. The chemical compositions of different binders and SCMs (obtained through XRF analysis) are provided in Table 2. In the case of mixes that cannot achieve slump value, a very small amount of additional water or plasticizing admixture (in case water addition does not increase slump) has been added to achieve the target slump, keeping the water-binder ratio constant.

Table 1 Composition of different concrete mixes considered in the study

Mixture	w/b	Cement (kg/m^3)	Fly ash (kg/m^3)	Slag (kg/m^3)	Coarse aggregate (kg/m^3)	Fine aggregate (kg/m^3)
CEM I	0.39	526	–	–	1048	630
CEM II		526	–	–	1048	612
CEM III		526	–	–	1048	618
CEM I + 30FA		368	158	–	1048	565
CEM I + 20FA + 30S		263	105	158	1048	580

Table 2 Chemical compositions of different binders and SCMs

Analyte	Mass %				
	CEM I	CEM IIB	CEM III-A	FA	Slag
CaO	68.24	45.40	54.95	1.14	45.86
SiO_2	17.02	26.57	23.82	68.12	31.35
Al_2O_3	2.53	10.40	8.59	18.00	8.52
Fe_2O_3	4.17	3.13	1.97	5.40	1.40

Na_2O	0.25	–	–	0.08	0.26
K_2O	0.59	2.87	1.13	2.45	0.74

2.2 Estimation of Chloride Diffusion Coefficient (D_{rcm})

Concrete Surface Resistivity A concrete surface resistivity test has been conducted to evaluate the chloride diffusion coefficient (D_{rcm}). The standard techniques to assess surface resistivity are two-point uniaxial and four-point techniques [12]. For this study, the four-point technique has been used. There are four electrodes evenly distributed in a linear arrangement. When the external electrodes apply an alternating current of intensity, I, to the concrete, the two inside electrodes detect electric potential, V [13]. Proceq Resipod has been used to obtain the resistivity values. Correction factors for geometric, temperature, and degree of saturation have been applied to obtain the corrected resistivity from the Proceq Resipod reading. The details of correction factors can be found elsewhere [5].

Chloride Diffusion Coefficient The chloride diffusion coefficient (D_{rcm}) was calculated using the correlation between D_{rcm} and concrete surface resistivity. Andrade et al. [14] suggested a correlation borrowed from the Nernst-Einstein equation.

$$D_{\text{eff}} = \frac{12 \times 10^{-5}}{\rho} \tag{1}$$

Where ρ is the resistivity of concrete, and D_{eff} is the effective diffusion coefficient.

2.3 Estimation of Service Life

A life cycle analysis of an exposed reinforced concrete (RC) wall (built of specified concrete mixtures of this study) with a 62.5 mm thick cover against corrosion from chloride ingress has been carried out using the Life-365 [10] environment. The Life-365 uses the migration coefficient of any concrete mix to compute chloride diffusion within the concrete by applying Fick's second law. According to the model's recommendation, time-dependent changes in the mixes' migration coefficients

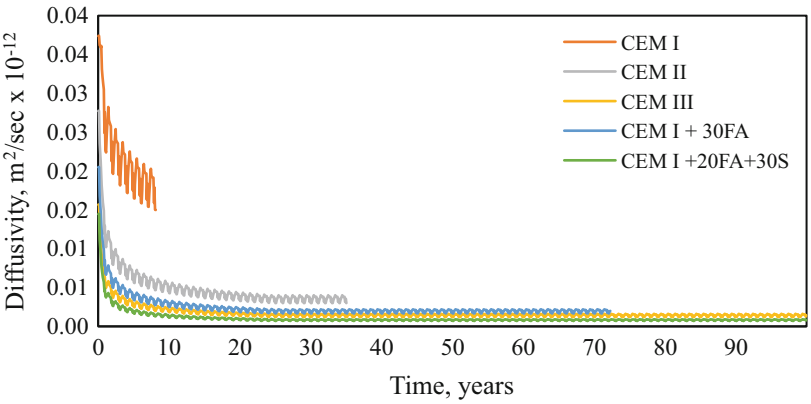

Fig. 1 Diffusivity variation of mixes with time

have been considered using a decay index, m [10]. With a maximum replacement level limit of 70% for slag and 50% for fly ash, the values of m have been determined by the percentage of SCMs in the binder. In order to ensure that the chloride ions reach the implanted rebars after covering the whole cover distance, Life-365 offers time-dependent modifications of migration coefficient values. Figure 1 illustrates the variation in migration coefficients of the mixes with time, as obtained from Life-365, for a 62.5 mm cover. It is evident from Fig. 1 that the incorporation of SCMs with a relatively higher amount of active silica has a considerable impact on the long-time pore refinement within the concrete matrix. As a result, the diffusivity of chloride ions through concrete pores reduces significantly.

As the exposure class, the marine splash zone, namely, XS3 [15], has been considered. The maximum concentration of chloride on the concrete surface and critical chloride content required for corrosion initiation has been assumed to be 1.0 and 0.05 wt. % of concrete, respectively. It has been assumed that maximum surface concentration occurred instantaneously due to the considered exposure class [10]. The concrete exposure temperature was determined by taking the monthly fluctuations in the average temperature of the coastal city of Cox's Bazaar, Bangladesh. The combined duration for both corrosion initiation and propagation is commonly employed to determine the service life of an RC structure affected by chloride-induced corrosion. The propagation phase is assumed to remain constant for a particular rebar type and is set at 5 years in this instance. This study considers the sum of corrosion initiation and propagation period to compare the service life values of different binders.

Following corrosion initiation and propagation, each interval of the corrosion propagation period includes one repair. Mixtures with extended service life are less frequently in need of repairs, thus fostering environmental sustainability. Furthermore, the life cycle cost due to chloride-induced corrosion has also been evaluated in cumulative present dollar (USD) value using Life-365 [10], factoring in inflation and discount rates. It includes the summation of concrete and reinforcement costs, repair

costs, and their cycles. The concrete and reinforcement costs have been estimated at USD 165/m^3 and USD 1.05/kg, respectively, and the repair cost for the RC wall has been considered as USD 190/m^2 [16]. Inflation and discount rates were approximated at 5% and 4%, respectively, to assess the impact of binding material selection on marine RC structure [16]. The repair cost for the RC wall was assumed to be constant, with a repair cycle of 5 years and a 10% repair area for each cycle. The life cycle cost was projected for 100 years of service, with a base year of 2022.

2.4 Estimation of Embodied Carbon Dioxide (CO_2) Emission

As mentioned earlier, five different types of binders have been examined for their impact on emissions. Only the CO_2 emissions from the CEM I portion have been calculated, while fly ash and slag within the blended mixes were considered waste by-products with zero CO_2-e contribution from raw materials. The construction mix ratio has been adopted according to the ACI Mix Design manual [11]. An arbitrary RC wall having dimensions of 10.0 m in length, 3.0 m in height, and a total thickness of 250 mm, with a concrete cover of 62.5 mm, has been considered for calculation. During construction, the CO_2 emissions from cement usage have been calculated based on the mix ratio and the quantity required according to the dimensions of the structure. Additionally, it has been assumed that 10% of the total area of the wall would undergo repair after each repair cycle. For repair purposes, non-shrink grout has been chosen as the material of choice. Non-shrink grout is a hydraulic cement grout composed of hydraulic cement, sand, and proprietary admixtures. Following industrial practices and ASTM specifications, this study has employed a grout mixture comprising 80% Ordinary Portland Cement (OPC) by weight. This ratio falls within the typical range of 70 to 90% OPC commonly used. Additionally, a grout-to-water ratio of 50:7 has been considered as per ASTM specifications. Also, the unit weight of non-shrink grout, as per ASTM specifications, typically ranges from 2240 to 2400 kilograms per cubic meter (kg/m^3). For this study, a unit weight of 2300 kg/m^3 for non-shrink grout has been adopted aligning with ASTM specifications.

After calculating the volume of concrete to be used for construction and repair from the dimensions, the weight of cement to be used has been estimated from its unit weight. Equation (2) has been used to calculate the embodied CO_2 emissions of the cement used for construction and repair.

$$E = \sum M \times \mathrm{EF} \tag{2}$$

where E is the total embodied GHG emissions of cement (in tons CO_2-e) (CO_2-e: CO_2 equivalent), M is the amount of particular building material (in tons), and EF is the GHG emission factor for that building material (in ton CO_2-e/ton) [17–19]. The value of EF for CEM I has been used as 0.913 tons CO_2-e/ton without considering emission during transportation [19].

3 Result and Discussion

This section presents and discusses the impact of different binder types on the initiation period of corrosion in typical RC wall construction in saline exposure. Additionally, it compares repair frequency and cumulative CO_2 emission for alternative binder options.

Table 3 presents resistivity values measured using the Proceq Resipod and corresponding diffusion coefficients for different binder types. These data demonstrate that resistivity values rise with the addition of SCMs, while the D_{rcm} values exhibit an inverse correlation as anticipated.

3.1 Corrosion Initiation Period

Figure 2 illustrates the time required for corrosion initiation of various mixes for a typical RC wall construction in extreme saline exposure. Binders incorporating CEM III (having around 45% SCMs) and CEM I with a blend of 30% slag and 20% fly ash experienced significantly prolonged corrosion initiation times as compared to other mixes. This behavior is attributed to the pozzolanic characteristics of active silica that facilitate the conversion of $CaOH_2$ (initial hydration products with less strength potential) into a relatively stable secondary CSH gel through pozzolanic reactions [20, 21]. Such pore refinement due to delayed secondary CHS formation hinders the pore interconnectivity.

3.2 Repair Frequency and Life Cycle Cost

The durability of concrete structures in marine environments is determined by three factors: the time to corrosion initiation (CIT), the time to crack initiation, and the time required for crack propagation [22]. The initial repair is usually scheduled at the end of the service life, followed by subsequent maintenance at particular intervals, that is, every 5 years in this case as discussed above. Table 4 outlines the number of repair cycles initiated for CEM I, CEM II, and CEM I with a blend of 30% fly ash as 18, 12, and 5 times, respectively. Conversely, CEM III (with around 45% SCMs,

Table 3 Resistivity and diffusion coefficient values of different binder types

Design strength	Mixture	w/b	Resistivity(Ω-m)	D_{rcm} (m^2/s 10^{-12})
35 MPa	CEM I	0.39	39.1	3.1
	CEM II		52.9	2.3
	CEM III		92.5	1.3
	CI + 30FA		70.5	1.7
	CI + 20FA + 30S		103.3	1.2

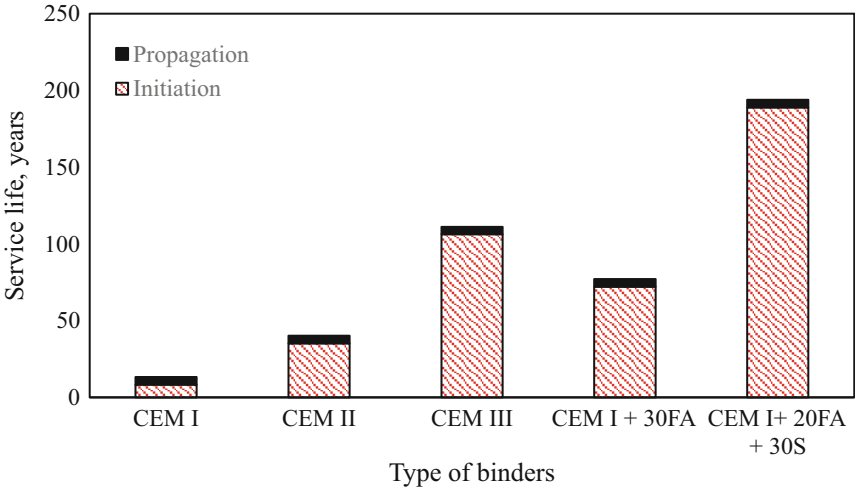

Fig. 2 Corrosion initiation and propagation time (obtained from Life-365) of different types of binders

Table 4 Service life and repair frequency of different types of binder

Types of binder	Initiation (years)	Propagation (years)	Service life (years)	No. of repair cycles required
CEM I	8.6	5	13.3	18
CEM II	37.8	5	42.8	12
CEM III	100.0+	5	100.0+	0
CI + 30FA	72.2	5	77.2	5
CI + 20FA + 30S	100.0+	5	100.0+	0

primarily slag) and CEM I with a blend of 30% slag and 20% fly ash, required no repairs during the 100-year analysis period.

Figure 3 illustrates the ratio of life cycle cost (LCC) to initial construction cost for typical RC wall construction with a 62.5 mm cover, analyzed over 100 years under extreme marine exposure conditions. It is apparent from Fig. 3 that the present value multiplier of life cycle costs is notably lower for CEM III and CEM I with 30% slag and 20% fly ash, compared to other mixes. This difference can be attributed to the considerably more extended initiation period experienced by these mixes.

3.3 Environmental Sustainability

Extending the service life of marine RC elements reduces the need for frequent repairs, thereby lowering the overall CO_2 emissions. Additionally, allocating budgets for periodic maintenance is economically not feasible. Figures 4 and 5 illustrate

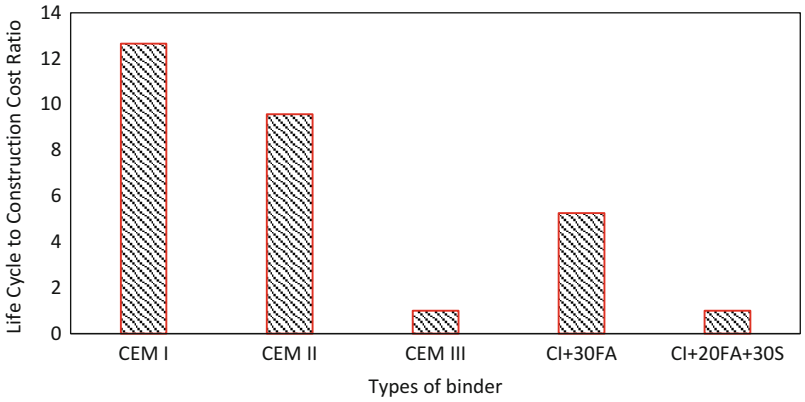

Fig. 3 Life cycle cost to construction cost ratio for different types of binder

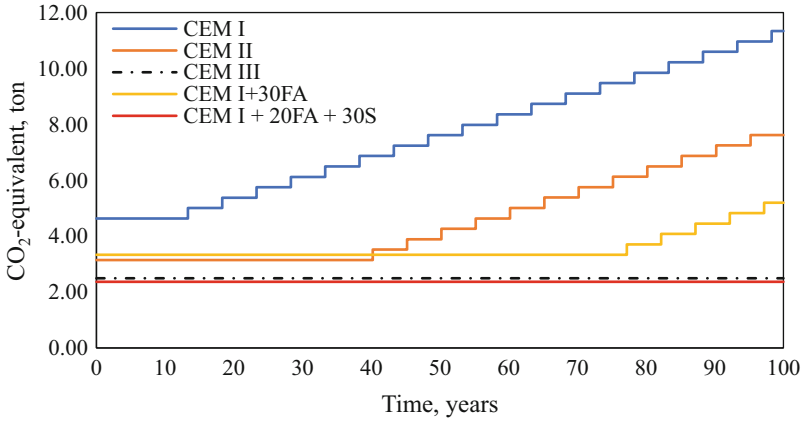

Fig. 4 Cumulative equivalent CO_2 emission of different types of binder

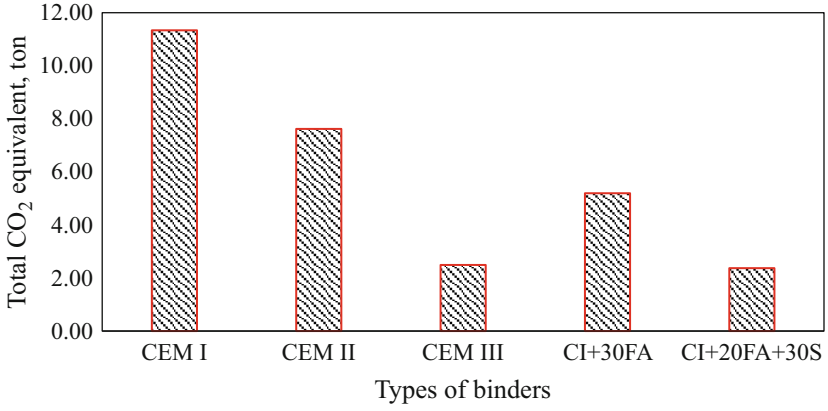

Fig. 5 Total equivalent CO_2 emission of different types of binder

that the total CO_2 emissions remain nearly constant when integrating higher SCMs into binders, aligning closely with constructional requirements. This highlights the potential of SCMs with pozzolanic characteristics as a significant means to work towards the NetZero goal by reducing the carbon footprint of concrete under extreme exposure.

4 Conclusions

The study highlights the significance of utilizing blast furnace slag and class F fly ash as SCMs into blended cement to enhance durability, particularly by ensuring resistance to chloride penetration. This approach ultimately aims to lower the LCC and carbon footprint of any reinforced concrete structures exposed to extreme marine conditions in Bangladesh. For instance, concrete prepared with CEM III and a customized mix having a blend of CEM I and 20% fly ash + 30% slag showed significantly reduced LCC and total CO_2 emissions in comparison with other mixes used in this study. This research, therefore, quantitatively indicates that incorporating a cement blend with higher proportions of fly ash and/or blast furnace slag can decrease CO_2 emissions significantly by extending service life. However, the findings are based on a limited study involving only five concrete mixes. Therefore, future studies with higher numbers of representative local mixes focusing on practical applications would definitely yield substantial benefits, emphasizing the need for further comprehensive research to establish more precise guidelines for Bangladesh.

Acknowledgments The authors extend their sincere appreciation to the diligent staff of the Concrete Laboratory at the Department of Civil Engineering, BUET, for their invaluable assistance in conducting the tests. The financial support for this research has been provided by the Research and Innovation Centre for Science and Engineering (RISE), BUET (Project ID: 2022-01-016).

1 Introduction

Cross-laminated timber (CLT) is an engineered wood product panel that is built from a minimum of three wood or wood-based material layers that are glued together [1]. Commonly, within CLT, the fiber direction of neighboring layers alters, usually by 90° between adjacent layers. Since symmetrical build-up is desired and the fiber orientation of neighboring layers alters, most CLT panels have an odd number of layers. As a result of the glued CLT lay-up, the panels show high in-plane rigidity and the ability to transfer loads in both panel directions when loaded out-of-plane. Consequently, CLT can be used as walls and flooring in various construction projects [1]. CLT is a proven, versatile building element that can be used for constructing multi-story houses while yielding a significantly lower environmental impact compared to other building elements based on concrete and steel [2]. Hence, the worldwide demand for CLT is rising [3].

In the production of CLT, wood is harvested, and planks are sawn and dried before the planks undergo strength grading [4]. Afterwards, planks meeting the required strength and stiffness criteria are finger-jointed together by the use of adhesive, forming a theoretically endless wooden plank. Subsequently, the endless plank is planned to the desired thickness and cut to length. Afterward, an adhesive is applied to the wide face of the planks before they are arranged in the required CLT lay-up and are then pressed. In the end, the CLT undergoes a finishing process in which the panels are cut to size.

During its growing phase, wood captures and binds carbon dioxide (CO_2), which is later released during natural decomposition or incineration (for energy). Thereby, wood that is used in the production of (long-term) goods (e.g., building structures), replacing other materials with a higher CO_2 demand, especially materials that are non-carbon-binding, contributes to the reduction of emissions. Within most European countries, the majority of the "waste" wood is incinerated for the production of energy after the end of the service life of the wooden product [5]. Ideally, wood should be reclaimed and reused after its initial service life, resulting in prolonging the storage of the stored CO_2 within the material.

Reusing reclaimed wooden products poses some key challenges. Structural grading (e.g., based on visual grading [6], X-ray CT scanning [7, 8], and ultrasound techniques [9]) is instrumental for re-use. At the time of writing this work, no grading standard for the regrading of reclaimed wood was in place. Efforts to publish such a standard are ongoing within Europe. Furthermore, reclaimed wooden products often hold metal fasteners at random locations, which must be removed before planing and (re-)shaping. Interestingly, the locations of the nails used to assemble single-use pallets are well-defined [10], thereby simplifying the issue of fastener location detection and, possibly, enabling automated fastener removal. In 2016, approximately 4 billion single-use pallets were in rotation within Europe [11], indicating sufficient supply for possible scaled-up re-use. Therefore, in this work, the feasibility of upcycling reclaimed pallet wood into CLT panels is studied.

An exploratory study revealed that CLT produced from solely reclaimed wood did not comply with the strength requirements in the ANSI standards [12]. To progress on this study, we produced CLT from combinations of virgin and reclaimed wood, in different layups, and their mechanical performance was directly compared with commercial (virgin) CLT. Incorporation of reclaimed materials in the cross-layers should have little influence on the overall bending properties (along the direction of the outer, longitudinal, layers) of these hybrid CLT panels. However, this incorporation may compromise the panel's rolling shear properties. Hence, to study these phenomena, (i) the feasibility of adopting common production processes on the prototype level and (ii) the bending- and shear strength, moduli, and failure modes of the panels, similar to [13–17], are assessed. Since grading regulations for the re-use of reclaimed wood are currently unavailable and the number of test specimens is relatively limited, the results are indicative of evaluating the general feasibility of re-using reclaimed wood for use in CLT. Nevertheless, the results indicate the potential for adequate re-application of reclaimed wood in CLT, thereby extending the carbon storage duration.

In the following, the production process of the CLT panels is described. Then, the considered bending and shear testing methods are given. Afterward, the results are presented and discussed, and, at last, the conclusions are drawn.

2 Materials and Methods

2.1 CLT Panel Lay-Up and Production

Overall, five CLT specimens were manufactured, acquired, and tested, consisting of both new and reclaimed (pallet) wood layers. All CLT panels consist of five layers, where layers 1 and 5 are the top and bottom layers, respectively. The specimen names, layer thicknesses (t_i), associated material, and total panel thickness (*total*) of all panels are given in Table 1. Commercial CLT is labeled "N" (new), while CLT made from pallet wood is labeled "C" (circular). Figure 1 shows a CLT panel with an indication of the layers, their fiber orientation, as well as the global coordinate system (1, 2, 3) that is used within this work.

Table 1 CLT test specimens, with specimen names (N = new, C = circular), layer thicknesses (t_i) with 1 and 5 being the outer layers, layer material type, and total thickness (t_{total})

	Layers 1 and 5		Layers 2 and 4		Layer 3		CLT
	t_1 and t_5	Material	t_2 and t_4	Material	t_3	Material	t_{total}

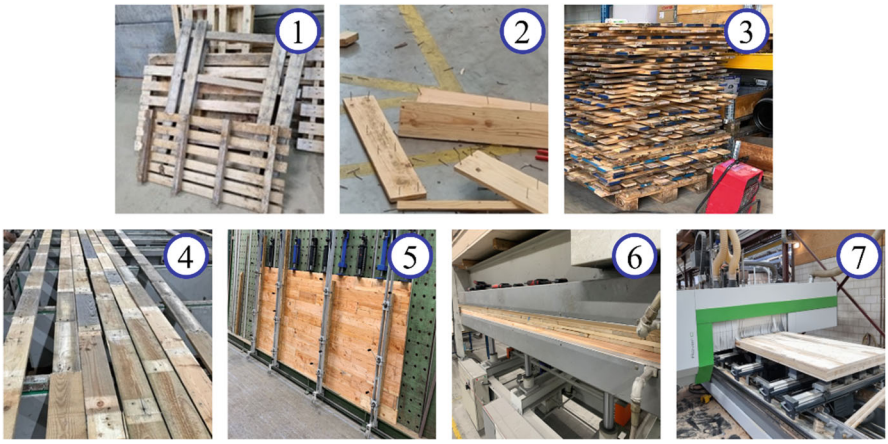

Fig. 2 Production process of C-CLT: (1) pallet acquisition, (2) disassembly and de-nailing, (3) drying, (4) finger-jointing, (5) edge-gluing, (6) face-gluing, and (7) planning and shaping

Two N-CLT panels of 1.2 × 3 m were kindly provided by *Heko Spanten* (*Ede, The Netherlands*), which does not produce the N-CLT themselves. Their supplier used C24 grade timber to create the panels. Unfortunately, some production and material details are unknown; however, it is believed, after thorough inspection, that the N-CLT panels consist of spruce, pine, Douglas fir, or other coniferous species that are commonly used in commercial CLT production. Furthermore, no sign of edge-gluing was found. Finally, a formaldehyde-free polyurethane (structural) adhesive was used to create the panels.

To create (parts of) the C-CLT panels, wood recovered from single-use pallets was used. It was assumed here that the wood is mainly spruce, as this is commonly used for pallets [11]. It is important to note that the exposure history of the pallets is unknown. Pallets may have experienced severe wetting, loading stress levels, chemicals, etc. The new wood used to create some C-CLT panels was spruce, yellow pine, and Douglas fir. Figure 2 displays the C-CLT production process, which is briefly described below:

1. *Pallet acquisition:* Approximately 110 pallets were acquired, all different types and signs of usage.
2. *Disassembly and de-nailing:* Various tools were used to manually disassemble and de-nail the pallets, which was a labor-intensive process. As the locations of the nails on most pallets are well-defined [10], this process can potentially be automated.
3. *Drying:* Since some of the wood showed high moisture content (*MC*) levels, the reclaimed wood was stacked and dried to an *MC* of below 20% in a 20 °C and 65% RH environment, to ensure adequate adhesion in the following gluing steps.
4. *Finger-jointing:* To create six-meter-long laminates, first a tooth-like profile was milled at both ends of the planks, which were, subsequently, glued using a non-structural adhesive. This was done at *Woodjoint* (*Veenendaal, The Netherlands*).

5. *Edge-gluing:* Three-meter long laminates were sawn from the finger-jointed laminates, which were edge-glued and pressed using a melamine urea-formaldehyde (MUF) adhesive, to form single-layer panels. These panels were planned prior to face-gluing. These steps were facilitated by *Boerboom* (*Bergeijk, The Netherlands*).
6. *Face-gluing:* Five-layer CLT panels were created by gluing the new and pallet layers according to the lay-up presented in Table 1, using alternating layer directions. A MUF adhesive was used with an applied pressure of 0.03 MPa. This was facilitated by *Boerboom* (*Bergeijk, The Netherlands*).
7. *Planning and shaping:* After adhesive curation, the CLT panels were planned and shaped to the desired dimensions. This was facilitated by *Boerboom* (*Bergeijk, The Netherlands*).

All panels (N-CLT and C-CLT) were stored at 20 °C and 50–60% RH, before being processed to the desired shape for bending and shear testing. As the above-described panel production process is labor-intensive, the sample size is currently limited.

2.2 Mechanical Testing

Following common definitions as shown in Fig. 1, in the global coordinate system of the panels, axis 1 is along the fiber direction of the outer layers, axis 2 is in the fiber direction of the even layers (2 and 4), and axis 3 is in the thickness direction of the panel. To assess the mechanical performance of the new and circular CLT panels, four-point bending and planar shear testing were employed (Fig. 3) [13–17].

Figure 3a displays a four-point bending test to determine the global bending strength and stiffness of the CLT panels described in EN 408 [19]. The test setup with four support/loading points leads to a shear-free zone between the central two

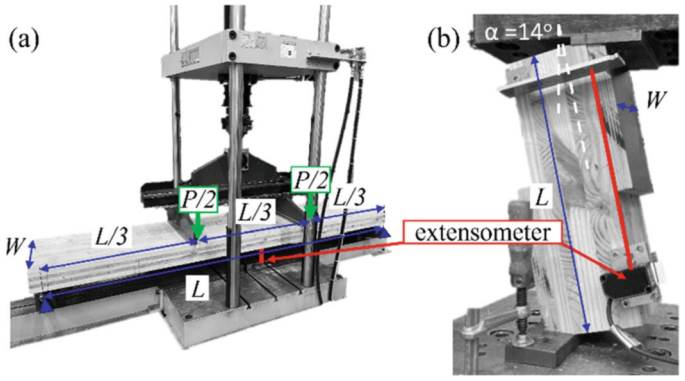

Fig. 3 Setups for mechanical testing, with (**a**) four-point bending and (**b**) planar shear

supports when the load is applied. Consequently, bending failures at the center are unaffected by the influence of shear. The four support/loading points were spaced at one-third of the overall span of the panel (L). Finally, the applied load (P) and the associated displacement (d) of the crosshead and the specimen at the center, using two laser extensometers, were recorded during the test. The sample amounts, dimensions, and displacement rates are given in Table 2. The displacement rates vary due to adjustments to reach failure within a desired time of 6–10 min.

From the load-displacement curves, the global modulus of elasticity of the CLT panel (E_{global}) is determined by,

$$E_{\text{global}} = \frac{23P \cdot L^3}{108\Delta \cdot \left(W \cdot t_{\text{total}}^3\right)}, \tag{1}$$

in which P/Δ is the slope of the initial linear (elastic) part (between 0.1 and 0.4 times the failure load (P_{fail}), as indicated in Fig. 4) of the load-deformation curve and the dimensions are given in Tables 1 and 2. Additionally, the bending strength (f_m) is determined using,

Table 2 Bending and shear test specimen amounts (#), sample length (L) and width (W), and displacement rate (*d-rate*)

Bending					Shear				
Name	No.	L	W	*d-rate*	Name	No.	L	W	*d-rate*
		(mm)	(mm)	(mm/s)			(mm)	(mm)	(mm/s)

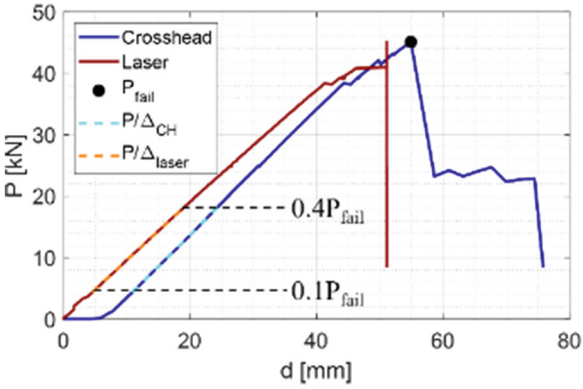

Fig. 4 Load-displacement curves of a bending test

$$f_m = \frac{P_{\text{fail}} \cdot L}{W \cdot t_{\text{total}}^2}. \tag{2}$$

Due to its layered structure, CLT is prone to "so-called" rolling shear issues. This refers to the significantly lower stiffness of the cross-laminations, commonly assumed to be only 10–20% of the shear stiffness of the longitudinal layers [20], and their effect on the global behavior of the panels during out-of-plane loading. The setup used for determining the global rolling shear stiffness and strength is displayed in Fig. 3b; similar test setups can be found in the work by Gong et al. [14] and Niederwestberg [13]. The method used herein was deduced from the shear property evaluation tests described in ASTM D2718-00 [21]. In this work, the specimen is placed in a compression stage under an optimized angle (α) of 14° [14]. Through the inclination and the dimensions of the specimen, it is ensured that the vector of the applied load travels through the center of the specimen.

Due to the lack of available material, samples were cut from the ends of the bending specimens where no failure had occurred. Note that despite no obvious failure occurring in these areas, a pre-loading in shear must be kept in mind. A total of 15 specimens were tested, and their amounts, dimensions, and displacement rates are given in Table 2. Due to the panels' thickness differences (Table 1), the length varies to maintain the 14° inclination and force alignment with the center. The displacement rates vary due to adjustments to reach failure within a desired time of 6–10 min. During testing, the applied load, the crosshead displacement, and the relative displacement between the outer layers were recorded using laser extensometers. Some specimens exhibited crushing failure in the loading regions, this was remedied by gluing additional material in the loading areas (Fig. 3b). This adjustment is deemed acceptable since the deformation within the longitudinal layer is considered to be small due to its high stiffness [21].

From the load-displacement curve, the global shear modulus (G_{13}) is obtained by,

$$G_{13} = \frac{P \cdot (t_2 + t_4)}{\Delta \cdot (L \cdot W)}, \tag{3}$$

in which P/Δ is the slope of the initial linear (elastic) part (between 0.1 and 0.4 P_{fail} as indicated in Fig. 6) of the load-deformation curve and the dimensions are given in Tables 1 and 2.

Due to the inclination, the applied load and the shear plane were not aligned. Hence, the applied load is corrected using a correction factor, k_{angle} (= $\cos(\alpha)$), to find the load in the shear plane. The shear strength ($f_{v,13}$) is then determined using,

$$f_{v,13} = \frac{k_{\text{angle}} \cdot P_{\text{fail}}}{L \cdot W}. \tag{4}$$

Finally, for both bending and shear testing, failure modes were established based on the recognized failure characteristics and the load-displacement behavior.

3 Results and Discussion

3.1 Bending Tests

Figure 4 displays the observed load-displacement curve of the bending tests using the laser extensometers and crosshead displacement. The failure load (P_{fail}) and P/Δ (between 0.1 and 0.4 times P_{fail}), which are used to determine E_{global}, f_m, G_{13}, and $f_{v,13}$, are annotated. The regression range between 0.1 and 0.4 times P_{fail} is chosen to address the initial settlement of the system at the lower boundary and avoid the inclusion of plastic deformation at the upper limit. The laser load-displacement curve is considered for determining the mechanical properties as the P/Δ values in both curves are similar and P_{fail} is identical. A difference in displacement and stiffness between the crosshead and the laser measurement can be seen. This is the result of these measurements reflecting different locations along the beams. While the laser reflects the displacements at the center, the displacement of the crosshead technically reflects the displacements at the loading locations.

Figure 5 displays the determined E-values (E_{global}), failure loads (P_{fail}), and bending strengths (f_m) for all tested CLT panels, including images of failure modes. The E-values for N-CLT are significantly larger than for all C-CLT specimens; the reasons are briefly discussed here. First, and likely most significantly, is the insufficient stiffness and strength of the finger-joints, which lead to a discontinued lamination that cannot transfer the axial tension loads as intended. This practically renders such a layer ineffective within the tension zone and reduces

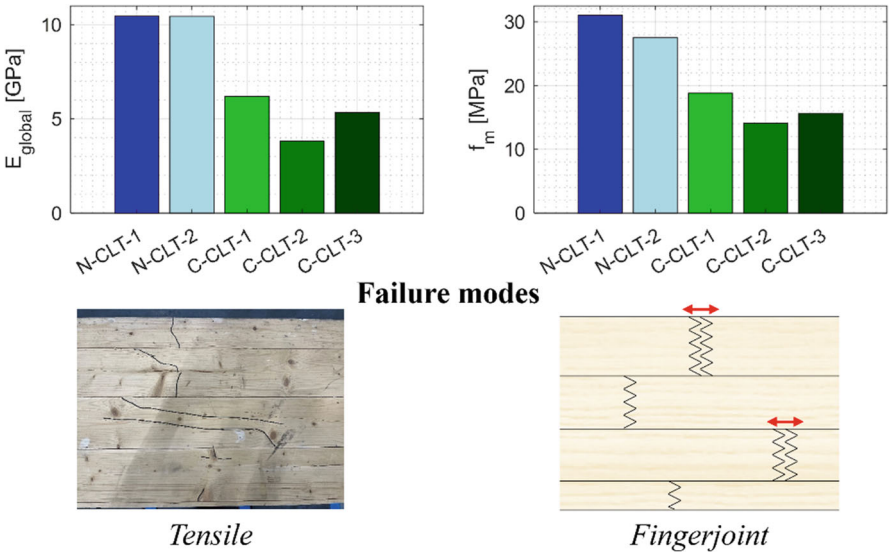

Fig. 5 Mechanical properties of the CLT panels made of new and reclaimed material obtained by the conducted bending tests. Images of tensile and finger-joint failures are added

the statical thickness of the CLT to a thickness where a layer can function as a continuous layer and can transfer the tensile forces. Given that the glue used in the finger-joints is not a structural adhesive, such a failure is reasonable. Second, lower quality of the wooden laminates in C-CLT, especially in the outer layers, compromises the overall panel stiffness. Thirdly, the thickness of the outer layers of the C-CLT specimens constitutes a lower percentage of the total thickness compared to the N-CLT panels (see Table 1), that is, 46.7% and 37.1–45.2% for N-CLT and C-CLT, respectively. Fourthly, lower bonding line stiffness leads to a less rigid overall cross-section, thereby compromising the panel stiffness.

Figure 5 also displays the failure modes from the bending experiments, which vary significantly between the two main specimen groups (N-CLT and C-CLT). While all N-CLT panels show the expected tensile laminate failure in the outer layers, all C-CLT specimens showed premature failure within the finger-joints. This strongly indicates that failure in the finger-joints is the main reason for the lower stiffness of the C-CLT panels. In future work, structural glues must be considered for finger-jointing.

Regarding the bending strength (f_m), similarly to E_{global}, the observed finger-joint failure significantly affected the determined bending strength of the C-CLT panels. Due to the prematurely failing finger-joint, the tensile capacity of the outer layers is not utilized, consequently leading to a lower bending strength of the C-CLT panels.

3.2 Shear Tests

Ideally, P/Δ is determined from the load-displacement behavior referencing the relative displacement of the outer layers, which is recorded by the laser extensometer. Unfortunately, technical problems affected the measurements of the laser extensometers, leading to a stepwise load-displacement curve (see Fig. 6), resulting in a faulty determination of P/Δ. Therefore, an additional load-displacement behavior, considering the influence of the angle correction factor, k_{angle}, was calculated.

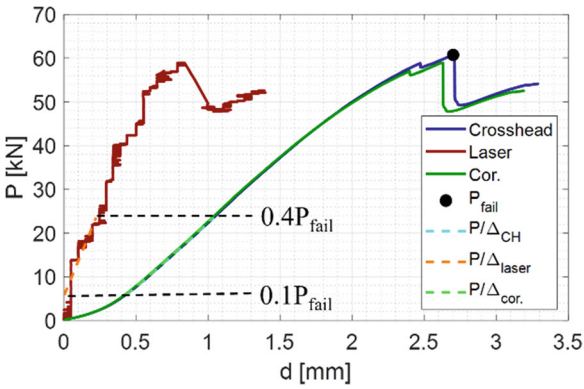

Fig. 6 Load-displacement curves of a shear test

Collectively, Fig. 6 displays three load-displacement curves, that is, based on (i) the applied load and crosshead displacement (Crosshead), (ii) the load corrected by k_{angle} and the laser extensometer displacement (Laser), and (iii) both load and crosshead displacement both corrected by k_{angle} (Cor.). Additionally, the associated P/Δ slopes are displayed. The stepwise curve obtained using the laser extensometer is significantly steeper than those for the other two graphs, which yield similar slopes. While the determined P/Δ for the laser measurement appears faulty, the shear properties obtained using the k_{angle} corrected load and crosshead displacement (Cor. in Fig. 6) still allow for a qualitative comparison between N-CLT and C-CLT. It must be noted that these measurements are affected by the inclined specimen and technically include deformations within the directly loaded (outer) layers. The deformation of these outer layers can be considered small within the load range of the regression for the shear moduli (0.1–0.4 P_{fail}), as the material for this load range is unaffected by failures.

Figure 7 displays the shear moduli (G_{13}) and bending strength ($f_{v1,3}$) for all CLT panels, including images of the failure modes. Regarding G_{13}, the crosshead-based values (17.34–34.63 MPa) are lower than values that can be found in the literature, while values based on laser measurement (72.06–95.63 MPa, deemed unreliable) are within the range of values from the literature [13]. Furthermore, on average, G_{13} is only slightly larger for N-CLT than for C-CLT.

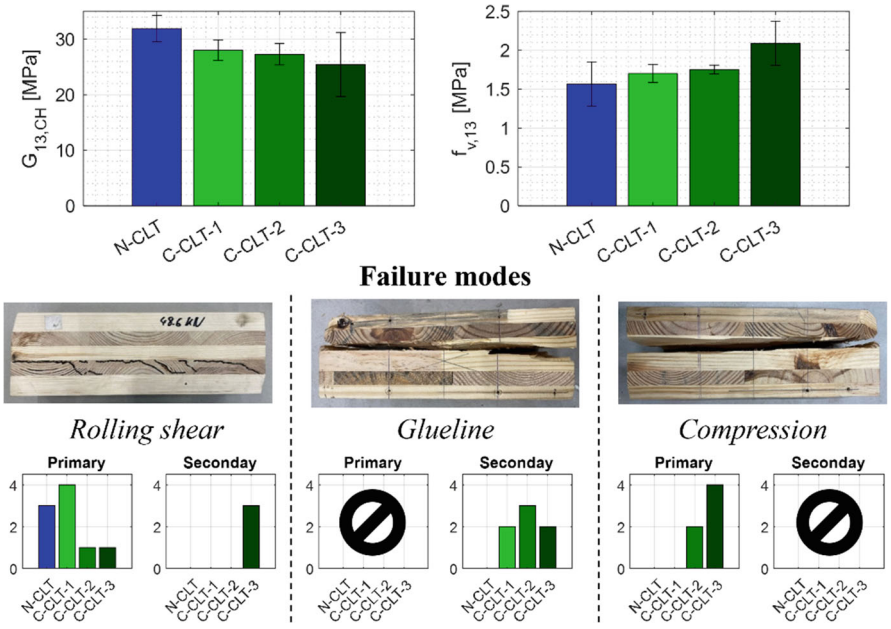

Fig. 7 Mechanical properties of the CLT panels made of new and reclaimed material obtained by the conducted shear tests. Images of all failure modes are added, along with their appearance as primary or secondary failure modes

Regarding the shear strength, $f_{v,13}$, the values for both groups given in Fig. 7 (1.24–2.35 MPa) are within the range of the literature [13]. Furthermore, on average, higher values are found for C-CLT than N-CLT. Lastly, the associated variation in $f_{v,13}$ and G_{13} for C-CLT is comparable and at times even lower than those for N-CLT.

Figure 7 displays three failure modes from the shear experiments, that is, the so-called rolling shear failure due to shear in the cross-layer (which is the expected failure mode as it confirms proper loading), glue line failure due to inadequate laminate bonding, and compression failure in the loading area, commonly due to insufficient contact area or low-quality fibers (as discussed before). The issue related to glue line failure in CLT with yellow pine is a known issue [22]. Furthermore, the graphs display the count of the failure modes occurring first or second. A lot of C-CLT specimens first exhibited compression failure, which is associated with the loading application rather than the desired failure. Nevertheless, since the failure occurred differently from rolling shear failure, the resulting failure loads are here considered to be conservative for the determination of the shear strength. Furthermore, failure in the glue line was also observed. This is promoted by oils within yellow pine bonding surfaces or uneven bonding surfaces [22]. Glue line failure was only observed as a secondary failure and, therefore, has no direct influence on the strength values. Nevertheless, it is advised to ensure higher surface quality in future work. Collectively, most specimens displayed rolling shear failure as primary or secondary (after compression failure). Hence, the obtained $f_{v,13}$ values are deemed appropriate.

Collectively, because the finger-joints are insignificant in the shear tests and the N-CLT and C-CLT specimens exhibit similar shear properties, it is believed that the reclaimed material yields similar potential as virgin material. However, adequate manufacturing considerations are essential. Even though the results of this work indicate that pallet wood can potentially be used to produce CLT, various open questions remain. For example, regarding durability, wood quality, stock variation, contaminants, etc., all require further research. Currently, digital technologies are evaluated to reduce the manual labor involved in the above-described panel production process. As the production process is refined, it is intended to produce additional samples to increase testing efforts and results.

4 Conclusion

The potential of upcycling single-use pallet wood into cross laminated timber (CLT) is explored by means of feasible production processes and bending and shear property characterization. Generally, common CLT production processes can be followed, while additional steps in the preparation of the material are needed, for example, fastener removal. This particular step shows potential for automation. In contrast to the new CLT specimens, all tested pallet CLT specimens exhibited premature failure in the finger-joints of the parallel layers when exposed to bending.

This led to significantly lower determined moduli of elasticity and bending strengths compared to the new CLT. Therefore, the bending test results of the pallet CLT are deemed not representative. It is believed that fully functioning finger-joints within pallet CLT can significantly improve its performance since no other failures were observed. The shear test results suggested that the pallet CLT has similar potential as the new CLT. This is reasonable since the functionality of the finger-joints is not significant to the shear tests. The obtained shear moduli and strength are similar for the pallet and the new CLT. Even though measurement issues occurred, the shear strength of the pallet CLT is comparable to the literature. In summary, this work presents promising results for the potential CLT made from pallets and other secondary sources and highlights key improvement aspects to be considered in a potential follow-up project, namely requiring high-quality finger-joints and more versatile testing methods.

1 Introduction

The imperative to reduce our construction's carbon footprint necessitates embracing natural or ecologically manufactured building materials, as well as those sourced from recycled waste. This adoption is not just an option but a critical step forward. By integrating these materials into our building practices, we can significantly mitigate environmental impact and move toward a more sustainable future. The environmental benefits would be greatly enhanced by choosing this type of concrete for repairing damaged concrete structures [1]. With the continual rise in the number

of deteriorating concrete structures necessitating maintenance, the significance of this approach is magnified.

Sandcrete represents one of the concrete formulations engineered to contribute toward meeting this objective. It was first used by François Coignet in the construction of the "Port Saïd-Egyp" lighthouse. Then widely used by the USSR in the reconstruction of roads, airfields, and buildings after the end of the Second World War [2]. In France, a program called "SABLOCRETE" was launched in 1988 [3]. The aim was to demonstrate the economic and ecological benefits that could be derived from using natural or crushed sand in concrete products, of which it would be the main component.

Several researchers have set out to formulate sand-based concretes using different types of sand. Abidelah et al. have developed a self-compacting sand-based concrete, reinforced by the incorporation of limestone [4]. The concrete formulations developed by these researchers fully comply with the standards set by the French Civil Engineering Association (AFGC) for self-compacting concrete. Li et al. studied the shear strength of concrete beams made from dune sand (DS) from the Gurbantunggut desert in China's province [5]. The results obtained demonstrate the viability of concrete made from dune sand for use in construction. In addition, the shear strength values measured were found to perfectly agree with the requirements specified by current design codes in China. Bédérina et al. undertook a study on the substitution of coarse aggregates by naturally available dune sand (DS) and river sand (RS) in the manufacture of sand concrete [6], Their research led to the creation of a sand concrete offering improved workability, compactness, and strength.

This experimental study aims to develop a sand-based concrete while making it self-compacting, to further enhance the ecological aspect of concrete. Consequently, the concrete was named "Self-Compacting Sand Concrete (SCSC)." The SCSC formulation has been optimized to achieve the characteristics of category 3a self-placing concrete (BAP) [7]. This category is distinguished by several criteria, including maneuverability in an unconfined environment, measured by Abrams cone spread of between 760 and 850 mm (class SF3), a minimum L-box value confined by 3 bar, which must be greater than or equal to 0.8, and a sieve test value not exceeding 15% [7]. Three types of SCSC were produced: SCSC-LF based on limestone fillers, SCSC-PZ based on natural pozzolan, and SCSC-PR based on perlite. The mixes were tested in the fresh state to determine their density and Abrams cone flow following standard EN 12350-8 [8], the filling rate of the L-box following standard EN 12350-10 [9], and finally, the percentage of laitance retained per sieve following standard EN 12350-11 [10]. In the hardened state, the compressive strength of all the specimens was measured following EN 13791, after curing periods of 7, 28, and 90 days. The SCSC developed has been used to repair ordinary concrete substrates. The composites B-SCSC were evaluated in tension by the PULL OFF test according to ASTM 1583 [11].

Finally, SCSCs developed from naturally available or even waste materials, and used without the need for vibration, have the potential to be environment-friendly concretes with a low carbon footprint.

2 Experimental Program

2.1 Materials

Cement The cement used is CEM I 52.5R from the LAFARGE Group, located in OGGAZ/MASCARA (north-west Algeria). This cement has a fineness, according to the BLAINE method, of between 4400 and 5400 cm^2/g, and an absolute density equal to 3.09 g/cm^3. The chemical and mineralogical compositions of clinker are given in Tables 1 and 2 respectively.

Aggregates Two sand types were used in this study. The first is a naturally available quartzite sand (SM) with a fraction ≤1 mm. The second is sand from quarry waste (SC), fraction 0/4 mm. Limestone gravel with a 3/5 mm fraction was also used. All aggregates were supplied by the SECH Spa quarries of the HASNAOUI Group, Algeria.

The size distribution and physical properties of the aggregates are presented in Table 3 and Fig. 1, respectively.

Mineral Additions

Limestone fillers (LF). The limestone fillers used in this study are manufactured by the Algerian Aggregates Company (ENG). These waste products, commonly called "dust," originate from the aggregate industry's operations within quarries.

Natural Perlite (PR). Perlite was extracted in the form of volcanic rock from the Boughrara area (Maghnia/Tlemcen/Algeria). It was washed, dried for 24 h at 80 °C, crushed and ground. The powder was passed through an 80 μm sieve, with 80% of fractions ≤63 μm.

Natural pozzolan (PZ). Pozzolan was extracted as a volcanic rock from the Beni Saf region (Ain Timouchent, Algeria). The same perlite preparation procedure was used to prepare the pozzolan. Seventy-eight percent of its fractions are ≤63 μm.

Admixtures The admixture used is MEDAFLOW 30. Manufactured by the Algerian company GRANITEX. It is a superplasticizer with high water-reducing properties. It is based on ether polycarboxylates. Its absolute density is 1.07 g/cm^3. Its solids content is 30%.

2.2 Preparation Method and Tests

This research aimed to formulate a self-compacting sand concrete (SCSC), by obtaining the best rheological parameters (slump, pourability, and resistance to segregation), as well as excellent mechanical characteristics, while complying with the recommendations of the French Civil Engineering Association (AFGC), relating to BAP. For this purpose, the most important BAP parameters were used [12]. These are the content of additions, which improves workability and increases paste volume; the equilibrium between the W/C ratio and the content of superplasticizing, water-reducing admixtures, which contributes to reducing the quantity of water used, improving the felicity of the mix and preserving its homogeneity and stability.

Three types of self-compacting sand concrete were produced: SCSC-LF, SCSC-PR, and SCSC-PZ based on limestone fillers, natural perlite, and natural pozzolan, respectively. For each type we modified the W/C ratios (0.45%, 0.5%, and 0.55%), so nine SCSC mixes were prepared (Table 6). To improve the flowability of (SCSC) and thus achieve the 80 cm spreading target, adjustments were made to the proportions of the components. In particular, the quantities of quartzite sand (SM) and limestone sand from waste (SC) have been increased, while coarse aggregates have been reduced and limited to a maximum size of 5 mm. This modification aims to increase the concentration of fine sand while reducing the proportion of coarse aggregate, thereby reducing friction between particles and promoting a smoother

Fig. 5 Segregation resistance

flow of SCSC, thus avoiding the risk of blockages [13]. The level of MEDAFLOW 30 superplasticizer was set at 3% by weight of cement (approx. 12.60 L/m^3).

The tests carried out are slump flow with ABRAMS cone (Fig. 3), passing ability in L-box (Fig. 4), segregation resistance (Fig. 5), and compressive strength (Fig. 6).

The SCSCs were applied as repair layers on slabs with dimensions (21 × 28 × 7) cm^3. The concrete used to make the slabs was ordinary concrete (OC). The average compressive strength of OC varies between 40 and 50 MPa. All slabs were subjected to wet curing for 6 months, after which the slab surfaces were treated with a

Fig. 6 Compressive strength

Fig. 7 Surface preparation by sandblasting

sandblasting technique (Fig. 7) to create the roughness required for bonding between the old and new concrete. For each type of SCSC, three slabs were prepared and smoothed in a wet cure.

The PULL OFF test according to American standard ASTM 1583 [11] was used to assess the bond between SCSC and OC slabs. After a curing period of 28 days, the composites (SCSC-BO) were removed from the cure, and 50 cm diameter cores, spaced 50 cm apart, were drilled to a depth of 2 cm into the OC slabs. Metal disks 50 cm in diameter were bonded with epoxy adhesive. A tensile force was progressively applied by the "PROCEQ dy-216" apparatus until failure (Fig. 8).

2.3 Results and Discussion

Slump flow Table 7 shows the slump flow results for SCSC specimens. Mixtures with a W/C ratio of 0.45 gave a spread between 51 and 53 cm for the three SCSCs (Fig. 9). The slump-flow class was SF1 according to the AFGC guide. Mixes with a W/C ratio of 0.50 produced a spread between 63 and 67 cm for the three SCSCs (Fig. 10). The slump-flow class was SF2. In mixes with a water/cement ratio (W/C)

Fig. 8 PULL OFF test

Table 7 Slump flow results of SCSCs

Slump flow [cm]	W/C = 0.45	W/C = 0.5	W/C = 0.55
SCSC-LF	51	63	78
SCSC-PR	53	67	79
SCSC-PZ	50	65	79

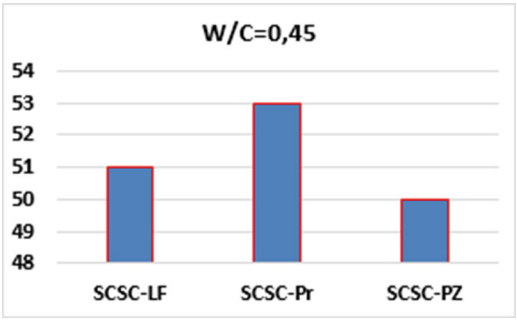

Fig. 9 Slump flow of SCSC with W/C = 0.45

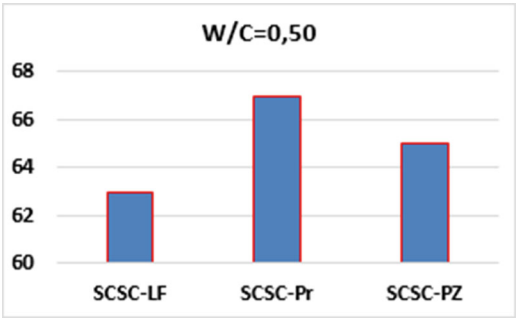

Fig. 10 Slump flow of SCSC with W/C = 0.50

of 0.55, we observed spread values between 78 and 79 cm for all SCSCs (Fig. 11). The slump-flow class was SF3. Additions (LF, PR, and PZ) had no significant influence on slump flow, except for a slight increase for SCSC-PR, perhaps due to

Fig. 11 Slump flow of SCSC with W/C = 0.55

Table 8 Passing ability in L-Box of SCSCs

Passing ability in L-Box	W/C = 0.45	W/C = 0.5	W/C = 0.55
SCSC-LF	0.8	0.9	1
SCSC-PR	0.8	0.9	1
SCSC-PZ	0.8	0.9	1

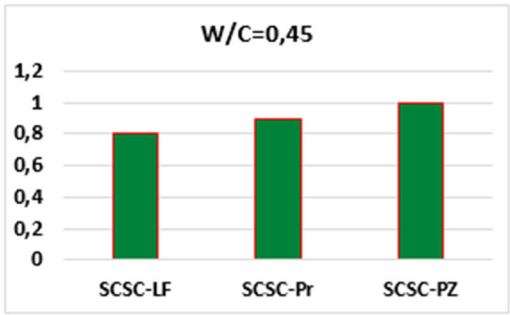

Fig. 12 L-Box passing ability with W/C = 0.45

the PR's excellent finesse. Increasing the (W/C) ratio from 0.45 to 0.55 had a significant impact on slump-flow. An improvement of 49% was observed. A W/C ratio of 0.55 and an SP dosage of 3% considerably facilitated the achievement of the desired fluidity (80 cm). No signs of bleeding were observed on the edges of the wafers for any of the formulations tested.

Passing ability in L-Box Table 8 and Figs. 12, 13, and 14 show the L-box passing ability obtained for the SCSCs. All SCSCs gave excellent results. The $h1/h2$ ratios were between 0.8 and 1. The small-sized aggregates used ($D_{max} = 5$ mm) facilitated the flow of mixtures into the L-box, despite the confinement provided by 03 bars with a diameter of 12 mm. Mixtures with a W/C ratio of 0.55 gave total flow ($h1/h2 = 1$). Raising the W/C ratio from 0.45 to 0.55 resulted in a notable enhancement in passing ability, with a recorded increase of 25%. The W/C ratio of 0.55 and the SP dosage of 03% were sufficient to fluidize all the grains and prevent any blockage caused by friction between them. As a result, the flow was completely in the L-box. The type of addition did not significantly influence the passing ability through the L-box, and the results were close for all SCSC types for each W/C ratio.

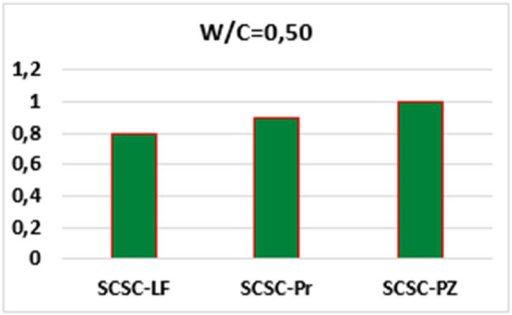

Fig. 13 L-Box passing ability with W/C = 0.50

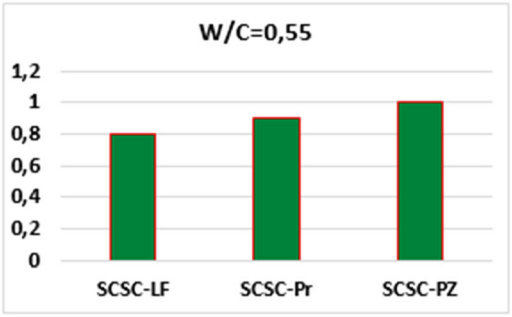

Fig. 14 L-Box passing ability with W/C = 0.55

Table 9 Segregation resistance of SCSCs

Segregation resistance	W/C = 0.45	W/C = 0.5	W/C = 0.55
SCSC-LF	0	2	6
SCSC-PR	0	2	7
SCSC-PZ	0	1.7	5

Segregation resistance Table 9 shows the segregation resistance results for SCSCs. All SCSC concretes have proven to be highly stable, with a homogeneous distribution of mixed constituents. The levels of laitance passing through the sieve varied between 0% for W/C = 0.50, 1.7 to 2% for W/C = 0.45, and 5 to 7% for W/C = 0.55 (Fig. 15). A dosage of 3% "MEDAFLOW 30" super plasticizing admixture had a positive influence on the mixes' homogeneity and viscosity. Their influence was highly significant for SCSC formulated with a W/C ratio 0.55. The type of addition did not significantly influence segregation resistance results. They were very close for all SCSC types, depending on the W/C ratio. The linear trend between the increase in the quantity of laitance passed and the increase in the W/C ratio appears more clearly than the influence of changing the type of addition.

Compressive strength Table 10 and Fig. 16 show the compressive strengths recorded. All the SCSCs tested developed acceptable compressive strengths. From an early age, SCSCs develop acceptable compressive strengths for all formulations (between 37 and 40 MPa). At 90 days of age, the SCSCs achieved excellent

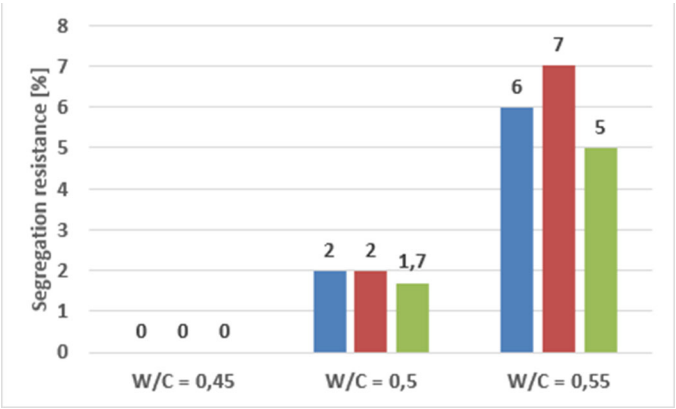

Fig. 15 Segregation resistance of SCSCs

Table 10 Compressive strength of SCSCs

Compressive strength	7D	SD	28 D	SD	90 D	SD
SCSC-LF	40	0.95	60	1.4	62	0.73
SCSC-PR	37	3.47	56	0.75	59	3.09
SCSC-PZ	38	2.81	54	0.9	61	2.26

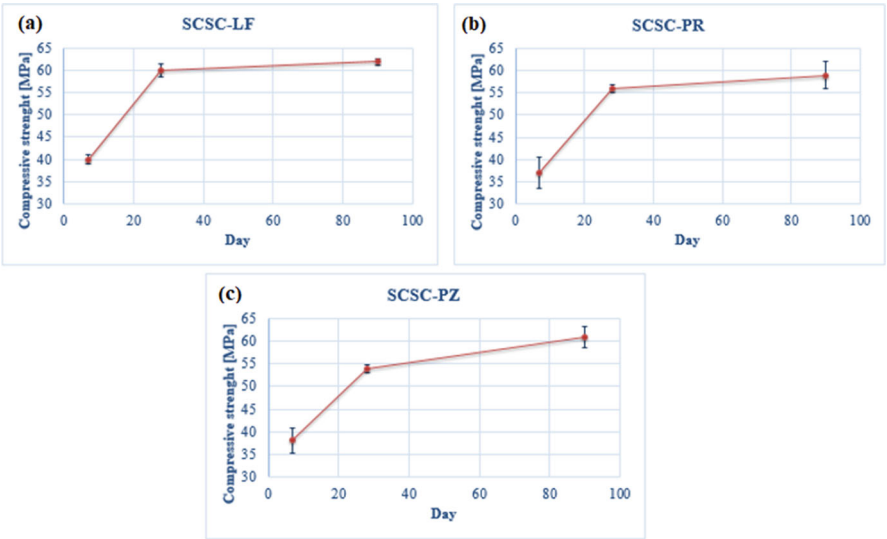

Fig. 16 Compressive strength of SCSCs: (**a**) SCSC-LF, (**b**) SCSC-PR, and (**c**) SCSC-PZ

compressive strengths (59, 61, and 62 MPa for SCSC-PR, SCSC-PZ, and SCSC-LF, respectively). The types of additions did not significantly influence compressive strength, although SCSC-LF gave the best results. Increasing W/C ratios up to 0.55 (57% increase) did not affect compressive strength.

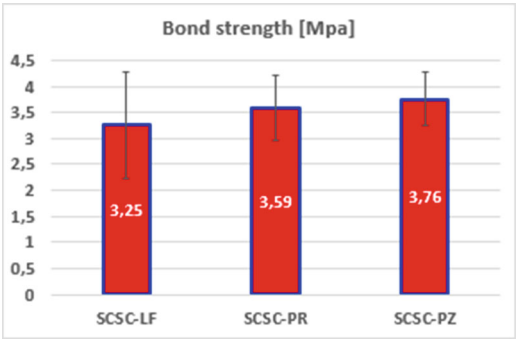

Fig. 17 Bond strength between SCSCs and OC substrates

PULL OFF test Figure 17 shows the results obtained by the PULL OFF test at 28 days of age. The forces of adhesion recorded were excellent. The pozzolan-based SCSC gave the best bond strength (3.76 MPs), followed by the perlite-based SCSC (3.59 MPa) and lastly, the SCSC formulated with limestone fillers (3.25 MPa). The bond between the OC substrates and the SCSCs was considerably influenced by the fluidity of the SCSCs, as well as their ability to penetrate effectively into the interface texture created by the sandblasting technique. All specimen failures were planned on the substrates, highlighting the robust bond between the OC substrates and the SCSC repair material. The tests showed that SCSCs have a higher tensile strength than OC since all the breaks were located in the substrates made by OC.

3 Conclusion

This experimental study aimed to design concrete with a low carbon footprint, in this case, self-compacting sand concrete (SCSC), to meet growing environmental requirements while maintaining optimum mechanical properties. At the end of this study, the following conclusions can be drawn:

- By using naturally available quartzite sand, as well as sand from quarry waste, and integrating mineral additions such as limestone filler, also a recovered waste, as well as perlite and pozzolan, recovered natural resources, we have undertaken the development of an environment-friendly concrete.
- The reduction in the carbon footprint of self-placing sand concrete composites (SCSC) is evident in the reduced use of industrial aggregates and the absence of mechanical vibration.
- Self-compacting sand concrete (SCSC) stands out for its exceptional fluidity and high strength, with a compressive strength of up to 62 MPa. This makes it ideal for repair work, with a bond strength of up to 3.76 MPa.

1 Introduction

Geopolymer (GP) or alkali-activated building materials are cement-free composites produced primarily with alumina-silica-rich waste materials. These materials are activated using sodium, potassium, or calcium-based alkaline solutions [1]. GP composites exhibit superior mechanical and durability performance compared to conventional building materials produced with Portland cement (CM). An early scientometric analysis of the use of geopolymer composites demonstrated their excellent compatibility for various construction applications [2]. GP composites were shown to be used for underwater placement, serve as effective fire and heat protection layers, contribute to repairing, retrofitting, and strengthening old and damaged structures, and function as masonry plaster or block materials [2, 3]. In addition to the aforementioned applications, fly ash and slag-based GP composites

were developed and compared with CM-based material for screed flooring applications [4]. Screed is a building material used in buildings, warehouses, and bridges [5]. Its primary purpose is to ensure a level surface and act as a protective layer for slabs or bridge decks [4]. The British standard (BS 8204 [6]) categorizes screed flooring materials based on the indentation formed on the surface of the screed. This indentation results from the impact of a drop of a specific mass through a cylindrical rod with a cylinder-to-screed circular contact area of 500 mm^2.

Different studies have focused on analyzing the environmental and economic impact of the production of GP- and CM-based materials [7–9]. According to Kanagaraj [7], the production of fly ash-based self-compacting GP and a blend of fly ash and ground granulated blast furnace slag-based self-compacting GP instead of cement-based counterparts reduced the greenhouse gas emissions by around 9.45% and 5.88%, respectively. In addition, for the same compressive strength values, fly ash-based-GP concrete had lower CO_2 emissions per m^3 than CM-based concrete [8]. Similarly, the production of metakaolin-based concrete decreased the CO_2 emissions by 27–45% [9]. Indeed, despite the high environmental impact of alkaline solution, which contributes the most to increasing the global warming potential (GWP) indices, the production of GP composites reduced greenhouse gas emissions compared to the production of Portland cement-based building materials. Thus, incorporating such materials in construction applications is environmentally beneficial while providing superior mechanical and durability characteristics.

This study presents an ongoing research work on the use of GP- and CM-based screed flooring composites produced with dune sand (DS) and crushed limestone sand (CS) as fine aggregates [4, 10]. Herein, the economic and environmental impact analyses of different types and categories of screed are examined. The environmental impact is measured based on the global warming indices of the total carbon dioxide emitted per m^3 of screed flooring production. Furthermore, the economic impact is analyzed according to different parameters, including the cost of raw materials needed to produce 1 m^3 of screed material. Additionally, the durability performance, including resistance to acids and salt attack and abrasion forces, is considered by evaluating the costs per unit strength before and after exposure to these durability tests. Furthermore, a multicriteria performance index analysis is carried out to determine the optimum mix based on mechanical and durability properties and economic and environmental impacts of various screed mixes.

2 Experimental Work

2.1 Materials

Type I OPC and fly ash (FA) were used to produce the cement-based (CM) screed flooring material at a ratio of 4:1. At the same time, ground granulated blast furnace slag and FA were blended at a 1:1 and activated with a sodium-based alkaline

solution to produce the geopolymer (GP) screed composites. The OPC, FA, and BFS were characterized by a specific gravity and Blaine fineness values of 3.16/3350 g/cm^2, 2.32/3680 g/cm^2, and 2.5/4350 g/cm^2, respectively. Moreover, X-ray fluorescence (XRF) analysis showed that the FA consisted mainly of silica and alumina, while calcium oxide and silica were predominant in Portland cement and BFS. Details of the chemical composition of the binding materials can be found elsewhere [4, 10].

The alkaline-activated solution (AAS) was produced by mixing a sodium hydroxide solution (SH) having a molarity of 8 and a sodium silicate solution (SS) with an SH-to-SS ratio of 1.5. The SS solution, with a density of 1506 kg/m^3, was composed of 26.3% SiO_2, 10.3% Na_2O, and 53.4% H_2O. Polycarboxylate superplasticizers, having a specific gravity of 1.2, and additional water were added to CM and GP mixes, respectively, to achieve the minimal targeted flow of 15 cm.

Dune sand (DS) and crushed limestone sand (CS) served as fine aggregates with a maximum particle size of 0.60 mm and 2.36 mm, respectively. Their corresponding d_{50} values were 0.80 mm and 0.26 mm. XRF analysis showed that CS is primarily composed of CaO, as it is made from crushed limestone aggregates, while DS was found to be mainly composed of SiO_2 and CaO. Detailed chemical and physical properties of the aggregates used herein can be found elsewhere [4, 10].

2.2 Mix Design

Tables 1 and 2 present the mix design of CM and GP screeds, respectively. Mixes were designated as X/Y/Z/U/W, where X, Y, Z, U, and W stand for screed category (A or B), type of screed (CM or GP), type of sand (DS or CS), binder-to-sand ratio, and liquid-to-binder ratio (water or AAS), respectively. The binder-to-sand and

Table 3 GWP indices and cost of raw material

	OPC	FA	Slag	DS	CS	Water	SS	SH	SP
Cost ($/kg)	0.076	0.089	0.076	0.005	0.007	0.002	0.272	0.544	1.928
GWP (kgCO_2eq./kg)	0.898	0.027	0.042	0	0.003	0.013	0.424	0.460	1.880
Reference	[11]	[11]	[11]	[11]	[11]	[11]	[12]	[13]	[11]

liquid-to-binder ratios were adjusted to produce Categories A and B screed flooring materials. Category A represents screeds with an indentation less than 3 mm due to BRE drop hammer testing, while Category B includes screed flooring with indentation values ranging between 3 and 4 mm. For example, mix B/CM/D/1:2/0.60 represents a Category B screed mix made with cement and fly ash as the blended binder, dune sand as the fine aggregate, a binder-to-sand ratio of 1:2, and a water-to-binder ratio of 0.60. In GP screed mixes, additional water was added to ensure an adequate flow for placement and compaction (flow >15 cm). A superplasticizer was used for the same reason in CM screed composites.

2.3 Global Warming Indices and Cost of Materials

The global warming potential (GWP) indices were measured by calculating the total mass of CO_2 emitted from the production of 1 m^3 of screed material (kgCO_2eq./m^3). To normalize the GWP against strength, the total mass of CO_2 emitted from the production of 1 m^3 of screed material was calculated per 1 MPa of 28-day compressive strength. The GWP indices and the cost per 1 kg of the raw materials used in this study are presented in Table 3.

The economic impact analysis of different screed samples was conducted based on the total price (in USD, $) of materials needed for the production of 1 m^3 of screed material. Furthermore, the cost of 1 m^3 of screed material per 1 MPa of 28-day compressive strength ($/$m^3$/MPa) was calculated prior to any durability testing. Subsequently, the cost per mass retained from abrasion ($/% LA) and the cost per strength retained from acetic acid ($/% f_c Acetic), hydrochloric acid ($/% f_c Hydrochloric), and salt attack ($/% f_c Salt) was determined to evaluate the cost of screed mixes as a function of their durability performance. The costs were calculated using Eqs. (1)–(6), where Price_i, Volume_i, 28d f'_c, Final Mass, Initial Mass, 56d f_c After Attack, and 56d f_c represent the price per unit mass of raw material i (in $/kg or $/$m^3$), volume of raw material i required per m^3 of screed, compressive strength achieved after 28 days of curing, mass of the screed after abrasion testing, initial mass of the material before abrasion testing, compressive strength after exposure ambient cured for 28 days and exposed to salt and acids for another 28 days, and compressive strength achieved after 56 days of curing, respectively:

$$\text{Cost } (\$) = \Sigma(\text{Price_}i \times \text{Volume_}i) \tag{1}$$

$$\text{Cost } \left(\$/\text{m}^3/\text{MPa}\right) = \text{Cost } (\$)/28\text{d}f'_c \tag{2}$$

$$\text{Cost } (\$/\%\text{LA}) = \text{Cost } (\$)/\text{Mass_retained} \tag{3}$$

$$\text{Mass_retained } (\%) = \text{Final mass}/\text{Initial mass} \times 100 \tag{4}$$

$$\text{Cost } (\$/\%f_c \text{ Acetic or hydrochloric or salt}) = \text{Cost } (\$)/\text{Strength_retained} \tag{5}$$

$$\text{Strength_retained} = 56\text{d}\, f_c \text{ After attack}/56\text{d}\, f_c \times 100 \tag{6}$$

2.4 *Multicriteria Performance Index Analysis*

Multicriteria Performance Indexing (PI) is a comprehensive tool designed to determine the optimal combination by considering various measures and data, encompassing mechanical characteristics, durability properties, cost, and GWP indices. This management tool effectively combines different performance criteria associated with distinct datasets into a single evaluation measure. The indexing and analysis process involve detailed steps, as shown in other work [14]. In this work, four distinct scenarios were selected to determine the optimal mix, as follows:

- Scenario 1: Mechanical properties including the BRE indentation, 28-day compressive strength (28d f_c), flexural strength (f_r), and pull-off bonding strength (f_b). Testing was carried out in accordance with BS 8204 [6], ASTM C109 [15], ASTM C348 [16], and ASTM D7234 [17], respectively.
- Scenario 2: Durability properties include water absorption (WA), mass retained caused by LA abrasion (LA), and compressive strength retained after acetic acid

attack (56d f_c Acetic), hydrochloric acid attack (56d f_c Hydrochloric), and salt attack (56d f_c Salt). Water absorption and LA abrasion were done following the ASTM C642 [18] and C1747 [19], while acid and salt attack testing was done following the ASTM C267 [20].

- Scenario 3: Cost and environmental impact analyses data.
- Scenario 4: All response criteria.

3 Results and Discussion

3.1 Environmental Impact

Figure 1 highlights the GWP indices for the various screed mixes. The results revealed a significant difference between the GWP and GWP/MPa values of CM and GP screed, ranging from 298.2 to 456.3 $kgCO_2eq./m^3$ and from 11.7 to 22.5 $kgCO_2eq./m^3/MPa$ for CM and 57.2 to 105.6 $kgCO_2eq./m^3$ and from 1.7 to 7.9 $kgCO_2eq./m^3/MPa$ for GP, respectively. This notably higher GWP in CM-based screeds is attributed to the substantial CO_2 emissions generated during the production of OPC, which stands at 0.898 $kgCO_2eq./kg$. While variations in the water content during CM production led to lower GWP values, GP screed experienced higher GWP with an increase in the AAS content. This outcome is primarily due to the elevated GWP values of the SS and SH (Table 3).

When considering the sand-to-binder content ratio, CM and GP screed materials exhibited reduced GWP when a higher volume of sand was used in the mix. Similarly, replacing CS with DS generally decreased the GWP. This reduction is attributed to the lower processing requirements of DS. It should be noted that GWP values for CM mix with similar design ratios, but different sand types showed minimal difference. For example, mix A/CM/D/1:3/0.6 had a GWP of

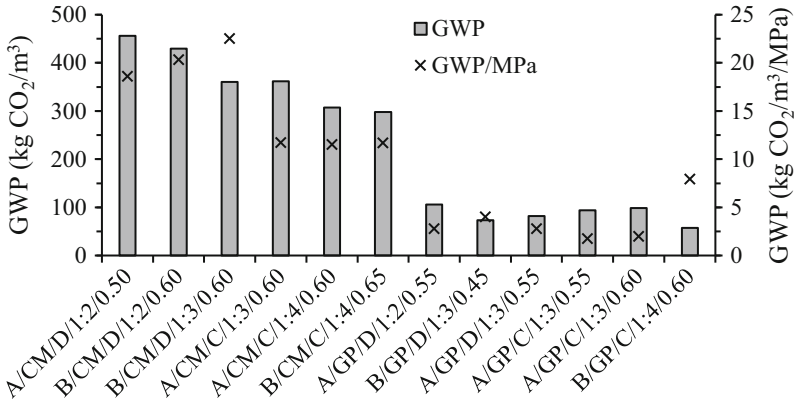

Fig. 1 Global warming potential indices of screed composites

360.7 $kgCO_2eq./m^3$, while mix A/CM/C/1:3/0.6 had a GWP of 361.5 $kgCO_2eq./m^3$. Although DS had a lower footprint than CS, the use of high-range water reducers in DS-based mixes for flowability purposes caused a slight increase in the GWP, leading to a similar overall GWP of the two mixes. Contrarily, for GP screed mixes, replacing CS with DS resulted in a noticeable decrease in the GWP, with values decreasing from 94.0 to 82.0 $kgCO_2eq./m^3$.

3.2 Economical Impact

The economic impact was measured using the cost per 1 m^3 of production ($/$m^3$), the cost per 1 m^3 of production per 1 MPa of compressive strength ($/$m^3$/MPa), and the ratio of the cost of 1 m^3 per mass or strength retained under abrasion, acid, and salt attack. For these calculations, the mechanical properties of the screed mixes before and after durability testing are presented in Table 4. Graphs, plots, and analysis of different parameter can be found elsewhere [4, 10].

The cost of screed mixes is shown in Fig. 2a. Meanwhile, the cost per unit strength and the cost as a function of a durability property are shown in the remaining columns of Fig. 2b. Upon analyzing the data, it is evident that the production cost of GP screed material is higher than that of CM-based mixes, with CM mixes ranging from $42.8 to $58.9/$m^3$ and GP mixes in the range of $60.2–$111.1/m^3. This increase in cost for GP materials can be attributed to the higher production costs associated with AAS. Furthermore, the cost of production tended to decrease with an increase in the sand and water contents, a decrease in AAS and binder contents, and the replacement of CS with DS. This indicates that these factors contribute to lowering the overall production expenses.

While GP mixes seemed to have higher production costs, the economic impact per unit strength led to different conclusions. For example, in mix A/GP/C/1:3/0.55, the cost of 1 m^3 of GP screed was reduced to as low as 1.8 $/MPa. As the mixtures incorporate more sand and water, reduced AAS and binder content, and replacement of CS by DS, the cost per 1 MPa of strength tended to increase. This suggests that while these adjustments may decrease production costs, they may increase the cost-to-strength ratio due to lower strength values. For example, the cost of mixes A/GP/D/1:3/0.55 and A/GP/C/1:3/0.55 were $87.5/$m^3$ and $98.4/$m^3$, respectively. However, when assessing the cost-to-strength ratio, these two mixtures displayed costs of $3.0/$m^3$/MPa and $1.8/$m^3$/MPa, respectively.

The cost analysis of screed composites was also conducted as a function of durability performance, including mass and compressive strength retention following abrasion, acid, and salt exposure. To obtain the cost per mass retention, the cost (Fig. 2b) was divided by the LA abrasion mass retention (Table 4). As for the cost per strength retained, the ratio of the 56-day strength after durability testing to the 56-day strength before durability testing was first found. Then, the cost was divided by this ratio to obtain the cost per unit strength retained. The cost ranged between $0.4 and $1.8/$m^3$/% of either mass or strength retained, except for Mix B/CM/D/1:3/

0.6, which reached \$4.6/m^3/% Mass Retained (LA). This shows that the variations in the mix design had a limited effect on the cost of screed mixes as a function of durability performance.

3.3 Performance Index Analysis

Following the four scenarios of Sect. 2.4, the PI results for various screed flooring mixes are summarized in Table 5. The mixes were classified under categories A and B. Among Category A screeds, GP-based mixes incorporating CS as fine aggregates demonstrated superior performance for "Mechanical," "Durability," and "All Results" scenarios. However, when cost and environmental impacts were individually considered, the A/CM/C/1:4/0.6 mix, composed of cement and fly ash as binder

Table 5 Performance index analysis for categories A and B screed mixes

	Mechanical	Durability	Environmental and economic impact	All results
Category A				
A/CM/D/1:2/0.50	8.8	1.4	4.9	0.0
A/CM/C/1:3/0.60	13.2	4.7	55.2	1.6
A/CM/C/1:4/0.60	11.9	3.3	100.0	1.8
A/GP/D/1:2/0.55	15.9	22.4	12.5	1.1
A/GP/D/1:3/0.55	7.2	6.0	34.9	0.4
A/GP/C/1:3/0.55	82.4	100.0	30.1	100.0
A/GP/C/1:3/0.60	100.0	50.7	13.2	24.3
Category B				
B/CM/D/1:2/0.60	59.0	33.7	5.7	1.9
B/CM/D/1:3/0.60	30.9	1.3	0.5	0.0
B/CM/C/1:4/0.65	100.0	100.0	39.0	100.0
B/GP/D/1:3/0.45	16.2	46.0	14.3	1.0
B/GP/C/1:7/0.60	4.0	4.4	100.0	0.1

and CS as fine aggregates, was found to be the most suitable mix, notably because of the high cost and GWP of the AAS solution used in producing GP screeds.

For Category B screeds, CM-based mixes incorporating CS as fine aggregates demonstrated superior performance across all scenarios except for the "Cost and Environmental Impact" scenario, where B/GP/C/1:7/0.60 mix was the most suitable mix, owing to its high dune sand content.

4 Conclusions

This paper evaluates the environmental and economic impacts of various screed composites produced with cementitious (CM) or geopolymeric (GP) binder and dune sand (DS) or crushed limestone sand (CS). A multicriteria performance index analysis was conducted to identify the optimal mixes for different scenarios. The following conclusions can be drawn:

- The environmental impact assessment of screed composites, as determined by the global warming potential, demonstrated that GP-based screeds exhibited lower values ranging from 57.2 to 105.6 $kgCO_2eq./m^3$ compared to their CM counterparts, which ranged from 298.2 to 456.3 $kgCO_2eq./m^3$.

- Economically, GP screed materials had a higher production cost per 1 m^3 than CM-based mixes. However, GP screeds exhibited a reduced difference when considering cost per 1 MPa of compressive strength, indicating competitive strength-related costs. Furthermore, GP samples showed competitive durability-related expenses ranging from \$0.4 to \$1.8/m^3/% Mass-Strength Retained.
- Among Category A screeds, GP-based mixes with CS showed superior performance in "Mechanical," "Durability," and "All Results" scenarios. In Category B, CM mix with CS excelled in all scenarios except "Cost and Environmental Impact," where the B/GP/C/1:7/0.60 mix was superior, attributed to its high dune sand content.

1 Introduction

The introduction of various standards and guidelines aimed at the design of steel fibre reinforced concrete (SFRC) structures has made the implementation of SFRC structures more widespread. For a multitude of years, SS812310 [1], an SFRC standard has been used, and now with the introduction of the new generation of Eurocode 2, which includes the informative Annex L [2] on fibre reinforced concrete

design, the application of SFRC in structures should grow even more. Although SFRC as a material is not new per se, the design methods and safety of the structures [3, 4] among other topics are still disputed and researched to achieve safe yet economically and environmentally viable solutions. One of the structures that are used extensively would be also ground-level slab supported on piles, which is discussed in detail in ACI544.6R-15 [5].

A novelty in the field of SFRC structures is the so-called steel fibre reinforced self-stressing concrete (SFRSSC), which is gaining popularity in the European, North American and other markets. The introduction of self-stressing agent in the randomly distributed fibre concrete matrix allows mimicking the traditional post-tensioned systems that would otherwise utilise steel cables, yet the self-stress would be achieved chemically. The system proves to be feasible for ground-level elevated slabs on piles [6, 7] and for other structures [8]. The chemical self-stressing of the structure acts similarly to traditional tensioned structures, giving the structure enhanced stiffness, reducing deflections, reducing cracking while also reducing the amount of necessary deformation joints. Previously, such a system has been looked at for slabs on ground where it proved to be a viable method of reducing CO_2 emissions [8] that can deliver tangible benefits already today which exceed those of introduction of GGBS or other supplementary materials to reduce the cement content in the concrete matrix.

The current publication is aimed to inform the community of the system being tested in full scale for ground-level elevated slabs on piles, once more proving the systems capability of reducing the CO_2 emissions by providing a stiffer, stronger slab when compared to conventional methods. The study shows the possible thickness reductions and subsequent CO_2 emission reductions and the differences in the behaviour of the SFRSSC in direct comparison to SFRC under the same conditions. The approbation of the system in said uses follows Eurocode 0 Section 5 Structural Analysis and Design Assisted by Testing.

2 Experimental Programme

The conducted full-scale experiments have been introduced to the public recently [9]. Nevertheless, the most crucial data will also be presented here for better context.

The full-scale test was conducted on two slabs, one of SFRC and one of SFRSSC. The tested slabs were directly placed on a grid of columns, mimicking piles, spaced at a grid of 3000 mm by 3000 mm, diameter of the columns being 300 mm. To imitate the internal span behaviour without influence from close edges, additional spans of various distances were introduced as shown in Fig. 1. The slabs were constructed as flat slabs, without drop panels or pile heads, freely supported and unconnected to the columns. The thickness of both slabs was 150 mm, with a span-to-depth ratio being 20 which is in the common range of industrial elevated ground slabs.

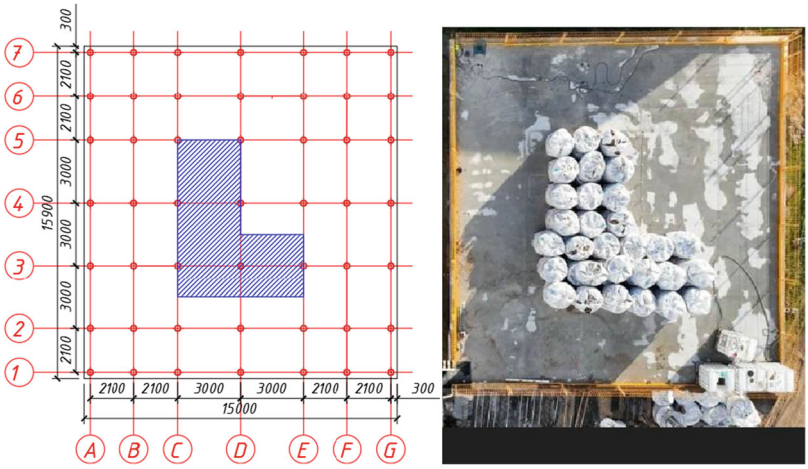

Fig. 1 Load layout: left: scheme and right: actual

Table 1 Material composition for SFRC and SFRSSC

Material	Amount (kg/m^3)	
	SFRC	SFRSSC
CEM II/A-LL 52.5 N	360	360
Water	162	162
w/c ratio	0.45	0.45
0–8 mm sand	952	952
5–16 mm crushed dolomite	914	914
PrīmX flow HRWRA	3.6	3.6
Hooked end steel fibres ($L = 60$ mm, $d = 0.9$ mm)	50	50
PrīmX DC	–	40

2.1 SFRC and SFRSSC Composite Composition

The material composition of the SFRC and SFRSSC is given int Table 1.

The mix designs show the only difference between the two slabs being a self-stressing agent with a brand name PrīmX DC. The reinforcement of the slabs is fibre only, 0.9 mm in diameter, 60 mm in length, and hooked-end steel fibres with 1500 MPa tensile strength. The concrete met the requirements of C30/37 concrete class with an S4 slump.

To reduce the necessary water amount and maintain workability, PrīmX Flow high-range water reducing admixture (HRWRA) was introduced for both mix designs.

2.2 Loading

The full-scale slabs were tested by placing loads on the slab in SLS levels and up to collapse; thus, the test was load-governed. The assumed SLS level for the comparison was set to be approximately 25 kN/m^2, but the actual SLS levels for the slabs given the criteria of deflections and cracking for such slabs were observed after the test based on measurements of the behaviour of the slabs. The loading layout was chosen following a similar test done for a similar structure [10].

The loading pattern allows achieving the maximum possible positive and negative bending moments and the largest possible deflections, see Fig. 1.

The slab was loaded by placing sandbags in layers, where each layer is regarded as a load level (LL). Seven distinctive points in the loading programme can be detailed, called loading situations (LSs), see Fig. 2.

The loading material chosen was dry, sieved sand, weighed, and secured in big-bags of 1000 kg or 10 kN per bag. This allows for the loading steps to be of uniform value, and the weight of the bags did not change due to rain and water puddling on the slabs. The usage of sand in big-bags allowed to alleviate any possible interlock between the bags, thus eliminating any arching effect which would otherwise be present in stiff materials, *p.e.* bricks, pavement bricks, concrete blocks etc. The assumed SLS load level, LL3, is set to be 25 kN/m^2.

2.3 Instrumentation on Site

To measure the structural response of the slabs, a multitude of measuring systems was introduced in the experiment, *p.e.* fibre optic sensors for strain measuring, digital image correlation, linear variable differential transformer displacement

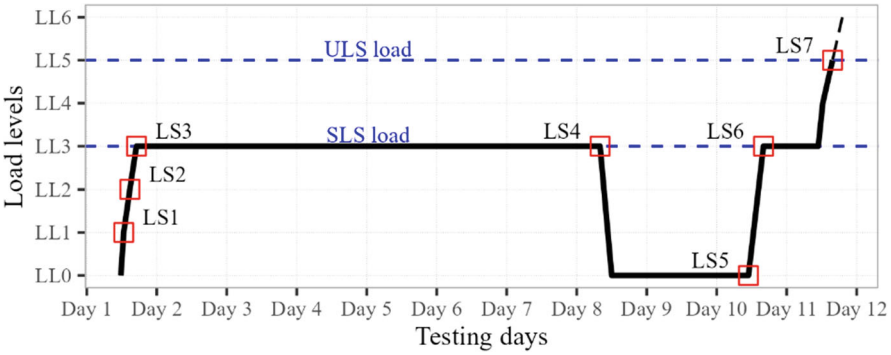

Fig. 2 Loading sequence with characteristic points denoted as loading situations

sensors (LVDTs) for deflection, piezoelectric strain gauges and vibrating wire strain gauges (VWSG), among others. The instrumentation is described in more detail in the following publication [9] and will not be further discussed in this publication.

2.4 Lab Tests

A multitude of samples were prepared during the pouring of the slabs to assess the various properties of the used concrete, *p.e.* concrete compressive strength, residual flexural strength and plastic tensile strength, among others. The samples created ranged from cubes of 100 × 100 × 100 mm^3 according to EN12390-2, 150 × 150 × 600 mm^3 beams according to EN14651 and EN12390-5, slabs $d = 800$ mm and $h = 100$ mm according to ACI544.6R-15, slabs $d = 1500$ mm and $h = 180$ mm according to ACI544.6R-15, up to samples of beams, cores, cylinders and slabs cut out and drilled from the tested structure itself.

The post-cracking residual strength and the plastic tensile strength of the concrete were evaluated for a comparison of a similar testing methodology for a similar composition of SFRSSC continuing a previously done experiment [11, 12] where a comparison between different testing methods and their results was done to evaluate the impact of chosen testing methodology on the necessary thickness of the structure.

3 Equivalent Design

The results of the two slabs revealed that the SFRC slab exhibited larger deflections, larger crack openings and longer cracks lengths under the same loading conditions as SFRSSC, see Fig. 3.

The final failure load of the two slabs was also significantly different where the SFRC collapsed at 45.7 kN/m^2 and the SFRSSC collapsed at 60.5 kN/m^2, thus a 32.3% increase over the performance of the SFRC. At the same loading levels, the SFRSSC exhibited 33% lower deflections at the assumed SLS load, LL3. 6 mm for the SFRSSC and 9 mm for the SFRC. Additionally, the top surface cracking of the SFRSSC was limited to a single crack of 0.04 mm width, while the SFRC exhibited a noticeable cracking fan pattern on the top surface after LL3 loading, see Fig. 4.

Taking the results into account, it can be concluded that the actual values of SLS loading that meets the SLS criteria for the two slabs is 19 and 28 kN/m^2 for SFRC and SFRSSC, respectively, thus a 47% increase in the loading intensity. To achieve the same load bearing capacity, the slab of SFRC with the same material properties should therefore be designed with a thickness of 180 mm versus the 150 mm SFRSSC slab, thus a 16.6% decrease in thickness.

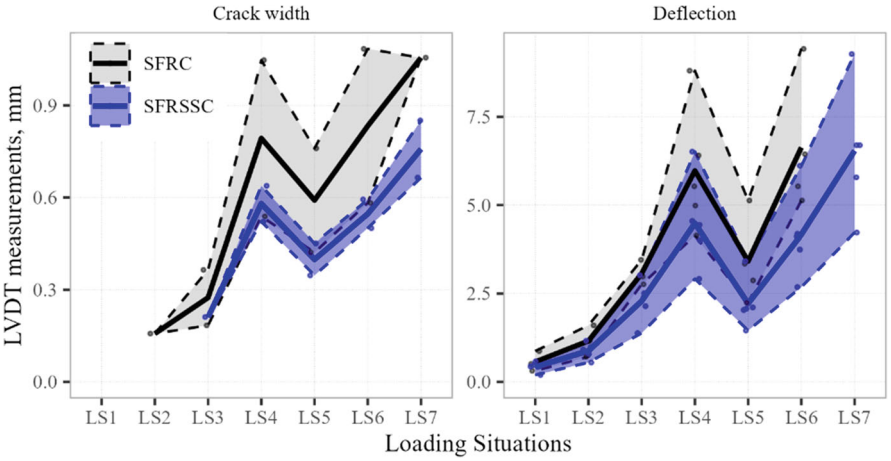

Fig. 3 Comparison of crack width and deflections measured by LVDTs for SFRC and SFRSSC slabs at different loading situations

Fig. 4 Comparison of crack patterns in place of maximums negative bending moment after LL3, left: SFRC and right: SFRSSC

4 CO_2 Emission Calculations

Based on the equivalent designs discussed in Sect. 4, a comparison of CO_2 emissions for multiple solutions, i.e., SFRSSC, SFRC and welded wire mesh reinforced concrete (WWMRC), can be done, see Table 2.

To develop an envelope of CO_2 emissions for the solutions ranging from the worst case to the best, a combination of the materials was used using either the greenest or the least green options. The outcomes and their comparisons are shown in Table 3. The greenest options are denoted with a letter "G." The solutions are ranked from 1 to 6 with 1 being the greenest and 6 the least green solution.

From Table 3, it can be clearly seen that at the same circumstances the SFRSSC solution emits the least amount of CO_2, while the WWMRC emits the most. This is true for both the greenest solutions and the less green solutions. Depending on the solutions to be compared, the SFRSSC solutions provide from 11% to 59% reduction while SFRSSC G solutions provide from 8% to 24% reduction when comparing similarly green solutions.

The presented calculation covers only the materials part and does not include other areas of productions, *p.e.* transportation of materials to site etc. Following that there is less material to be transported and poured in situ, the actual CO_2 savings are even higher than the values presented here, yet it is not feasible to cover this topic in this publication due to the transportation costs being highly linked with the location of the project and may highly vary.

Table 2 Comparison of CO_2 emissions for different components of concrete

Material	Specific emissions	CO_2 emissions (kg/m^2)		
		SFRSSC	SFRC	WWMRC
Concrete C30/37 [13]	273 kg CO_2eq/m^3	40.95	49.14	49.14
Green concrete C30/37 [13]	230 kg CO_2eq/m^3	32.25	38.70	38.70
Reinforcement [14]	1.14 kg CO_2eq/kg	–	–	36.94
Green reinforcement [15]	0.30 kg CO_2eq/kg	–	–	9.72
Steel fibres [16]	1.24 kg CO_2eq/kg	9.26	11.12	–
XCarb steel fibres [16]	0.37 kg CO_2eq/kg	2.74	3.29	–
HRWRA [17]	0.30 kg CO_2eq/kg	0.16	0.2	0.2
PrīmX DC [18]	0.65 kg CO_2eq/kg	3.9	–	–

Table 3 Comparison of CO_2 emissions for different systems

System	CO_2 emissions (kg/m^2)	Rank
SFRSSC	54.28 kg CO_2eq/m^2	4
SFRSSC G	39.05 kg CO_2eq/m^2	1
SFRC	60.45 kg CO_2eq/m^2	5
SFRC G	42.18 kg CO_2eq/m^2	2
WWMRC	86.27 kg CO_2eq/m^2	6
WWMRC G	48.62 kg CO_2eq/m^2	3

5 Results and Discussion

The full-scale tests showed that the SFRSSC slab exhibited smaller deflections, less crack widths and less overall cracking at the same load levels as explained previously. The actual SLS load for SFRC was of 19 kN/m^2, while the SFRSSC reached SLS state at 28 kN/m^2; thus, for the same loading conditions, the SFRSSC slab can be thinner when compared to the SFRC slab due to the self-stressing effect of PrīmX DC.

From the premise that the SFRSSC slab can be thinner than the SFRC slab for the same loading conditions, it is possible to estimate the CO_2 footprint of the systems, which shows significant benefit in reduction of the CO_2 gas emissions by up to 59%. The calculations of the CO_2 emissions also show that at the worst case the SFRSSC solution has less emissions than at any of the best cases of the comparative solutions. In case green concrete and green fibres can be used, the greenhouse gas savings are increased significantly by up to 24%.

6 Conclusion

The full-scale tests of SFRC and SFRSSC along with appropriate calculations shown in this publication reveal the following conclusions:

- At failure, the SFRSSC slab held 33% higher load than SFRC.
- At the same loading conditions, SFRSSC exhibited approximately 33% lower deflections.
- At the same loading conditions, the SFRC exhibited almost no cracking on the top surface.
- For the same loading conditions, the SFRC would render a slab of 180 mm thickness versus 150 mm for SFRSSC.
- The usage of SFRSSC system lowers carbon emissions by 8–55% when compared to regular SFRC and by 10–51% when compared to WWMRC.

Acknowledgement The data presented in the publication are based on the research project executed by Primekss SIA, which has been funded based on an agreement No. 5.1.1.2.i.0/1/22/A/CFLA/005 between CFLA and Primekss SIA, which has been granted from "Atveseļošanās un noturības mehānisma līdzfinansējums."

1 Introduction

The conventional method of producing concrete with Ordinary Portland Cement (OPC) significantly contributes to pollution, primarily through the release of carbon dioxide during cement production and construction activities. Additionally, the disposal of concrete waste further exacerbates environmental issues, as it remains in the environment for extended periods of time. Consequently, researchers have turned their attention to finding sustainable alternatives to OPC. One such alternative gaining significance is geopolymer, which is formed through the reaction of various

materials, including natural pozzolans, industrial by-products like fly ash (FA) and Ground Granulated Blast Furnace Slag (GGBS), and agricultural waste such as rice husk ash and sugarcane bagasse. When activated with alkalis, these materials offer a promising substitute for OPC in concrete production [1, 2].

Geopolymer concrete (GPC) is a viable alternative to conventional concrete. Recent research on this rather new type of concrete has revealed promising outcomes concerning its tensile and compressive strength and durability across different curing conditions [3].

Researchers have examined the performance of GPC using various nanomaterials and additives, with varied percentages of components under various conditions [4]. One extensively studied variant of GPC is fly ash-based GPC, which has been subjected to rigorous experimental studies and comparison with the outcomes obtained from incorporating other additives such as GGBS [2, 5].

This study aimed to assess the impact of various components on the compressive strength of fly ash-based GPC. For that purpose, a comprehensive experimental dataset was gathered. Initially, the accuracy of linear regression to estimate the compressive strength of the specimens was investigated. Subsequently, a machine learning approach, such as XGBoost, was implemented. Finally, the significance of each feature in influencing the compressive strength of fly ash-based GPC was analyzed and evaluated.

2 Dataset Construction

2.1 Experimental Data Collection

In the framework of this study, the effect of various constituents within fly ash-based geopolymer concrete on compressive strength $\left(f'_c\right)$ of GPC has been explored. The dataset collected to assess through a machine learning approach is outlined in Table 1. Notably, all examined specimens feature fly ash-based geopolymer concrete, with some incorporating Ground Granulated Blast Furnace Slag (GGBS), Coal Bottom Ash (CBA), and Copper Slag (CS), alongside additional additives like steel fiber and rubber. A comprehensive dataset comprising 157 specimens has been compiled for analysis.

In the selected specimens, GPC with alkaline activator of NaOH and Na_2SiO_3 with concentration ranging from 1.4 to 16 M was studied. To ensure a comparable dataset, the specimens that are cured in ambient condition and tested on the 28th day were selected.

2.2 Data Visualization

The components constituting a standard FA are elaborated in Table 2. It is evident from the data that SiO_2 comprises the largest portion of FA. Following closely is Al_2O_3, with Fe_2O_3 being the third most prevalent component.

Table 1 Experimental dataset

Research	Source Material	Alkaline solution	Coarse aggregates	fine aggregates	Extra additive	Curing condition	Testing age (Day)
Hassan et al. [6]	FA	NaOH and Na_2SiO_3 (10 M)	√	√	–	Ambient	28

As the target is to evaluate the effectiveness of each component on the compressive strength $\left(f'_c\right)$ of GPC, the first step it to compare the effect of all features on f'_c using Probability and Statistics. A total of 16 features are investigated, in which SiO_2, Al_2O_3, Fe_2O_3, CaO, P_2O_5, SO_3, K_2O, TiO_2, MgO, Na_2O, MnO, steel fiber, rubber, coarse aggregates, and fine aggregates are in Kg/m^3 and NaOH is in Mol/Liter.

The correlation matrix offers statistical insights into the relationships between input and output parameters [21, 22], which is shown in Fig. 1a, b. The figure indicates that there is a strong correlation between the amount of CaO and MgO, with values of 0.55 and 0.54, respectively, and f'_c of the selected specimens. These positive values signify that as the quantities of these features increase, it results in an increase in f'_c. Additionally, the weakest correlation is related to SiO_2 and f'_c.

2.3 Linear Regression

Linear regression (LR) can be used to estimate the relationship between a dependent response and independent variables [23, 24]. To mitigate overfitting, where a model excels on the training dataset but fails to perform properly on new data, it is crucial to evaluate the model using a separate test dataset. This evaluation enhances the accuracy of the model. Additionally, employing the R^2 score method, as depicted in Eq. (1), enables the determination of the level of agreement between two parameters, namely the actual values and the predicted targets [25]. In Eq. (1), $y_{\text{test},\ i}$ and $\widehat{y}_{\text{test},i}$ represent the actual and predicted values for this set, respectively. The mean value of the target for this dataset is denoted by $\overline{y}_{\text{test}}$, and N represents the number of specimens.

$$R^2 = 1 - \frac{\sum_{i=1}^{N}\left(\widehat{y}_{\text{test},i} - y_{\text{test},i}\right)^2}{\sum_{i=1}^{N}\left(\widehat{y}_{\text{test},i} - \overline{y}_{\text{test}}\right)^2} \tag{1}$$

Using LR, as shown in Fig. 2, R^2 value for train and test data was obtained 0.73 and 0.78, respectively. This indicates that LR can predict the f'_c of the gathered specimens with an acceptable accuracy.

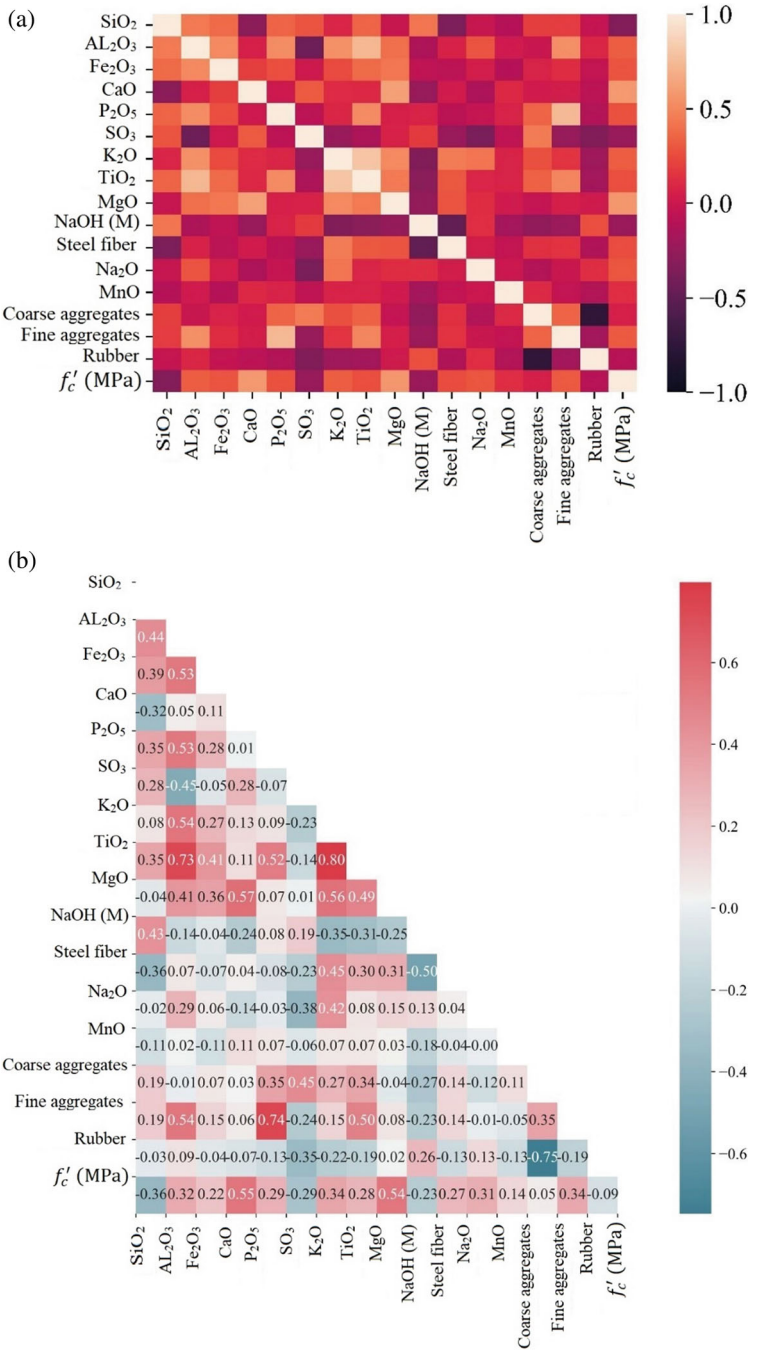

Fig. 1 Correlation matrix between input and output parameters

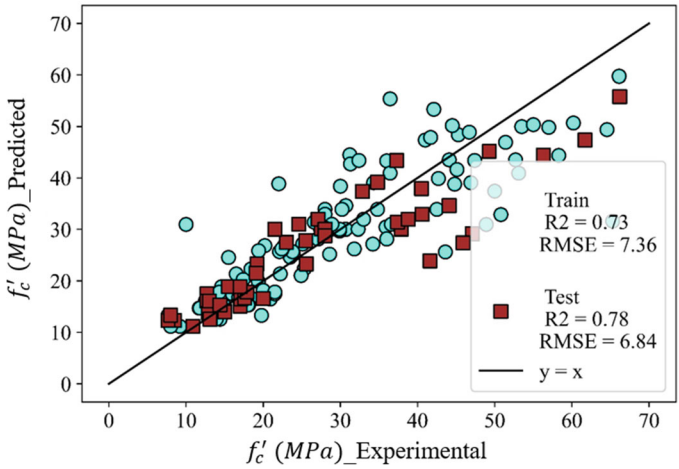

Fig. 2 f'_c prediction using linear regression

2.4 Machine Learning Method

2.4.1 XGBoost Method

Recent research across various domains, particularly in structural engineering, has demonstrated the effectiveness of machine learning techniques in accurately predicting the characteristics and behavior of diverse structural systems and materials [26–30].

In this study, XGBoost method was employed to evaluate the effect of different components of fly ash-based GPC on f'_c.

3 Results and Discussion

3.1 XGBoost Output

Figure 3 compares the experimental data and the predicted f'_c using XGBoost approach. As can be seen, R^2 values of the train and test data are 0.98 and 0.86, respectively. This indicates that this approach can predict the f'_c using the provided dataset with excellent accuracy. In addition, this shows that the method is more accurate than LR method in foreseeing the f'_c of the specimens.

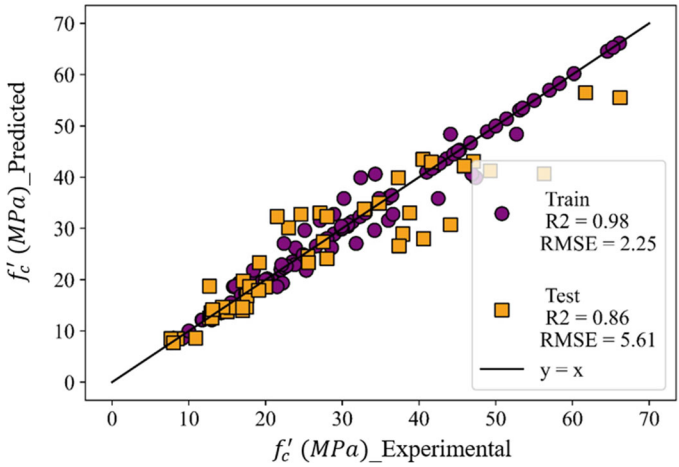

Fig. 3 Prediction of f'_c using XGBoost method

3.2 Shapley Values Technique

Figure 4a, b illustrates the findings of Shapley values technique, which assesses the significance of each feature on the target value (f'_c). It is evident from Fig. 4b that elevated levels of SO_3, SiO_2, and MnO are associated with a negative impact on f'_c, whereas the remaining features demonstrate the opposite trend.

Figure 4a shows that MgO is considered to be the most influential factor affecting the value of f'_c. In addition, as depicted in Fig. 4b, a high value of this feature leads to an increase in the value of f'_c.

Coarse aggregates and SO_3, identified as the second and third features with significant effects on f'_c, demonstrated completely opposite impacts. While an increase in the quantity of coarse aggregates positively influences the target value, SO_3 follows a reverse trend.

Interestingly, despite SiO_2 and Na_2O sharing the same level of significance, as seen in Fig. 4a, their impacts on f'_c are opposite. An increase in the quantity of SiO_2 results in a decline in f'_c, whereas the opposite is true for Na_2O.

Though SiO_2, Al_2O_3, and Fe_2O_3 account for a significant portion of the specimens, as demonstrated in Table 2, the impact of Al_2O_3 and Fe_2O_3 on the target value was found to be less than that of other features with lower values. Furthermore, SiO_2 negatively influences f'_c. This suggests that these features are not as significant when providing concrete mixtures where compressive strength is of utmost importance.

Additionally, the figures highlight the importance of fine aggregates in determining the f'_c of the specimens under study, though its importance is identified to be less than half that of coarse aggregates.

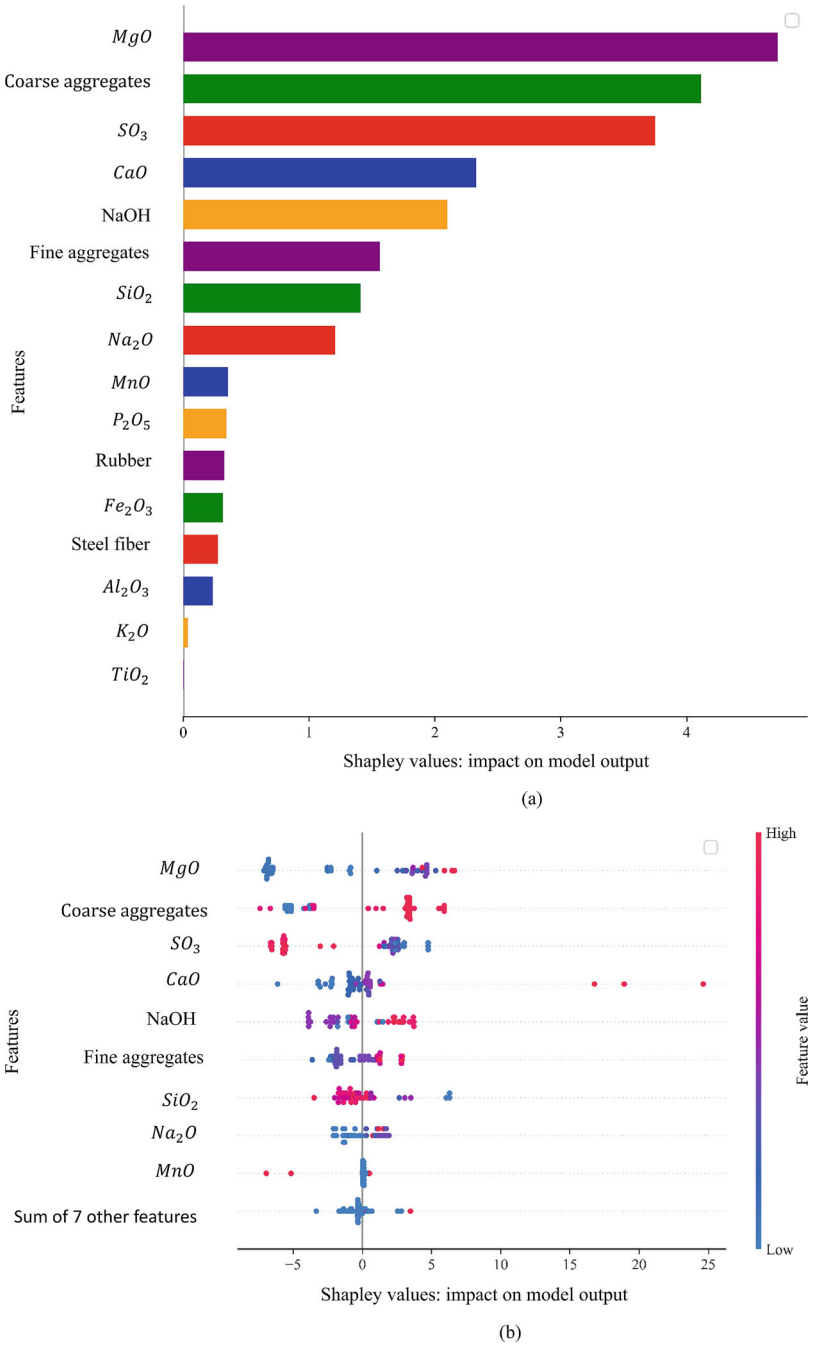

Fig. 4 Utilizing Shapley values technique to evaluate the significance of various features on f'_c

The increase in the molarity of the alkaline activator, NaOH, has a positive impact on the f'_c. Furthermore, according to the findings, TiO_2 is considered the least effective component of FA-based GPC on the target value. In addition, additives such as steel fiber and rubber showed a similar response, indicating an insignificant impact on compressive strength.

To ensure the validation of the obtained results, other machine learning methods, namely Decision Tree, Random Forest, or other methods, which are out of the scope of this research, can be used. In addition, this study focused on the experimental specimens cured in the ambient condition. To obtain a more comprehensive outcome, in future studies, the dataset acquired in varied temperatures can be selected to investigate the role of the curing temperature as a feature.

4 Conclusion

To evaluate the compressive strength (f'_c) of fly ash-based GPC, a machine learning approach was employed. The effect of various features, namely SiO_2, Al_2O_3, Fe_2O_3, CaO, P_2O_5, SO_3, K_2O, TiO_2, MgO, Na_2O, MnO, steel fiber, rubber, coarse aggregates, fine aggregates, and NaOH, was assessed using Linear Regression and XGBoost methods. Additionally, the effect of each feature on the target output (f'_c) was assessed utilizing the Shapley values technique. The findings of this research can be highlighted as follows:

- The linear regression method successfully predicts f'_c of fly ash-based GPC, achieving R^2 values of 0.73 for the training data and 0.78 for the test dataset. However, when utilizing the XGBoost method, the predicted f'_c demonstrates even higher accuracy. The R^2 values for the training and test data are notably improved, reaching 0.98 and 0.86, respectively. This suggests that the XGBoost approach can accurately predict f'_c using the provided dataset. Consequently, the XGBoost method outperforms the linear regression method in forecasting f'_c of the specimens.
- The increased concentrations of SO_3, SiO_2, and MnO are linked to a negative effect on f'_c, while the other features indicated a contrasting pattern.
- MgO is regarded as the most significant factor influencing the value of f'_c. Furthermore, a high level of this feature results in an increase in the f'_c value. Coarse aggregates and SO_3, identified as the second and third features with significant effects on f'_c, exhibited contrasting impacts. An increase in the quantity of coarse aggregates positively affects the target value, whereas SO_3 follows a reverse trend. Similarly, though SiO_2 and Na_2O are equally significant, their impacts on f'_c are contradictory. While an increase in SiO_2 decreases f'_c, the opposite is observed for Na_2O.
- The outcomes underscore the significance of fine aggregates in determining the f'_c of the specimens under study, although their importance is found to be less than

half that of coarse aggregates. Additionally, an increase in the molarity of the alkaline activator, *NaOH*, positively impacts f'_c.

- According to the results, TiO_2 is regarded as the least effective component of FA-based GPC on the target output. Moreover, additives such as steel fiber and rubber exhibited a similar response, both of which were considered insignificant.
- Despite SiO_2, Al_2O_3, and Fe_2O_3 being a significant portion of the specimens, the findings indicated that these features are not as crucial when it comes to providing concrete mixtures where compressive strength is of importance.

produce concretes with alternative materials. Therefore, many natural and artificial minerals have been tested for this purpose. Among these materials are silica fume, fly ash, Metakaolin, and slag [2]. With the increase in steel production in the world, the amount of blast furnace slag, which is a byproduct of this industry, is also increasing. Since the conducted researches point to the high potential of using steel slag in the concrete industry, both as aggregate and as a cement supplement, currently the most important part of slag consumption in the world is the cement and concrete industry [3]. Of the four types of slag produced in the steel industry, ground granulated blast-furnace slag (GGBS) is the most widely used cement material [3]. GGBS is an industrial waste that is rich in CaO, SiO_2, and Al_2O_3, which makes its use as a substitute for cement valuable. The use of GGBS as a part of the cement can lead to a reduction in cement consumption and thus a reduction in greenhouse gas production [4, 5]. By improving the cement paste structure and strengthening the transition zone, GGBS improves the strength and durability of concrete [6]. Many articles have confirmed the positive effect of GGBS on different properties of concrete [7–9].

On the other hand, in recent years, the problems of using steel, such as heavy weight, corrosion, and its difficult implementation, have led researchers to seek to replace steel with a suitable material. Using fibers is one of the alternative methods. One of the most famous known ways to improve tensile and bending strength is the use of fibers [10]. Many studies have shown the positive effect of steel fibers on concrete properties, especially tensile strength [11–13].

Lightweight concrete has less weight than ordinary concrete, and the reason for this lightness is due to the use of lighter aggregates in its structure. Making lightweight concrete with these aggregates makes its compressive strength and density lower than ordinary concrete, and for this reason, lightweight concrete is used less as structural concrete. On the other hand, in lightweight concrete, the bond between aggregate and matrix is stronger than in normal concrete. Due to the porous nature of the aggregates, the cement paste penetrates it. Therefore, there is no transition zone between the aggregates and the matrix, or if there is, it is very small. This issue is very important in terms of concrete reliability because this area is the weakest area in normal concrete [14].

In this study, the simultaneous effect of waste steel fibers and GGBS in lightweight concrete has been investigated. Considering that the use of GGBS improves the durability and compressive strength of concrete in the long term, and also that steel fiber can improve the tensile strength of concrete, the use of these two materials in lightweight concrete can compensate for the loss of strength and durability caused by the use of lightweight aggregates in concrete. In addition, the use of two waste materials in concrete is an action towards sustainable development.

2 Materials and Methods

The fine aggregate used in this study is river aggregate. Coarse aggregate is also light aggregate obtained from natural mines. The properties of the aggregates are given in Table 1.

Table 1 Properties of aggregate

Properties	Fine aggregate	Lightweight coarse aggregate
Specific gravity (kg/m^3)	1843	466
Maximum size of aggregate (mm)	4.75	12

Fig. 1 Steel Fiber

Used cement is ASTM type II from Nayin factory, Iran, and GGBS is obtained from Isfahan Zobahan Factory, Iran. The chemical composition of GGBS and cement is shown in Table 2.

In this research, waste steel fibers (Fig. 1) have been used, the specifications of which are given in Table 3.

The mix designs are shown in Table 4. In this table, the word S means slag and the word F means steel fiber, and the percentage written in front of each letter means the percentage of its use in the mix design.

To make the samples, in the first stage, cement and fine aggregate were completely mixed together, and then, if used, slag or fibers were added, and the slag or fibers were completely mixed, and then light coarse aggregate was added and mixed. In the last stage, water and superplasticizer are added and mixed for 10 minutes until a homogeneous mixture is obtained. After preparation, the samples were cured in saturated lime water until the test was performed, and then compressive strength (7, 28, and 90 days), tensile strength (28 and 90 days), and water absorption (28 and 90 days) tests were performed on the samples. Compressive

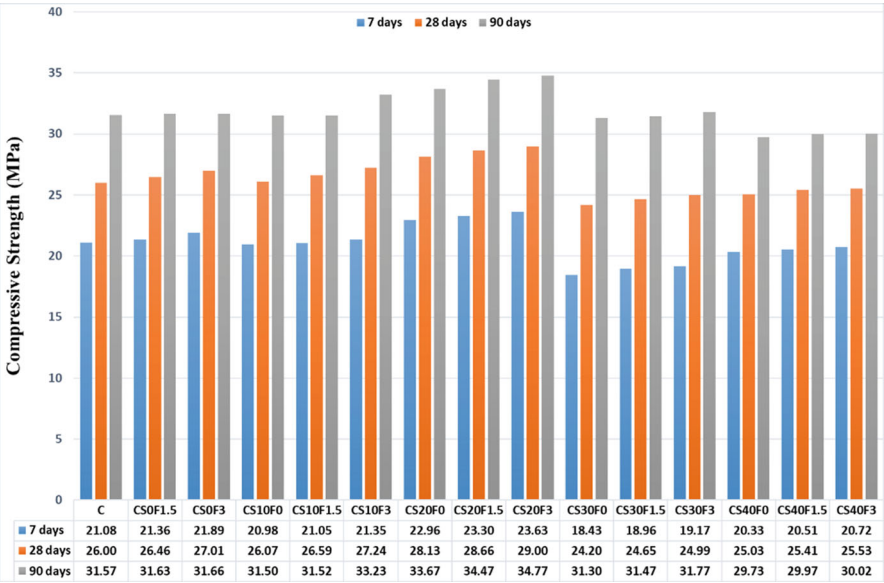
strength tests were conducted in accordance with the BS EN 12390 standard, tensile strength tests were performed following the ASTM C496 standard, and water absorption tests were carried out according to ASTM C642.



Each test was performed on three samples and 316 samples were prepared for 15 mix designs.

3 Results and Discussion

The compressive strength test has been performed for 7-, 28-, and 90-day cubic samples (10 × 10 × 10 cm). The results are shown in Fig. 2.

The compressive strength has not changed much with the use of fiber. Fiber has little positive effect on compressive strength due to the confinement of steel fibers in samples [15] and no negative effect has been observed. In higher amounts of fiber use, the use of slag has the effect of increasing fiber effect and has led to improved strength. One of the reasons for increasing the compressive strength by using fibers is the reduction of microcracks in the cement paste structure [16].

The use of slag has probably had a positive effect. At the age of 7 days, a slight decrease in strength has been observed in some samples, at older ages, especially at

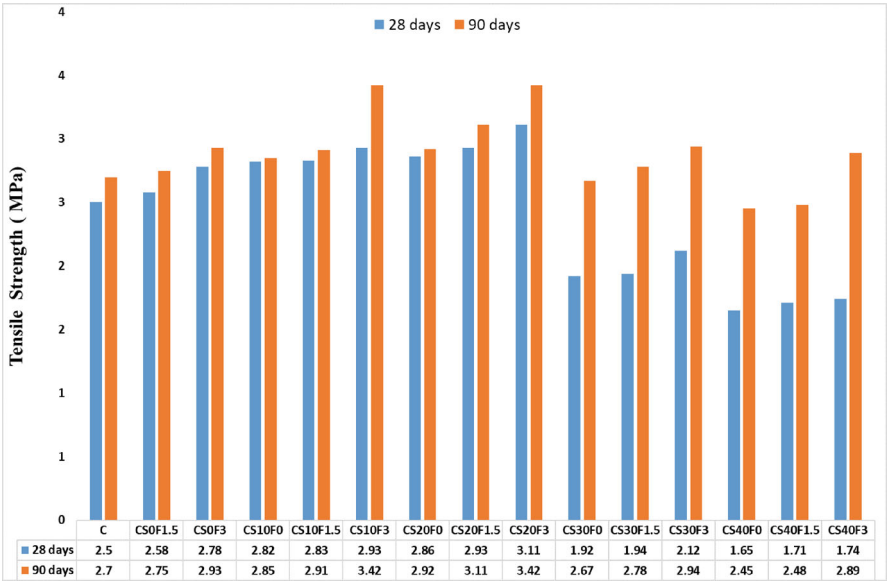
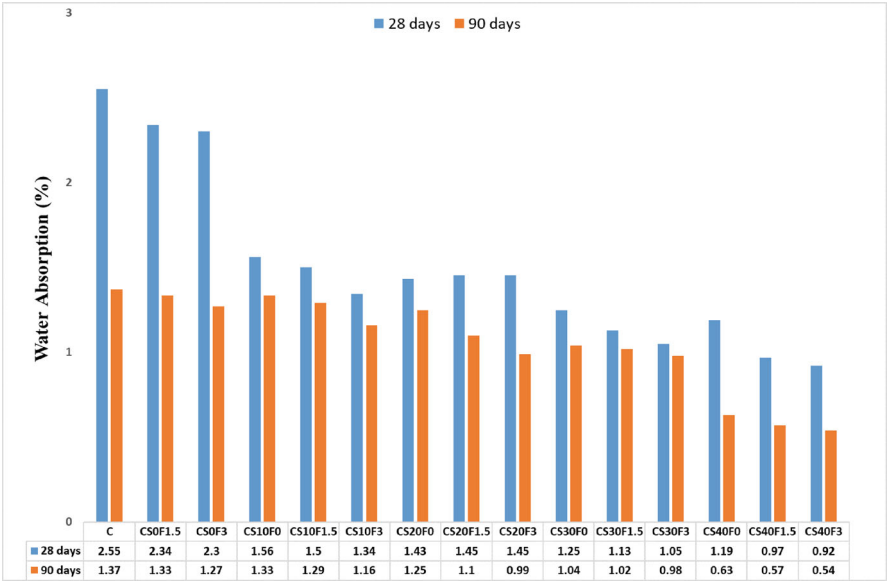
Fig. 2 Compressive strength



the age of 90 days, the increase in strength with the use of slag is quite evident. The reaction of SiO_2 in GGBS with CH leads to the production of new cement components, which improves the structure of cement paste and improves the strength properties of concrete [10].

The maximum compressive strength obtained was related to the sample containing 20% slag and 3% steel fiber, which had a compressive strength of about 10% more than the control sample. Because of the dilution effect, the use of 30% slag has led to a decrease in strength [10]. Therefore, it can be said that 20% of slag is the optimal amount of use.

The tensile strength test has been performed for 28- and 90-day cylindrical samples (15 × 30). The results are shown in Fig. 3.



The effect of slag on the tensile strength was similar to the effect of this material on the compressive strength of concrete, but steel fiber had a better effect on the tensile strength as expected. Some studies have shown that the use of GGBS has a better effect on the compressive strength compared to the tensile strength of concrete [3, 6].

Steel fiber leads to an increase in tensile strength and this positive effect is increased by increasing the amount of fiber used. The highest strength obtained is related to the samples containing 10 and 20% of slag along with 3% of steel fiber, which is about a 27% increase compared to the control sample. Therefore, the positive effect of steel fibers can be seen in this study. Usually, small cracks are formed in concrete due to various reasons, including thermal stresses [17], which lead to a decrease in tensile strength. Fibers with increased tensile stress lead to a reduction of these cracks and improvement of concrete structure. Improvement of tensile strength using steel fiber has been reported in many studies [10–13, 18].

Fig. 4 Water Absorption

The water absorption test has been performed for 28- and 90-day cubic samples (15 × 15 × 15). The results are shown in Fig. 4.

The use of fiber has not had a great effect on water absorption and no specific conclusion can be drawn in this regard, but the use of slag has reduced the water

absorption of concrete. This reduction in water absorption has increased with the increase in the use of slag. For the 28-day sample, the maximum reduction in water absorption compared to the control sample was about 60%. The production of a less porous cement paste structure using GGBS has led to a decrease in the permeability of concrete [19].

4 Conclusion

In this study, the simultaneous effect of GGBS and steel fibers in lightweight concrete was investigated. After the tests, the following results were obtained:

- GGBS can compensate for the decrease in strength caused by lightweight concrete particles and improve the compressive strength and durability of concrete in the long term. The optimal percentage of using this material in lightweight concrete is 20%.
- The use of steel fiber can improve the tensile strength of lightweight concrete while not having any negative effect on other properties of concrete.
- The use of GGBS as a waste material as a substitute for part of cement, as well as the use of steel fiber waste, is an action to reduce greenhouse gases and an action in line with sustainable development.

1 Introduction

Cement production represents 5-8% of global CO_2-equivalent (CO_2-eq) emissions and is a major challenge on the path towards a future of net zero emissions while remaining a critical building material without many viable replacements [1, 2]. It is imperative to find low-emissions solutions that can reduce the overall global impact of concrete by finding new mixtures and binders for cement production, which are the main contributing factor for emissions from concrete and the largest contributor to emissions from construction materials [3–5]. Alternative concrete binders that have lower emissions are being developed, and one such binder is called geopolymer

cement. Geopolymer cement is made by mixing industrial wastes (typically from mining or incineration processes) with an alkaline solution, such as sodium- (NaOH) or potassium hydroxide (KOH), which can completely replace ordinary Portland cement [6]. Geopolymer concrete can be used in identical applications to standard concrete and can even have improved mechanical strength [7]. Life cycle assessment (LCA) studies of geopolymer concrete have shown a potential CO_2 emissions reduction estimated at 32–70% compared to standard concrete [8–11]. Further studies evaluating KOH show that compressive strength after 28 days is nearly equivalent to standard cement with a tangible reduction in environmental impacts [12, 13], though there are few LCA studies focusing on KOH as an alkaline solution.

In Norway, the company Saferock is developing a new geopolymer cement which utilises mine tailings from ilmenite production combined together with KOH [14]. Saferock utilises feedstock in their production process from ilmenite mine tailings found in the Norwegian area of Sokndal. The Sokndal site has more than 100 million tons of easily accessible norite materials for Saferock to use for producing geopolymer concrete. It is important to understand the environmental impacts of alternative materials and to see if they are beneficial for exploitation or not. Thus, the purpose of this study is to evaluate the environmental impacts of Saferock's geopolymer cement. This is done by using life cycle assessment (LCA) to quantify the emissions that come from producing the geopolymer cement and concrete.

2 Methods

This study uses standard LCA methods as described in ISO 14040, where goal and scope, inventory analysis, impact assessment and interpretation are carried out [15]. LCA is a useful tool for understanding the environmental impacts of systems or processes with a standardised methodology that can be used to quantify impacts throughout the life cycle of a product or system (Fig. 1).

The goal of this study is to understand the environmental impacts of the Saferock concrete mix based on their pilot production facility near Stavanger, Norway. The scope of the study is cradle-to-gate, which covers the emissions of the production of their geopolymer concrete based on real-inputs from the Saferock process. Life cycle inventory (LCI) data was collected for this study from communication and meetings with Saferock, technical documents from the company, and basic calculation from an assumed distance of 80 km for materials for aggregate materials and transport to the Saferock production site. Material mixes for aggregate in the concrete mix were given from Saferock. The assumed energy in production is based on the Norwegian market energy mix.

SimaPro was used to carry out the analysis with the EcoInvent 3.7.1—"-allocation, cut-off by classification" database and the ReCiPe 2016 (midpoint, H) impact assessment method. The functional unit is 1 m^3 of B35 geopolymer concrete with the geographical boundaries of Norway. The study is a cradle to gate study encompassing the production at Saferock in Sokndal, Norway.

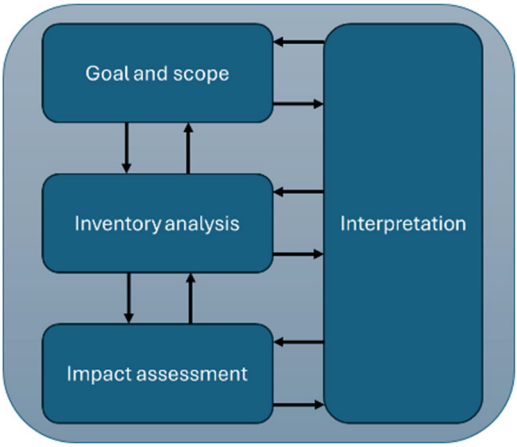

Fig. 1 Life cycle assessment methodology

3 Case

The Norwegian company Saferock is in the development phase of its geopolymer concrete. They make the cement and the concrete in a laboratory, but they have received support to build a pilot factory to test production on a larger scale, which is scheduled to be completed in early 2024 and have a production capacity of 30 m^3 geopolymer concrete per day. The next step is to build a factory at the Titania norite mine, where norite waste materials from ilmenite production can ground into a fine powder of less than 63 μm (Fig. 2). This is then sent out, along with activator in powder form, for customers who will mainly be concrete mixing plants. In the mixing plants, this powder is mixed with KOH as an activator, water and aggregates. Saferock's geopolymer concrete has compressive strengths equivalent to B35. It is assumed that the concrete is reinforced in the same way as normal concrete, although this has not been tested when this study was carried out. There are also challenges with the regulations for which cement can be used in constructions. This geopolymer concrete is not approved for use in Eurocode 2. According to the concrete standard NS-EN 206, only cements from three standards can be used: EN 197-1, NS-EN 14647 and NS-EN 15743, where geopolymer concrete is not yet approved [16] (Fig. 3).

The basic system description and system boundaries of this study are shown in Fig. 4.

The system includes all processes from collecting and grinding mine tailings from the Titania site, addition of sand and gravel in the aggregate, KOH and water in activator material, and mixing in the plant. The resource and emission loads in the life cycle inventory are normalised to 1 m^3 of geopolymer concrete. The study does not account for the transport of concrete to construction site, nor the construction, maintenance, and end-of-life processes, which are assumed to be identical to standard B35 concrete.

Fig. 3 The Titania ilmenite mine and tailings in Sokndal as seen from above

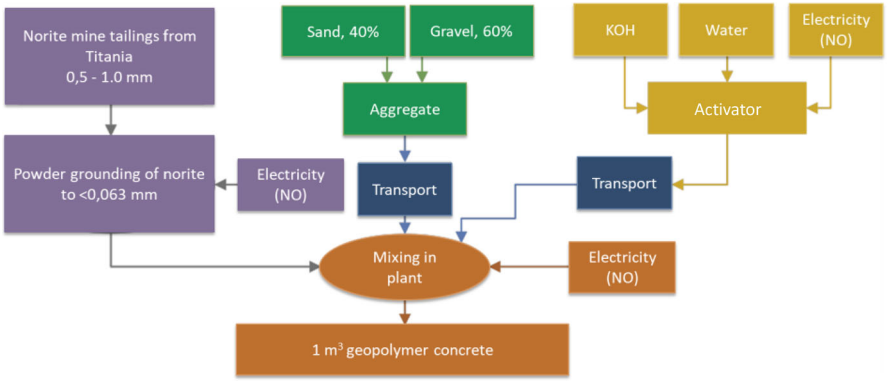

Fig. 4 Saferock B35 geopolymer concrete production LCA system boundaries

4 Results

Table 1 shows the LCI of the production mix of the Saferock concrete. The mix is based on the Saferock's production recipe for normal geopolymer concrete as well as an optimal mix that reduces the amount of norite powder and KOH powder considerably. The optimal mix is what Saferock would like to achieve in the future where water is reduced to under 4.25% of the total mix of the activator materials (KOH and water) is under 5% of the total mass. The optimal mix is a theoretical mix tested in the Saferock laboratory while the Normal geopolymer concrete mix is the mix that Saferock has achieved in their pilot testing.

Figure 5 shows the total impact assessments results for the normal geopolymer concrete mix. The dominant process in all impact categories is the activator mix, almost entirely due to the KOH powder, which is assumed to have a European average production mix. The aggregate, sand and gravel process also has an impact ranging between 10 and 30% in most categories, where the norite powder is

Table 1 Saferock material inventory for 1 m^3 B35 geopolymer concrete

	Normal geopolymer concrete		optimal mix	
Material	%	kg	%	kg
Norite powder	35	1120	25	800
KOH-powder	2.25	46	0.75	15
Water	12.75	127	4.25	42
Sand	20	540	28	810
Gravel	30	780	42	1040
Additional materials	0	0	>0.001	2
Total	100	2613	100	2710

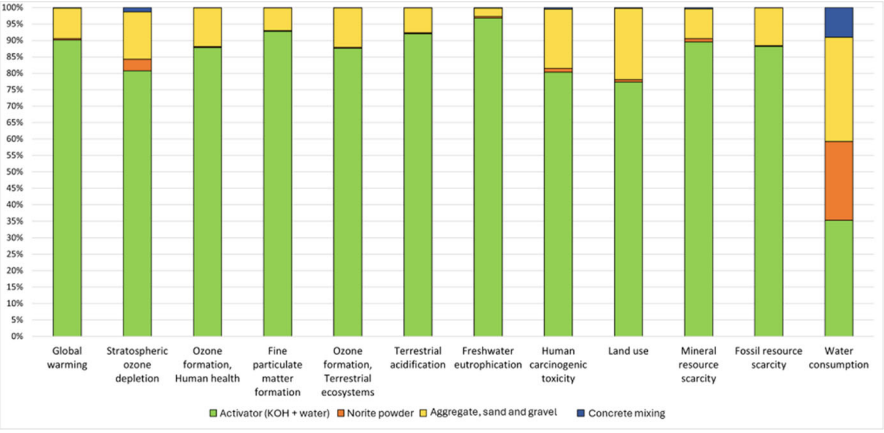

Fig. 5 Impact assessment results for 1 m^3 of Saferock normal geopolymer concrete (ReCiPe 2016. Midpoint H)

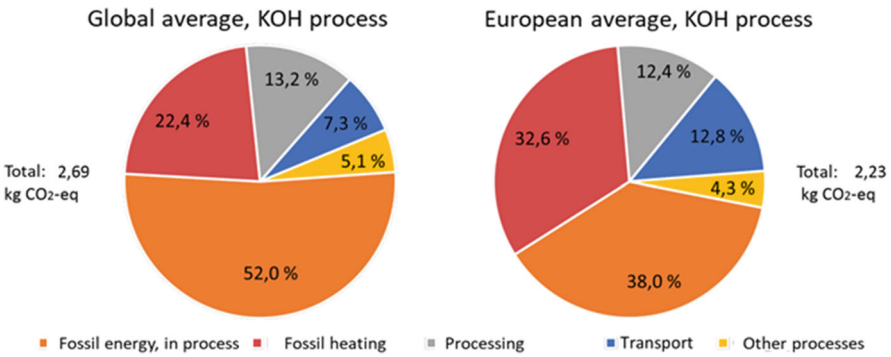

Fig. 6 Kg CO_2-eq. emissions per kg KOH produced, global and European averages

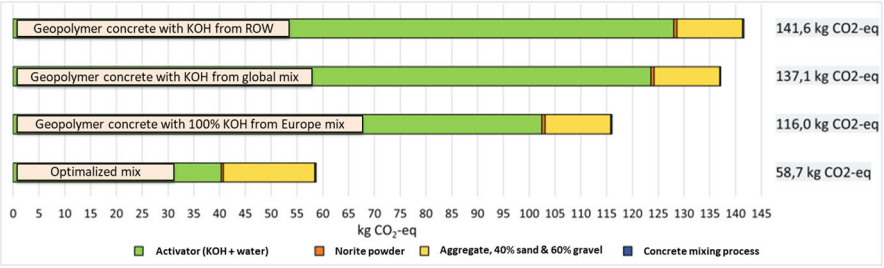

Fig. 7 GWP results of 1 m^3 B35 Saferock concrete based on alternative sources for KOH and optimal mix

insignificant in almost all impact categories. The dominance of the KOH process is due the choice of KOH in the EcoInvent database. At the time of this study, there were no significant or relevant LCA studies on KOH production, so the European average KOH process was used. This process is assumed to use a high level of fossil fuels in the production process.

Figure 6 shows the CO_2-eq. emissions profile of the KOH production process for the global and European average processes within EcoInvent 3.7.1 database. Fossil energy is assumed to be used in the production process, for heating, for additional processing, and in transport of the materials. The European average has slightly lower CO_2-eq. emissions due to overall higher process efficiency.

Figure 7 shows the GWP of 1 m^3 of Saferock concrete mix using the global average KOH, a generic rest-of-world mix, a European average KOH mix and an optimised concrete mix that reduces the need for KOH by more than 65% while also significantly reducing the norite powder as well. The range for 1 m^3 B35 Saferock concrete is 116 to 141.6 kg of CO_2-eq., while the optimised mix is significantly lower at 58.7 kg CO_2-eq per 1 m^3.

5 Discussion

The results of the LCA study show that the CO_2 emissions from the geopolymer concrete are less than half of those of a comparable standard concrete. Saferock concrete meets the Norwegian branch standard for "Low Carbon Extreme" concrete when using a generic European KOH mix. The KOH accounts for 90% of the emissions, but the background data on the emissions from this process are insufficient. The lack of data on KOH emissions is a considerable uncertainty in this study. It is recommended that Saferock acquire potassium hydroxide produced using renewable resources to further reduce their emissions and that their KOH supplier should carry out a full life cycle assessment of their production process (Table 2).

Previous LCA studies on sodium hydroxide-based (NaOH) geopolymer concretes had higher emissions than Saferock's geopolymer concrete, but had a GWP reduction of 10 to 45% relative to normal B35 concrete [18, 19]. These studies are not directly comparable to the Saferock process given the advancements in cement production and different admixtures used. The Saferock study results confirm previous study results showing the environmental advantages of geopolymer concrete.

The Saferock concrete is still in the development phase and has not yet been used in constructions at the time this study was carried out. This means that there are unknown uncertainties regarding logistics, use and safety of the final product, although these are assumed to be like normal concrete production.

An additional uncertainty is the use of reinforcing steel. Concrete technology is a complicated field that involves understanding many different chemical processes and how they affect each other. The basic environment in the geopolymer concrete should be a good starting point for the reinforcement, as it is similar to normal concrete. It is nevertheless conceivable that unwanted chemical reactions may occur due to the various ingredients in the concrete. This can have negative consequences for the reinforcement and should be investigated before the concrete can be put into use.

Saferock concrete is currently not approved for structural use in the Norwegian market. As the regulations are today, it is not allowed to use cements other than those

Table 2 Norwegian branch standards for GWP per 1 m^3 B35 concrete [17]

Concrete standard	kg CO_2-eq. per m3 B35 concrete	Reduction compared to branch standard (%)
Branch reference standard	270	0
Low Carbon A standard	210	−22
Low Carbon Plus standard	160	−41
Low Carbon Extreme standard	120	−55
Saferock (European KOH mix)	116	−57
Saferock optimal mix	59	−78

described in the concrete standard NS-EN 206 [16]. Saferock will have to go through extensive verification and testing to be able to use the geopolymer concrete in future construction projects. This study has not taken this into account but recognises the potential emissions savings and material savings from using such a concrete. Future studies should investigate more closely the mechanical properties of the Saferock geopolymer concrete through laboratory and pilot testing.

6 Conclusion

The potential for emissions reductions using geopolymer cement is significant and crucial for reducing the overall emissions of the concrete industry. The Saferock concrete process investigated in this study uses mining waste and potassium hydroxide as a replacement for standard Portland cement in concrete mixtures. Although there are uncertainties with the emissions associated with the potassium hydroxide production process used in this this study, the overall potential for reduced emissions for geopolymer concrete is confirmed. Saferock concrete contributes to a broader circular economy in the construction industry by utilising waste materials and drastically reducing emissions of a key construction material. Future studies should on geopolymer concrete should focus on carrying out more comprehensive LCA studies on activator materials and testing of mechanical properties of geopolymer concrete.

1 Introduction

The development of cover systems for Municipal Solid Waste (MSW) landfills has advanced from simple soil coverings to intricate, multi-component structures designed to effectively regulate infiltration and mitigate landfill gas (LFG) emissions. Cost considerations and resource availability have posed challenges to the use of typical landfill cover materials, such as gravels, sands, and clays, in recent years. The use of alternative materials, such as those obtained from waste, has garnered interest due to their potential to save expenses, conserve natural resources, and improve sustainability by reusing waste streams. Furthermore, this falls in line with international environmental regulations that give priority to minimizing waste, promoting recycling, harnessing energy, and conserving resources. Nevertheless, these materials must satisfy certain requirements for hydraulic, shear strength, and compatibility to be considered as feasible alternative materials. Prior studies on the use of alternate materials in landfill cover systems have mostly

focused on the hydraulic efficiency of materials, disregarding a thorough investigation of veneer slope stability. Several researchers have investigated the appropriateness of using materials such as recycled asphalt pavement [1], tire-derived aggregates [2], glass culets [3], recycled concrete aggregates [4], and steel slags [4, 5] as drainage components in landfill cover systems. Significantly, previous research has extensively examined the failure of veneer shear at geosynthetic interfaces in traditional landfill covers [6–13]. However, there is a dearth of studies focussing on the interaction between geosynthetics and alternative waste materials.

In this context, the present study aims at investigation of the feasibility of use of recycled concrete aggregates (RCA) as an alternative material for the drainage layers in landfill final cover systems. The first phase involves the determination of fundamental geotechnical properties of RCA, followed by the assessment of the interface friction angle between RCA and HDPE geomembrane through large-scale direct shear tests. To showcase the practicality of employing RCA within the drainage layer, a numerical model of a municipal solid waste landfill located in Este, Italy, was developed utilizing Finite Element Method (FEM) software, GeoStudio. The validation of this model was achieved by applying the analytical two-wedge theory of veneer shear failure within layered strata, as introduced by Koerner and Soong (2005) [14]. An investigation on the use of recycled asphalt pavement (RAP) aggregates, employing identical methodology, has also been conducted by the authors [15]. While RAP aggregates demonstrated favourable results as a potential alternative material for drainage, it must be noted that most of the RAP produced during road construction and demolition activities is commonly reintegrated on site.

2 Materials and Methods

2.1 Description of Site

The MSW landfill under investigation in this study is owned by *Società Estense Servizi Ambientali* (SESAS p.a.), a limited liability company operating in Italy that specializes in waste collection and treatment. The landfill is situated in the municipality of Este, which is in the southwestern region of Padova Province. The landfill in its entirety encompasses a surface area of 13 ha and a volume of approximately 1.5 million cubic metres [16].

2.2 Sample Procurement and Preparation

The RCA for the present study were obtained from the structural laboratory of the Department of Civil Engineering at the Indian Institute of Technology Roorkee (IITR). Several pre-existing concrete cubes from the laboratory, originally cast for determining the characteristic compressive strength of concrete in various projects,

Table 1 Properties of recycled concrete aggregates

Parameter	Unit	Value	Test Procedure
Specific gravity (G_s)	–	2.55	ASTM D 854
Maximum bulk density (γ_{max})	kPa	12.8	ASTM D 4253
Minimum bulk density (γ_{min})	kPa	11.9	ASTM D 4253
Hydraulic conductivity (k)	cm/s	1.4×10^{-2}	ASTM D 2434
Internal friction angle (ϕ)	Degree	40	–
Cohesion (c)	kPa	0	–

Table 2 Properties of geomembrane

Parameter	Unit	Value	Test Procedure
Material	–	HDPE	–
Thickness	mm	2	ASTM D 5199
Density	kg/m^3	940	ASTM D 792
Tensile Strength	kN/m	57	ASTM D 6693
Puncture resistance	N	675	ASTM D 4833
Tear resistance	N	249	ASTM D 1004

were manually crushed using a hand rammer. The concrete cubes did not conform to a predetermined strength specification. Rather, a varied composition was used to reflect the inherent heterogeneity of RCA typically obtained from construction and demolition (C&D) waste processing facilities. For compatibility with the large-scale direct shear test, particles over 20 mm were excluded from the sample through sieving, and those under 4.75 mm were omitted to prevent material washout. The fundamental geotechnical characteristics of the RCA were determined at the geotechnical laboratory IITR (Table 1). The shear strength parameters of RCA were taken from literature [17].

The HDPE geomembrane (GM) utilized in the studies was obtained from Megaplast India Pvt. Ltd. and its properties (provided by the manufacturer) are presented in Table 2. The GM had a thickness of 2 mm and was supplied in rolls with a width of 1 meter. The GM was divided into sheets of 35 cm × 55 cm to be positioned on the lower shear box, which has an overall size of 35 cm. To secure the GM in position, 10 cm overhangs were maintained on both sides, positioned perpendicular to the shearing direction.

2.3 Experimental Program

To assess the functionality of the drainage layer in combination with the geosynthetic membrane (GM), the shear strength of the interface between RCA and GM was evaluated using the guidelines outlined in ASTM D5321-12. For this purpose, a direct shear apparatus with a shear box of size 30 cm × 30 cm × 30 cm was utilized. The GM interface was set over the top of the lower half of the shear box, which was first filled with standard sand as filler material. This was done by pouring

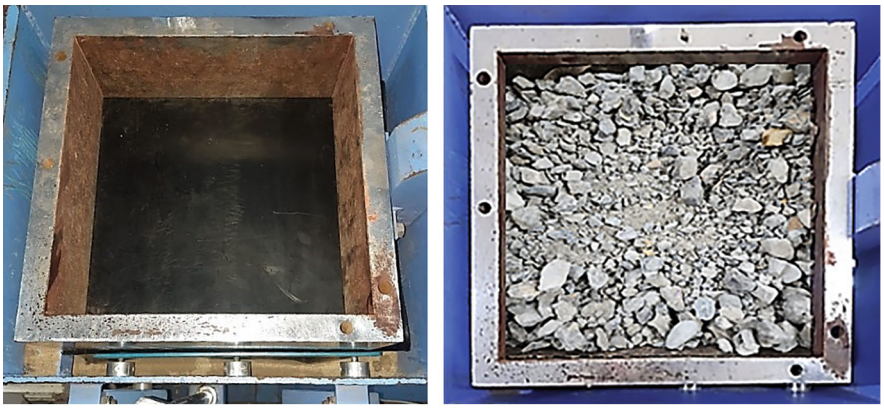

Fig. 1 (**a**) Geomembrane fastened to lower box using a fabricated clamping device (**b**) Upper box filled with RCA

sand in 4 layers and tamping each layer 25 times by a hand tamper. The 35 cm × 55 cm GM sheet was then firmly secured over the top of the lower box using a custom-made clamp designed to hold the GM through reaction force against the outer box as shown in Fig. 1a. The upper box was then placed over the GM and properly aligned with the lower box. The upper box was filled with RCA in four layers and tamping each layer by 25 blows of hand rammer, to achieve a relative density of 95%. After assembly of the direct shear apparatus, the sample was subjected to shearing at standard loads of 50 kPa, 175 kPa, and 275 kPa, with a strain rate of 1 mm/min. The displacements were measured LVDTs, while the associated shear load was recorded using a data logger. During testing, it was observed that the shearing resulted in stripping of cement mortar from the aggregates a shown in Fig. 1b. This suggests a need for selecting RCA with minimal adhered cementitious material to ensure the optimal performance and durability of the drainage layer. Further testing may be necessary to identify suitable aggregates for drainage applications.

2.4 Numerical Program

A numerical analysis of the failure of the cover slope was conducted for the case study of Este landfill, Italy, to illustrate the practicality of utilizing RCA as a drainage medium in conjunction with geosynthetics. The landfill simulation was conducted using the SLOPE/W module of the widely accessible FEM program GeoStudio. The Morgenstern-Price approach was used to analyse the factor of safety (FOS) as it considers both force and moment equilibrium. Below are the specifics of the simulation:

Landfill Geometry and Material Properties The research utilized a 2-D plane strain geometry, focussing specifically on the steepest cross section of the landfill. The analysis was performed on the left half section of the geometry because of the structural symmetry. Figure 2 depicts the landfill geometry, including the slope that was examined for potential collapse. The numerical simulation utilized material characteristics reported by Trivellato (2014) [16], which are outlined in Table 3.

Modelling of Geomembrane The software GeoStudio facilitates the application of geosynthetics as reinforcements with primary purpose of determining their pull-out resistance. However, this approach fails to consider the influence of the interface friction angle on the FOS. Consequently, the GM was constructed using two techniques. The initial approach involved representing the GM as reinforcement, following the conventional protocol. In the second approach, the GM layers were represented as thin layers with thicknesses significantly less than the cover layers (10 mm) using Mohr-Coulomb model, and the interface adhesion and friction angle were taken as the shear strength properties [18].

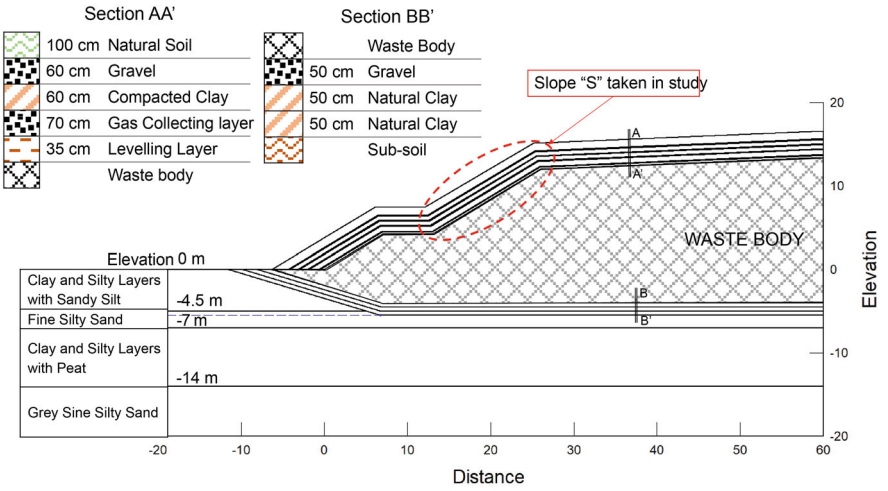

Fig. 2 Geometry of Este MSW landfill taken up in this study [15]

Table 3 Properties of the materials used in numerical model

Material	γ_{dry}	c	ϕ
Natural soil	11	8	19.6
Compacted clay	16	24	29.2
Levelling layer	18.2	0	33.8
Gravel	18	0	28.3
Clay with silty layers	17	4	20.4
Fine silty sand	16	0	24.7

γ_{dry}: dry unit weight (kPa); c: cohesion(kPa); ϕ: internal friction angle (°);

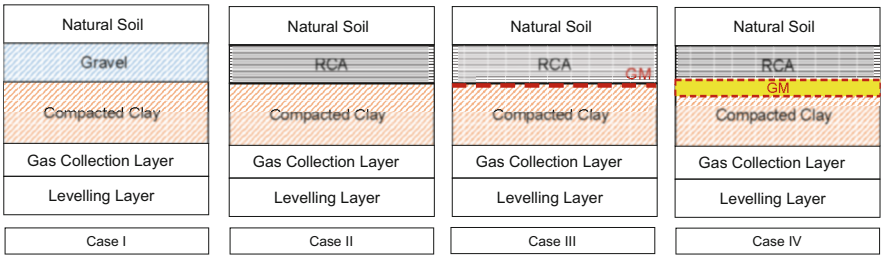

Fig. 3 Cover system profiles for numerical model cases

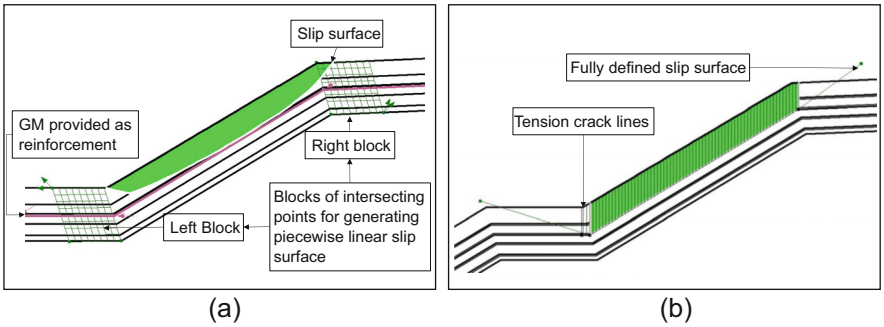

Fig. 4 (**a**) Block specified slip surface method (**b**) Fully specified slip surface method [15]

Modelling of Landfill Cover Cross-Section The landfill cover slope S was analysed in for four cases as depicted in Fig. 3.

Case I: Landfill analysed in its original form.
Case II: Gravel from the drainage layer replaced by RCA.
Cases III: GM was added to the analysis below the drainage layer as reinforcement.
Case IV: GM was added as a thin layer (10 mm) below the drainage layer.

Modelling the Slip Surface The analysis of the landfill cover slope was conducted using two distinct methods (Fig. 4): (i) the block specified slip method, which generates slip surfaces that are parallel to the cover slope, indicative of translational slope failure. This method involved positioning right and left point grids at the slope's crest and toe, respectively, with the software identifying the most critical slope along the cover system. (ii) For calculating the FOS along the actual interface between RCA and geomembrane, a fully specified slip surface parallel to the slope was used, accompanied by a tension crack line based on the approach outlined by Krahn (2004) [19].

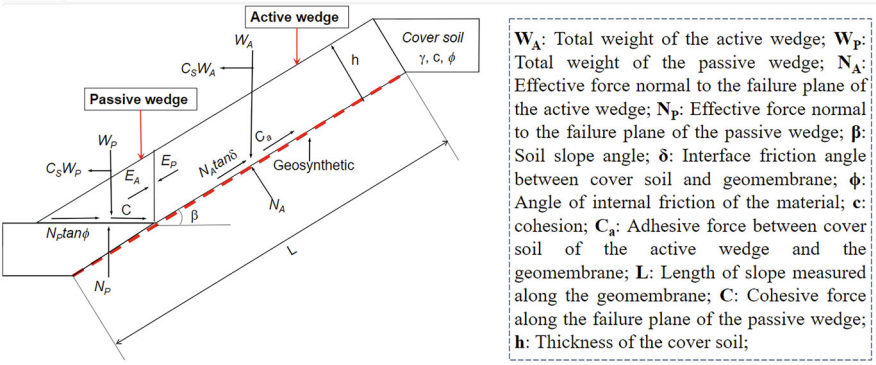

Fig. 5 Free body diagram of forces on cover soil. (After Koerner & Soong (2005) [14])

2.5 Analytical Program

The validation of the numerical model was performed using an analytical approach for veneer failure analysis, as described by Koerner & Soong (2005) [14]. This method considers a linear potential failure surface for veneer cover soils, where the cover soil slides in relation to the interface having the lowest friction angle in the section below. The FOS is determined as the ratio of total resisting forces to destabilizing forces. Considering that the slope is relatively shorter as compared to those typically assumed for infinite slope analysis, the evaluation incorporates the consideration of a passive soil wedge at the toe of the slope. Figure 5 illustrates the forces on the cover slope and the identified failure surface. For comprehensive details, readers are encouraged to consult Koerner and Soong (2005) [14]. To validate the model, failure interfaces within the numerical model were identified for each scenario, followed by the derivation of analytical solutions tailored to these specific failure interfaces.

3 Results and Discussion

The shear strength parameters for RCA were derived from available literature, showing a range of 40–50° [17]. A sensitivity analysis was conducted to establish a specific value for use in the simulation. The internal friction angle of RCA was conservatively varied from 35° to 45°. As can be seen in Fig. 6a, the FOS consistently exceeded 1.5 across the entire range. Based on this, a friction angle of 40° was selected for subsequent analyses. Further, the FOS was found to be insensitive to variations in the interface friction angle of the geosynthetic material when it was specified as a reinforcement in the software. This indicates that the program will produce inaccurate results if the geosynthetic membrane is incorporated in as per conventional method.

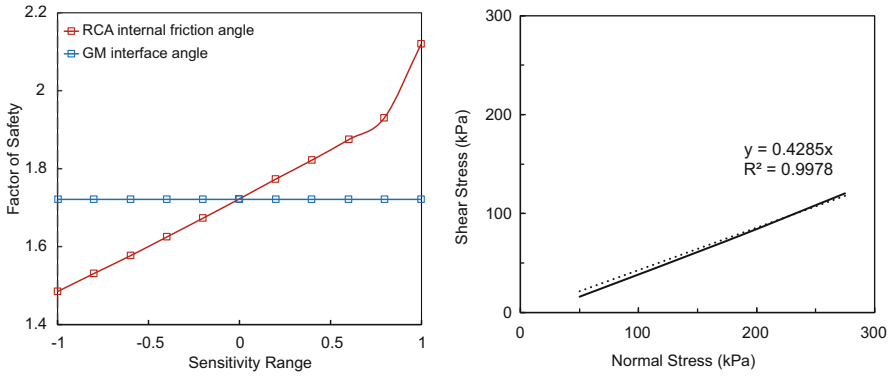

Fig. 6 (**a**) Sensitivity Analysis for internal friction angle of RCA aggregates and interface friction angle of GM (**b**) Results of large-scale direct shear test

Table 4 Results of analytical and numerical analysis

Slip surface specification method	Case	Factor of safety		
		Numerical Results	Analytical Results	Error
Block specified method	Case 1	1.171	1.161	0.8%
	Failure interface	*Gravel-clay*	*Gravel-clay*	
	Case 2	1.72	1.65	4%
	Failure interface	*RCA-clay*	*RCA-clay*	
	Case 3	1.72	1.65	4%
	Failure interface	*GM*	*RCA-clay*	
	Case 4	1.46	1.22	16%
	Failure interface	*GM*	*GM*	
Fully specified slip surface	*RCA-GM interface*	1.39	1.22	16%

The agreement between the outcomes of the analytical and numerical investigations, which are presented in Table 4, provides strong support for the numerical model. It is critical to acknowledge that a steeper landfill cover slope (1:1.6) was utilized in this specific instance, deviating from the recommended range of 1:3 to 1:5. As a result, the study is mostly concerned with comparing several cases as opposed to identifying particular FOS values.

The FOS for Case I, i.e. original cover system with gravel was 1.171 while on replacing the drainage layer material with RCA in Case II, the FOS increased to 1.72. Hence, the RCA layer demonstrated superior shear strength compared to the gravel layer, primarily due to a higher internal friction angle. Additionally, RCA exhibited favourable drainage properties with a hydraulic conductivity of 1.4×10^{-4} m/s. These positive hydraulic characteristics underscore the potential of RCA to contribute to improved slope stability in landfill cover systems.

In order to evaluate the efficacy of alternative cover systems utilizing geosynthetics, GM was integrated into the model for Cases III and IV. The shear strength characteristics of the RCA-GM interface, as determined by large-scale direct shear experiments, are illustrated in Fig. 6b. A negligible intercept of the curve was obtained, which was fixed to zero by linear curve fitting, yielding a Pearson's r value of 0.999 (R-Square = 0.9994). The angle of contact friction (δ) was calculated to be 23.2°.

Case III exhibited no sensitivity to FOS when GM was incorporated as reinforcement, while in Case IV, the FOS value decreased from 1.72 to 1.48 due to formation of a weak interface in the cover system. This, in addition to the results of sensitivity analysis highlights that, the software exhibits a limitation in recognizing the effects of a weak interface along the geosynthetic in Case III. The software demonstrates a constraint in identifying the consequences of a weak interface along the geosynthetic in Case III, as evidenced by this and the sensitivity analysis results. Syed and Mishra (2023) [18] explain that in order to address this concern and guarantee precise evaluation of slope stability, it is crucial to incorporate the geomembrane as a thin layer beneath the drainage layer.

It is worth mentioning that the analytical techniques employed in this research were specifically designed to compute the Factor of Safety (FOS) at the interfaces between soil and geosynthetic materials. In contrast, the block failure slip surface method enables the software to independently identify the most critical slip surface along a cover slope. To facilitate a significant comparison, the numerical analysis was used to identify the materials at the top and bottom of the slip surface in each case, which was then used to substitute the properties of the failure interface for each case. The results obtained from this comparative analysis indicated that the analytical model and the numerical model exhibited a significant level of agreement.

4 Conclusion

The study delves into the integration of recycled concrete aggregate (RCA) in landfill cover systems, examining its potential as a sustainable alternative to natural aggregates. Through geotechnical tests and numerical simulations, the performance of RCA in drainage layers and its interaction with geomembranes were assessed. Following are the conclusions drawn from the study:

- The geotechnical tests conducted on recycled concrete aggregates (RCA) have demonstrated their suitability for use as a drainage materials in cover systems. With a hydraulic conductivity of 1.4×10^{-4} m/s, the material possesses the desirable permeability characteristics for effective drainage layers in various applications. However, it is recommended that aggregates with minimum cementitious mortar adhered should be used to ensure the optimal performance and durability of the drainage layer.

- RCA aggregate layer outperforms the gravel layer in terms of shear strength mainly on account of higher value of internal friction angle. There was a 47% increase in the FOS value from of Case I and Case II.
- The interface friction angle between RCA and GM was experimentally determined to be 23.2°. Upon numerical simulation, this resulted in the formation of a weak interface in the cover system.
- Sensitivity analysis and numerical analysis result for Case III revealed that the software is insensitive to changes in interface properties of geomembrane when applied as a reinforcement.
- On the introduction of the GM as a thin layer in the cover system, the FOS experienced a decline from 1.71 to 1.46. This was supported by similar outcomes obtained from the analysis of a fully specified slip surface along the RCA-GM interface.
- Analytical methods for determination of FOS at soil-geosynthetic interfaces were utilized to obtain FOS values for soil-soil interfaces with good agreement.

Acknowledgements The authors are thankful to the management at Megaplast Pvt. Ltd. for providing the geomembrane specimens and their friendly cooperation. Additionally, we acknowledge Mr. Nishant Varshney, an intern under the SPARK Program at IIT Roorkee, for his invaluable contributions to the experiments.

1 Introduction

The building/construction industry significantly contributes to resource depletion and environmental pollution [1]. Twenty per cent of the environmental impact stems from processes associated with buildings, encompassing the manufacturing and disposal of building materials [2]. The industry contributed 38% of all energy-related carbon dioxide (CO_2) emissions in 2020 [3] and is also one of the largest consumers of virgin materials. In terms of environmental impact, construction and demolition (C&D) wastes make up a large percentage of materials that end up in landfills. For example, 40% of the landfill volume in the USA is from C&D wastes,

mainly wood, drywall, and plastic [4]. A fibre-reinforced polymer (FRP) material is typically a composite of synthetic fibres, particularly carbon, glass, or aramid, and a polymer matrix, typically polyester, vinyl ester, or epoxy resins [5]. Owing to its high strength, corrosion resistance, and lightweight nature, the popularity of this material has surged in the construction industry. Specifically, they have been used to develop structural shapes that could be used in various building and bridge applications, sandwich construction, and as internal and external reinforcement for structural elements [6]. Since FRP composites are commonly made with synthetic materials, rising environmental concerns are associated with their production and disposal. These concerns fuel the development of bio-based composites, which describe composites made from natural sources that can invariably reduce the consumption of virgin materials and are more eco-friendly. These bio-based polymer composites, or biocomposites, are poised to be non-abrasive and reduce CO_2 emissions and dependence on petroleum products [7]. Given the recycling challenges and toxic emissions associated with synthetic FRPs [8], biocomposites present a promising avenue for embracing the principles of the circular economy, particularly if they exhibit biodegradability [9]. A variety of natural fibres sourced from plants and animals have been utilised to create functional biocomposites. These biocomposites, in comparison to synthetic fibres, exhibit lower density, are biodegradable, potentially more accessible, and are less abrasive [10]. Consequently, they present a promising alternative to reinforcement material for FRP composites.

Biocomposites are becoming increasingly attractive, and their manufacture and supply in recent years have been accompanied by political incentives and tax reductions in some countries [11, 12]. Natural fibres are now used instead of synthetic fibres to create biocomposites across the automobile, sports, aerospace, and other industries. The automobile industry has embraced the use of natural fibre biocomposites to achieve weight reductions and improved mechanical properties of automobile components like door panels, interior carpets, boot lining, dashboards, bumpers, and so on [13, 14]. Specific policies like those established by the European Union and Japan that required 85% (95% for Japan) of a vehicle to be either recycled or reused as of 2015 have encouraged the research and development of biocomposites [15]. Cost is also a crucial factor that encourages the use of natural fibres over synthetic fibres. Natural fibres are cheap compared to their synthetic counterparts, increasing their commercial and research potential [12].

Properties of biocomposites, such as their lightweight, high strength-to-weight ratio, corrosion resistance, and thermal insulation properties, make them suitable building materials, and their adoption in the industry offers several benefits. From an environmental perspective, biocomposites reduce reliance on fossil fuels and mitigate greenhouse gas emissions throughout the product lifecycle [16, 17]. Biocomposites are often biodegradable or recyclable, minimising waste generation and contributing to a circular economy. Economically, bio-based composites can reduce material costs and create new opportunities for rural development and job creation in agricultural communities. The potential for biocomposites in the construction industry lies in the current applications of conventional synthetic FRPs. Bakis et al. [6] outlined the specific applications of FRP composites for construction,

including bridge decks, sandwich construction, internal reinforcement, and externally bonded reinforcement. Biocomposites have also found their place in the building industry, where they have been developed for non-structural applications such as furniture, insulation boards, and partitions. This study explores the various practical applications of biocomposites in the construction industry as available in existing literature. Biocomposites, though promising, still have their limitations; standardisation, durability, and strength concerns have widely limited their acceptance for their practical usage in the construction industry. This paper also seeks to examine the challenges limiting their use in the building industry.

2 Bio-Based Polymer Composites

An FRP composite comprises a matrix material and a reinforcement material. The matrix defines the shape of the material and guards against chemical and mechanical damage, while the fibres provide the strength and stiffness of the composite [12, 18]. Biocomposites can be a blend of organic and inorganic components [16], i.e. natural fibres with a synthetic polymer, synthetic fibres with a bio-based polymer, a hybrid of natural and synthetic polymers, or a pure biocomposite with all organic components. Natural fibres can be sourced from plant sources like leaves (sisal, pineapple, banana), bast (jute, flax, hemp, kenaf, ramie), seed/fruit (cotton, coir), stalk (rice, wheat), cane (bamboo), wood, animal (wool, silk), and mineral sources (basalt, asbestos) [19]. For the polymer matrix, thermosets or thermoplastics like polyester, vinyl ester, and epoxy, polypropylene, low-density polyethene, high-density polyethene, and nylon serve as the matrix. Typical thermosets and thermoplastics are not biodegradable, so the ideal polymers for the sustainable development of FRP products would be biodegradable bio-based polymers, also known as bioplastics or biopolymers. Bioplastics are crop-derived renewable resources, such as cellulose plastics, polylactides, starch plastic, soy-based plastic, and polyhydroxyalkanoate polymers [20].

3 Biocomposites in the Building Industry

Biocomposites can be used for non-structural (non-load-bearing) and structural (load-bearing) applications in the building industry. These applications are presented in Fig. 1 and will be examined in this section.

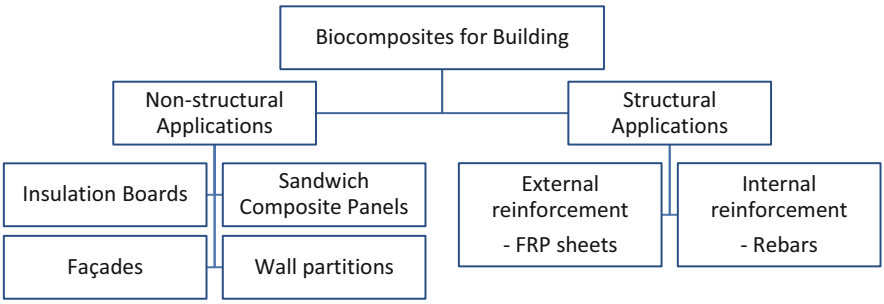

Fig. 1 Classification of biocomposites for building

3.1 Non-Structural Applications

Building Insulation Material Energy consumption in the building industry is responsible for 40% of global CO_2 emissions [21], and this can be reduced with building thermal insulation. The commonly used materials for thermal insulation in buildings are fibreglass, mineral wool, polymers, aerogels, etc. [22]. More eco-friendly materials like primarily sourced plant fibres or agricultural wastes, can be used to develop more sustainable building thermal insulators [23]. These fibres have lower density and heat retardant properties, which make them suitable insulators [24]. Several authors have developed biocomposites for specific use as thermal insulation materials. Madival et al. [22] developed rice straw/furcraea foetida boards with an epoxy matrix for thermal insulation. They evaluated the fabricated composite's thermal stability, conductivity, transmittance, resistance, specific heat capacity, and flammability properties. The authors were able to create a composite that was thermally stable up to 272 °C. Le and Pásztory [24] developed boards with rice straw and reed/phenol formaldehyde, coir fibre/phenol formaldehyde, and a binder-less coir fibre panel that can be used as thermal insulating material. Though the thermal resistance of the developed material was evaluated and found to be suitable, no comparisons were made with existing commercial thermal insulation boards. Bhuiyan et al. [21] fabricated jute/polypropylene biocomposite boards and established that the porous morphology and low thermal conductivity of cellulose fibres make them good heat insulators. The developed biocomposite's water absorption and mechanical properties were then compared to those of a commercial gypsum/polyvinyl chloride plasterboard and found to be superior. The biocomposite had superior thermal resistance to the commercial board, but the commercial board had higher thermal stability at higher temperatures. Low thermal conductive fillers in the biocomposites were proposed to improve the heat barrier performance.

Acoustic insulation is also an essential aspect of the service life of a building. Insulating materials are sometimes developed to have both thermal and acoustic insulation properties. Vasconcelos et al. [25] developed green high-density

polyethylene composites with natural powdered cork to have thermal and acoustic insulation properties. It was found that the acoustic absorption coefficient was dependent on the reinforcement ratio within the composite. Urdanpilleta et al. [26] used the wool fibres of the Latxa sheep breed combined with a soy protein isolate matrix to develop a sound-insulating biocomposite material. It was found that the fibrillary microstructure in natural fibres and the presence of empty cells ensure high porosity and absorption properties, making them have good sound absorption coefficients at medium and high frequencies. Alencar et al. [27] proposed using expanded natural rubber as the polymer matrix reinforced with a wood filler (eucalyptus) in developing biocomposites with acoustic insulation. The developed material had three times the acoustic insulation capacity of polyurethane foam, a commercially available acoustic absorbent.

The use of waste in developing biocomposites is also a significant circular economy consideration. Polyethylene (PE) and polypropylene (PP) are projected to account for over 60% of global plastic production by 2050 and are projected to account for 20% of global petroleum consumption by 2050 [28]. The construction industry is responsible for 19% of the world's consumption of plastics and is the second largest stack globally [25]. Waste plastics can also be repurposed to reduce the environmental pollution associated with their disposal [28].

Sandwich Composite Panels A sandwich composite is a type of material typically consisting of two outer stiff layers called the face sheets bonded to an inner core material sandwiched between them [6]. The face sheets are usually made of strong and stiff materials, while the core material is often considerably thicker and lighter and can use foam [17], honeycomb [29], or wood design. This design provides high strength and stiffness while keeping the structure's overall weight relatively low. The facing typically provides the bending resistance, while the core provides shear resistance and insulation [30, 31]. This type of material has applications in the aerospace, marine, and automotive industries, and in the building industry, it has found its place. Chomachayi et al. developed a sandwich structure from polyhydroxyalkanoate, polylactic acid, and cellulose microfibres to act as a building envelope vapour retarder, reducing mould growth and providing proper building insulation. The developed composite had a water vapour permeance value within the limits set in the national building code of Canada. Fu and Sadeghian [30] developed sandwich composite beams with flax/bio-based epoxy facing and a paper honeycomb core that could be used as building and cladding systems.

Sandwich panels can also be made to be prefabricated building modules that can be assembled off-site to ensure fast assembly and construction. Laraba et al. [32] developed a sandwich panel with an alfa fibre/epoxy core and jute/metallic mesh sheets to be potentially used as building partitions or roof panels. Conventional fabrication techniques such as manual lay-up, vacuum moulding and resin transfer moulding were used. Recently, 3D printing technology has also been used to fabricate sandwich composites with more intricate geometry [29]. Dweib et al. [17] developed a structural sandwich panel for potential residential building applications such as roof, wall, or floor material. The authors made sandwich beams with

different face sheets made of flax fibre, chicken feathers, and cellulose from recycled paper with a soybean oil-based resin as the matrix. The sandwich beams were designed to have vertical webs and a structural polyurethane foam core that provided both acoustic and thermal insulation. The manufactured samples, except those made of flax fibre, had comparable strength and flexural rigidity to the available lumber sections. Their further work in [33] saw the successful development of the recycled paper composite into a prototype roof structure.

Façade and Partitions Biocomposites can be developed for their specific use as vertical wall panels. Ks et al. [34] developed a sandwich composite with a flax/epoxy sheet and coir/polyurethane foam core as an alternative to conventional building partitions. The light weight of biocomposites and their insulation properties make them suitable alternatives. Astudillo et al. [35] set out to develop four different biocomposite products: an interior partition system with 40% bio-content, a multi-layered wall system with 70% bio-content, and a curtain wall with 30% bio-content. The products were designed according to the European Building Code and tested for structural performance, fire performance, air quality, thermal insulation, and durability. The developed biocomposites also underwent a monitoring phase where full-scale prototypes were found to have comparable performance to commercially available alternatives. A green vertical system is an innovative solution to introduce green areas directly in urban cities by having vertical gardens either supported by the façade or incorporated directly into the façade [36]. This green wall has been shown to improve air quality and the thermal and acoustic performance of a building. Cork agglomerate boards produced from waste from cork oak agglomerated with natural resins are one such nature-based solution in the building system [37].

Given their natural source, biocomposites have been shown to have less environmental impact when used as partition and façade systems. Morganti et al. [16] examined the global warming potential of three prefabricated façade system modules made with bio-based resin reinforced with basalt fibres and wooden particles. The biocomposite modules, through the product lifecycle from cradle to practical completion, reduced associated CO_2 emissions across all the categories considered compared to a conventional alternative.

3.2 Structural Applications

External Reinforcement Among the different structural retrofitting techniques, using FRP sheets, which are typically bonded to concrete members, is one of the least disruptive. In recent years, natural fibre composites have been developed to be a more sustainable alternative to the popularly used carbon and glass fibre FRP sheets used as external reinforcement to retrofit structural members. A holistic review of their use was done in [38], which saw the strengthening of beams, columns, walls, and slabs across concrete, masonry, and wooden structural elements. Structural elements were strengthened with biocomposites made with different natural fibres,

including bamboo [39], hemp [40], kenaf [41], pineapple leaf [42], sisal [43], flax and jute [44], and so on. Bio-based polymers have also been used in this regard to develop completely green biocomposites [40, 45], or to make partial biocomposites when in conjunction with synthetic fibres [46]. In instances where the biocomposite was designed and the thickness increased to compensate for the lower strengths of natural fibres as compared to their synthetic counterparts, the RC beam strengthened with the biocomposite had a comparable load-carrying capacity with those strengthened with carbon FRP [41, 44].

The advantage of biocomposites as an external reinforcing material lies in their eco-friendliness, cost, and lower strength. Since they are developed from bio-based materials, the composite could be biodegradable. Composites could also be cheaper since they are produced from locally available materials. The high strength and stiffness of synthetic FRPs have resulted in more abrupt debonding failures [19], but natural FRPs have lower strengths that are more compatible with concrete.

Internal Reinforcement Due to durability considerations, FRP rods have been developed as a non-corrosive alternative to conventional steel rebars. Its advantage lies in its non-reactive nature, which makes properties unchanged in aggressive environments where steel rebars would corrode [47]. Attai et al. fabricated 12 mm diameter glass FRP and jute FRP reinforcement bars with the hand lay-up technique. Though the glass FRP had much superior performance, the developed jute FRP rebars had tensile strength and elastic modulus up to 178.42 MPa and 12.15 GPa, respectively. Though these strength values are lower than the steel alternative, they can be used in low-loading structural applications. It was also established that the fibre volume fraction greatly influences the strength of the developed composite rebars. Sharkawi et al. [48] used an infusion technique to make reinforcement bars with jute and flax yarn fibres. Though the bars had modest strength, they still enhanced the strength of a normal-weight concrete slab and that of a lightweight concrete slab by 175% and 56%, respectively. Elbehiry et al. [49] made banana fibre/polyester as reinforcement bars in a concrete beam. Though the natural FRP rebars had a much lower strengthening effect than conventional steel bars, they enhanced the beam's flexural strength by up to 25% more than the plain concrete beam. The natural FRP bar can be a low-cost alternative in low-strength applications. Joyklad et al. [50] used sisal fibre rope embedded in epoxy as post-installed shear reinforcement in flat concrete slabs. The natural sisal fibre performed better than the carbon and aramid FRPs, although it had the lowest strength.

4 Challenges and Future Directions

There are associated challenges with adopting biocomposites in the building industry, some of which are discussed in this section.

1. Natural fibre viability: The mechanical properties of natural fibres are not consistent and predictable; they depend on the age of the plant, plant species, plant

origin, and the soil and weather conditions in which the plant was cultivated [51]. This viability can affect the consistent and predictable material performance of biocomposites.

2. Processing technique: Various techniques, such as wet lay-up, compression moulding, resin transfer moulding, and vacuum infusion, have been used to make biocomposites. Sophisticated apparatus is hardly needed to make samples for laboratory testing and prototyping. However, in developing larger sizes and amounts, some of the techniques used become labour-intensive, and the quality of the manufactured composite becomes challenging to ensure as there could be inconsistencies within the produced samples [18]. The specific process used to manufacture biocomposites affects the quality of the composite produced. As long as the manufacturing process remains unstandardised and has no specific methodology, the quality of biocomposites with natural fibres will remain uncertain [52].
3. Water absorption: Polymers are hydrophobic, while lignocellulosic natural fibres absorb moisture. The increase in fibre content in biocomposites directly increases the moisture absorption capabilities of natural fibre composites. When biocomposites absorb moisture, they swell and return to their original state after drying; this causes the fibres to lose their bond with the matrix material [53] and consequently reduces the mechanical performance of the developed biocomposite.
4. Thermal performance: When there is a fire outbreak in a building, elements within should be able to maintain their intensity for particular durations. Natural fibres are organic materials that degrade at high temperatures. The initial degradation of natural fibres, which results in the breakdown of hemicellulose, occurs between 220 °C and 280 °C, while a second and much faster degradation, involving the breakdown of lignin, occurs between 280 °C and 300 °C [54]. If biocomposites are to be used as a building material, their fire performance must be ensured.
5. Degradation behaviour: Degradation behaviour: The biodegradability of biocomposites is essential in advocating for their adoption. Natural fibres are often paired with resins that are not eco-friendly or degradable.

The methodology for material development, from the initiation of an idea to product testing in a laboratory to final integration into a building as a usable product, was outlined in [35]. A semi-industrial-scale sample prototype development should be done after material development and laboratory testing. A life cycle cost analysis and monitoring should then follow the prototype development. As researchers continue to develop biocomposites for use in the building industry, more prototype development should be done, and the abovementioned issues should be addressed further. Standardisation is encouraged within the industry to create more consistent composites. The durability of biocomposites given actual service life loads should be considered, and pure biocomposites with bio-based polymers should be developed.

5 Conclusion

Biocomposites have great potential for creating a more sustainable built environment. Natural fibres sourced directly from plants or indirectly from waste materials and bio-based polymers hold potential as raw materials in creating more eco-friendly building materials that can reduce the buildings industry's associated CO_2 emissions, reduce the non-biodegradable waste that ends up in landfills, reduce the dependence on virgin materials, and reduce building costs by utilising locally available materials while empowering local communities. Researchers have made substantial efforts to develop biocomposites that can be used within the building industry for structural and non-structural applications. The weight, strength, and insulation properties of specific biocomposite modules in the form of panels, sandwich composites, partitions, or building facades make them suitable building materials. This review also saw the development of natural fibre reinforcement rebars for concrete and bio-based structural retrofitting materials. Though the potential for the increased adoption of biocomposites within the building industry exists, associated stakeholders, from researchers to manufacturers should address making the industry more standardised and making more durable biocomposites.

1 Introduction

According to the World Green Building Council, the building sector contributes about 40% of global emissions, 75% of which comes from building operations and 25% from carbon embodied in building materials [1]. As buildings are becoming more energy-efficient and moving toward reduced operational carbon, embodied carbon emissions will constitute a higher proportion of the whole-life carbon in the future [2]. Yet, efforts to mitigate embodied carbon from the design, manufacturing, and deployment of building materials like cement, steel, and aluminum are significantly lagging behind [3]. The majority of material economies remain linear rather than circular, relying heavily on energy-intensive production of virgin and non-renewable materials, applying the take–make–use–throwaway approach. Consequently, there is a shortage of recyclables in terms of both quantity and quality to

M. Kioumarsi, B. Shafei (eds.), *The 1st International Conference on Net-Zero Built Environment*, Lecture Notes in Civil Engineering 237,
https://doi.org/10.1007/978-3-031-69626-8_72

meet the current material demands. Adopting the product circularity concept that aims at minimizing the use of virgin resources, energy, and waste flows has the potential to reduce embodied carbon emissions [4].

Structural systems such as concrete, steel, and masonry contribute the most to the total embodied impact associated with buildings. Adapting building codes and educating construction professionals can result in reduction in associated emissions, up to 25% from cement and concrete. Currently, concrete accounts for 7% of the global carbon emissions, thus emphasizing the need for immediate decarbonization through low-carbon mix and other design innovations [5]. With steel ranking as the second most used material in the architecture, construction, and engineering (ACE) industry and contributing 7.2% to global greenhouse gas (GHG) emissions, prioritizing its reuse and recycling has become crucial as part of the decarbonization effort [8]. This joint effort is necessary to avoid an increase in raw material extraction as the world's population continues to increase, given that manufacturing steel products from scrap can save between 60% and 80% of the embodied energy. However, a widening gap between the demand for reusable steel components and the limited quantity of available steel scraps remains a key challenge to the massive adoption of recycled steel in the industry.

According to reviews in the World Green Building Council report, global cement consumption is expected to rise by up to 23% by 2050 and global steel production is projected to increase by 30% during the same period. It is, however, believed that recycled secondary steel will be a critical component of this increase, outpacing the virgin steel content used in the manufacturing process [1]. Beyond structural materials, the building envelope, particularly components like window systems (e.g., aluminum), and insulating materials also contribute significantly to embodied carbon emissions, accounting for 48–50% of the associated emissions in a typical house [1, 5, 6]. For example, the research findings by Azari and Abbasabadi show that windows designed with aluminum framing with no recycled content have the highest impact from building envelopes [7].

This chapter presents preliminary research on the low-carbon options available for conventional building materials in the Canadian ACE industry. It investigates the performance of structural concrete and steel, as the two key materials having relatively high carbon intensity and are expected to remain the most used construction materials in the future. The chapter summarizes opportunities to reduce embodied carbon emissions using strategies to decrease the material quantities of these high-impact constituents and replace them with low-carbon options and alternatives with higher recycled content. The results from this investigation can perhaps serve in developing innovative design concepts and guidelines for the creation of low-carbon building materials, applicable in the (ACE) industry and the built environment at large.

2 Methodology

Embodied carbon represents the global warming potential (GWP), measured in kilograms of carbon dioxide, CO_2 equivalent ($kgCO_2e$), of a material or product. GWP quantifies the heat absorbed by the atmosphere due to greenhouse gas emissions. For a whole life cycle approach to evaluating the carbon performance of materials, the International Organization for Standardization (ISO) considers embodied carbon life cycle assessment (LCA) as consisting of the: (i) product stage (A1–A3) from raw material extraction to manufacturing; (ii) construction process stage from transportation to installation (A4–A5); (iii) use stage (B2–B5) from maintenance and repair to replacement and refurbishment; and (iv) end-of-life stage from deconstruction and waste transportation to waste disposal (C1–C4) [9]. Embodied carbon emissions are irreversible and primarily stem from upfront emissions, occurring before construction. Geographical location significantly influences the embodied energy and carbon impact from construction due to variations in manufacturing and production practices, energy supply grid systems, construction methods, local energy infrastructures, transportation modes, distance to local or international suppliers, and other region-specific economic factors.

This chapter provides preliminary information on low-carbon structural materials applicable to the construction of high rise commercial buildings in Canada, utilizing mainly concrete and steel frame design. It summarizes alternative strategies for material selection, design specifications, and construction approaches to reduce embodied carbon impact, particularly for concrete and steel. However, specific design specifications information will need to be directed toward individual project details and design team expectations during the design development (DD) stage before actual construction of the project.

This research employs quantitative data analysis by reviewing manufacturers' and suppliers' websites to gather data on the low-carbon material options available in the market. This includes reviewing online resources as third-party information available to the general public, utilizing embodied carbon information available from environmental product declarations (EPDs), identifying the key stages in the life cycle of products at which carbon emissions are most substantial or finding evidence of potential reduction in impacts throughout the life cycle stages. An environmental product declaration (EPD) is built upon a comprehensive product life cycle assessment and is thus a verifiable key research tool for understanding the life cycle embodied impact of products and manufacturers' commitment to product circularity. Further analysis includes telephone interviews and site visits to obtain specific information on manufacturing procedures and industry techniques not made available to the public.

3 Research Findings and Analysis

3.1 Carbon Reduction in Concrete

Concrete mix comprises of crushed stone, sand, water, and Portland cement. Cement in concrete is the primary contributor to embodied impact due to the high carbon intensity during its production. Thus, to attain low carbon in concrete, there is a need to target reducing the quantity of cement content in the mix, as it is primarily responsible for 75% of the entire CO_2 emissions [8]. Mix aggregates such as crushed stone and sand contribute less than 20%, which is often linked to electricity usage and, to a lesser extent, to excavation, hauling, blasting, and transportation. The contemporary approach to low-carbon concrete involves incorporating by-products (e.g. fly ash, slag) into the concrete mix. By minimizing the use of virgin materials and maximizing the utilization of by-products, a substantial reduction in the carbon footprint can be achieved.

This subsection discusses the strategies to reduce the embodied carbon emissions associated with concrete, focusing on ready mix concrete products, manufacturer and suppliers.

Manufacturer: CarbonCure Ready-Mix Solution The CarbonCure mix solution highlights the effective use of carbon dioxide (CO_2) to mitigate the environmental impact of concrete through carbon removal technology. The process involves injecting a precise dosage of CO_2 into the concrete during mixing, leading to a chemical reaction that converts it into a mineral, specifically calcium carbonate, permanently sequestering CO_2 in a stable form. CarbonCure collaborates with concrete mix plant locations across provinces in Canada, seamlessly integrating the CarbonCure Valve Box and Control Box for precise CO_2 injection during mixing. This sustainable concrete technology significantly enhances performance and compressive strength by reacting with calcium ions, enabling adjustments in cementitious content, reducing carbon footprints, and yielding cost savings. CarbonCure Ready Mix, applicable to various concrete production methods, demonstrates substantial carbon savings per unit, thus fostering environmental sustainability without compromising either quality or performance of the concrete mix. The observed improvements, up to a 10% increase in compressive strength beyond 28 days, highlight the technology's potential for delivering low carbon concrete while maintaining strength in performance [10]. Research findings show that by integrating CarbonCure Ready Mix with CarbonCure Reclaimed Water, the cementitious content and water in the slurry tank can be revitalized, converting them into valuable upcycled resources. This innovative approach results in additional CO_2 savings of 10–25 lb per cubic yard (5–11 kilograms per cubic meter), contributing to an overall carbon reduction of approximately 10% compared to traditional concrete practices [11] (Fig. 1).

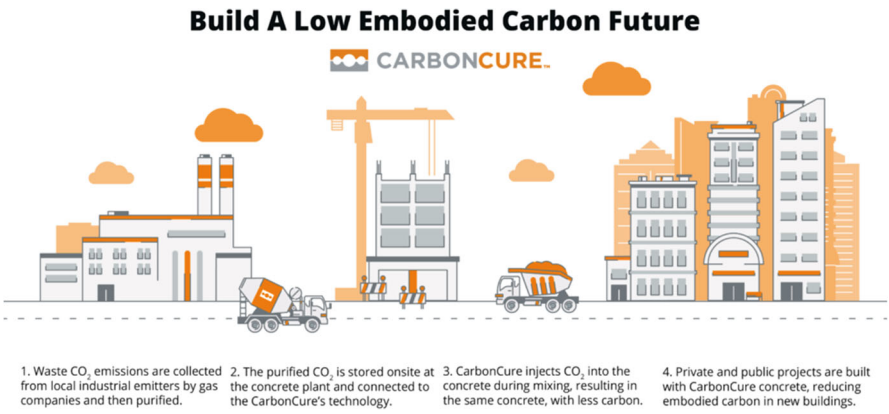

Fig. 1 The CarbonCure Ready Mix process. (Adopted from CarbonCure Technologies Inc, 2024)

Supplier: LafargeHolcim and Lehigh Hanson LafargeHolcim and Lehigh Hanson are the two main local suppliers of low carbon ready-mix concrete in across Canadian provinces. These mixes include supplementary cementitious materials (SCMs) and admixture ingredients. ECOPact by Lafarge offers a significant reduction in embodied carbon emissions (scope A1–A3) compared to standard ready-mix concrete without cement substitution [12]. ECOPact is available at various plants across six provinces in Canada, including British Columbia, Alberta, Manitoba, Saskatchewan, Ontario, and Quebec.

Low-carbon product range:

- ECOPact: 30–50% CO_2 reduction from a baseline mix with 0% SCMs, utilizing blended cement
- ECOPact Prime: 50–70% CO_2 reduction, engineered with higher blends and supplementary materials
- ECOPact Max: 70–90% CO_2 reduction; the lowest carbon range manufactured with a cement alternative technology like alkali activators

When comparing concrete alternatives, Lafarge ECOPact demonstrates an advantage over other conventional designs with a high SCM content, ensuring stability in various weather conditions and enabling year-round pouring without compromising performance. When regulatory conditions allow, ECOPact integrates upcycled construction and demolition materials, thus contributing to a circular design. The ECOPact Prime variant emphasizes specifying a 56-day strength for effective design and construction. The carbon reduction achieved with ECOPact depends on concrete strength, requiring early collaboration with concrete suppliers to determine optimal mixes for different structural elements due to potential performance implications.

Lehigh Hanson, on the other hand, has introduced low-carbon concrete mixes in their EvoBuild Bronze and EvoBuild Silver series. Both series come with verified environmental product declarations (EPDs) that support reductions in global

Table 1 Average material content for 1 metric ton (1000 kg) of the GU and GUL types are converted to percentages.

Material inputs	Type GU (%)	Type GUL (%)
Clinker	92	83
Limestone	3	12
Gypsum (including anhydrites)	5	5
Total	**100**	**100**

Adopted from CAC [14]

warming potential (GWP). The Bronze series generally achieves a reduction of 30–50%, whereas the Silver series attains a more substantial 50–70% reduction compared to the industry average mix. Leigh Hanson's EvoBuild places a priority on carbon optimization without compromising on mix performance, striving to minimize any design and construction implications [13]. It is worth noting that certain Silver mixes may have elevated supplementary cementitious material (SCM) content and necessitate a 56-day design strength, as indicated in the relevant EPDs.

Product Ingredient: General Use Limestone (GUL) Cement General use limestone (GUL) cement can be a viable alternative to general use (GU) Portland cement in various concrete structural constructions, providing approximately 10% reduction in GWP compared to GU cement. However, it is important to recognize that GUL cement is susceptible to "sulfate exposure," posing potential risks in specific elements like footings, piles, and slab-on-grade applications. Some concrete suppliers have developed specialized GUL cement formulations to address these risks, emphasizing the need for verification with the supplier before design specifications [14] (Table 1).

The positive synergy between GUL cement and SCMs has been the focal point of contemporary research studies. This interaction enhances concrete sustainability and reduces embodied carbon impact compared to standard GU cement. Utilizing GUL cement requires a nuanced approach, considering both its environmental benefits and potential challenges in specific structural applications. Further research and development could refine the understanding and application of GUL cement in sustainable construction practices.

Product Ingredient: Supplementary Cementitious Materials (SCMs) Supplementary cementitious materials (SCMs) are natural or industrial by-products that exhibit cementitious properties when mixed with water or other compounds. Examples include fly ash, slag cement, and silica fume from coal power stations of steel and silicon metal production. Natural SCMs, like calcined shale, calcined clay, and metakaolin, undergo controlled heating and purifying processes. These materials are sustainable, promoting recycling and reducing cement in concrete mixes, thereby lowering GWP. Hydraulic SCMs, like ground granulated blast furnace slag (GGBFS), react directly with water, whereas pozzolanic SCMs, such as fly ash and silica fume, chemically react with calcium hydroxide.

SCMs significantly influence the concrete properties affecting water requirements, workability, and setting time during the fresh stage as well as strength, permeability, and other characteristics once hardened. Their positive effects encompass reduced bleeding, enhanced strength, and lower permeability. However, their drawbacks include extended set time and potential construction cost implications. General recommendations include specifying performance criteria over SCM limits, utilizing maximum percentages under freeze–thaw conditions, and close collaboration with stakeholders for optimal low-carbon mix design, considering the potential impacts on construction schedules.

SCMs Availablity in Canada by Provinces SCMs have a long history in Canada. Fly ash and slag are extensively used, with the former being predominantly and widely adopted in most provinces. Currently, 60% of concrete manufacturers in Ontario incorporate GGBFS into cast-in-place concrete production. In the prairies and western Canada (e.g. Alberta), approximately 90% of concrete manufacturers integrate fly ash as cement replacement Fly ash, a coal combustion by-product, is classified based on its calcium oxide (CaO) content, with high-calcium fly ash acting as a sole cementing material, providing moderate strength, and mitigating heat of hydration. Silica fume, on the other hand, mainly serves for specific purposes, primarily used to enhance specific mix properties. Silica fume, derived from silicon metal manufacturing, enhances the durability of structures subjected to corrosion, abrasion, and chemical attacks. Natural pozzolans, like volcanic ashes, have limited applications in Canada.

Regulating Supply Market for SCMs in Canada The supply chain for SCMs, such as slag and fly ash, is not managed by the ready-mix industry, posing a potential risk to interested end users such as contractors and design team. For instance, slag, a by-product of steel manufacturing, is supplied by steel manufacturers in Ontario and sourced from the United States. Lafarge offers products like NewCem and NewCem Plus, blending slag and fly ash and allowing for high replacement rates. Several suppliers, including Carbon Upcycling Technologies, Lehigh Hanson, and Holcim, contribute to the SCM supply chain in different regions of Canada.

3.2 Carbon Reduction in Steel Products

Steel is produced using a blend of raw primary materials (ore) and recycled materials (scrap steel). The majority of the embodied carbon in fabricated structural steel, approximately 90%, occurs during the cradle-to-mill-gate stage. Opting for electric arc furnace (EAF) structural products, boasting up to 97% recycled content, can significantly reduce embodied carbon by up to half (50%) compared to basic oxygen furnace (BOF) steel, which relies on virgin iron. Table 2 presents characteristics of EAF and BOF (Table 2). The choice between EAF and BOF depends on factors such as scale, raw material availability, energy sources, and environmental considerations. Despite EAF's sustainability advantages, BOF remains crucial in the steel

Table 2 Comparison of electric arc furnace (EAF) and basic oxygen furnace (BOF)

Factors	Electric arc furnace (EAF)	Basic oxygen furnace (BOF)
Raw materials	Utilizes scrap steel as the primary raw material, making it more environmentally friendly by recycling existing steel	Relies on iron ore, which requires mining, and metallurgical coal, contributing to a higher carbon footprint
Energy consumption	Consumes less energy, particularly when powered by electricity from renewable sources	Requires significant energy input, mainly from burning fossil fuels during iron ore smelting
Carbon emissions and environmental impact	Tends to have lower carbon emissions, especially when powered by cleaner energy sources. Generally considered more environmentally sustainable due to its use of recycled materials and lower emissions	Emits more carbon dioxide due to the use of coal in the reduction of iron ore. Involves more environmental concerns, including deforestation for iron ore extraction and higher greenhouse gas emissions
Cost	Initially more expensive to set up but can be cost-effective in the long run, especially with the availability of affordable scrap	May have lower initial setup costs but is more susceptible to fluctuations in raw material prices, impacting long-term profitability
Technology and innovation	Allows for easier integration of advanced technologies, including enhanced process control and automation	Traditional technology with limitations on rapid integration of cutting-edge advancements
Flexibility in design	Offers flexibility in adjusting production levels and can quickly switch between different steel grades	Typically designed for continuous production of large batches, making it less flexible for smaller-scale operations

industry, balancing cost efficiency and production scale, as approximately 71% of global steel production relies on the BOF process [15–17]. Scrap metals originate from pre- and post-consumer steel, car scraps, household steel wastes, etc., from recycling centers (Table 2).

Manufacturer: Structural Steel Products Numerous manufacturers of structural steel, steel deck, and cold-formed steel have released EPDs tailored to their products, enabling the direct specification of maximum CO_2 for these elements. The ArcelorMittal XCarb™ initiative, for example, dedicated to achieving carbon-neutral steel, integrates reduced carbon products, steelmaking activities, and low-carbon innovations. XCarb™ structural steel, produced using EAF technology with 97% recycled content and powered by renewable energy, exhibits a 60% lower CO_2 than does conventional steel and a 73% reduction compared to the North American average. This initiative aligns with ArcelorMittal North America's commitment to a 25% CO_2 reduction by 2030, contributing to the broader goal of carbon neutrality by 2050. The use of "recycled and renewably" produced steel, powered by 100% renewable energy in the EAF process, results in an impressively low CO_2 footprint, potentially reaching 300 kg of CO_2 per ton of finished steel with 100% scrap metallics [14].

Product Ingredient: High-Recycled-Content Scrap-based steels offer lower embodied carbon than most virgin steel manufacturing [16, 18]. High-recycled-content steel from EAFs, with more recycled content than BOFs, can effectively reduce embodied carbon in construction projects. However, challenges in the supply chain may impact the desired reductions. It is recommended for design consulting team to engage early with steel manufacturers to identify feasible low-carbon options within project locations. The recycled content in structural steel varies based on factors like scrap availability, product type, chemical composition, and production route. Importing steel to regions without shape mills, such as the west coast of North America, may increase carbon impact.

ArcelorMittal manufactures rolled sections for the North American market in Luxembourg, Europe, using EAF with 51–98% recycled iron content [19]. Given that GHG emissions of overseas transportation are associated with steel manufacturing in Luxembourg, conducting a comprehensive embodied carbon study comparing ArcelorMittal's steel to North American EAF-produced steel is advisable. North American EAFs may have higher manufacturing emissions, especially when compared to potentially less environmentally friendly electrical grids. However, ArcelorMittal's EPD for structural steel from Luxembourg (GWP = 0.84 kg CO_2e/kg for A1–A3) demonstrates a 31% lower GWP than does North America's national average according to the American Institute of Steel Construction (AISC). In Canada, ArcelorMittal has four tubular facilities producing mechanical steel tubing and seamless/welded precision tubes with 30–60% recycled content. ArcelorMittal Contrecoeur (Quebec) is Canada's largest rebar manufacturer, using locally extracted iron from northern Quebec mines [20]. The flat mill in Hamilton, Ontario, employs a blast oxygen furnace. To minimize embodied carbon, rolled sections should be prioritized over hollow structural sections.

Promoting the Use of Locally Produced Steel Specifying domestic steel can mitigate embodied carbon in steel production and transportation, depending on project and source locations. Domestic hot-rolled sections are EAF-produced, whereas structural plate and coils forming high strength steel (HSS) may come from BOF or EAF furnaces. Imported structural products are more likely BOF-produced, but the global BOF to EAF ratio is 70:30. Not all EAF steel is equal; Canadian BOF-produced steel may have lower embodied carbon than foreign EAF steel, depending on the mill's input mix of scrap, direct reduced iron (DRI) or pig iron, and energy grid source. Checking producer-specific EPDs is recommended [21].

Examples of Canadian concrete rebar suppliers include AltaSteel in Edmonton, Alberta, using EAF technology with 100% scrap [22]. ArcelorMittal Montreal in Contrecoeur, Quebec, offers a wide range of long products, including concrete reinforcement bars, with a published EPD showing 1.29 kg CO_2e/kg GWP [23]. Due to complexities in the steel supply chain, reducing carbon emissions in steel involves minimizing tonnage, favoring high-strength steel for efficient designs, smaller foundations, and replacing complicated sections with rolled sections.

However, confirming the carbon emissions of higher-strength steel with the producer is advisable. The greatest challenge remains the lack of publicly available EPDs for steel products [21].

4 Conclusions

This research provides valuable insights into the challenges and opportunities associated with reducing embodied carbon in the construction industry, focusing on key materials such as concrete and steel. Here is a summary of the key points:

1. Structural concrete: There is evidence of low-carbon options for concrete, emphasizing the use of CarbonCure Ready Mix and Lafarge ECOPact. The findings highlight the potential for substantial carbon reduction through innovative technologies and replacing cement content with SCMs as an alternative mix design. Improving strength in concrete is considered a key priority for decarbonization, such as reducing the clinker-to-cement ratio, embracing renewable energy for production, and incorporating carbon capture technologies. Decarbonizing cement requires a shift to alternative binders, prefabrication of reusable circular units, and transitioning to electric kilns powered by a decarbonized electric grid [3].
2. Structural steel and steel reinforcement: In primary steel production, transitioning from blast furnace to direct reduced iron technology, utilizing electric arc furnaces powered by renewable energy, and integrating high recycled content in manufacturing product ingredients show potential for substantial reduction in carbon emissions.

Initiating a prompt and collaborative process during the design development stage is crucial to the overall decarbonization effort. This design iterative approach should be supported by both the "supply and demand sides of stakeholders" [1]. Exploring hybrid alternatives and adopting systemized manufacturing further optimizes construction techniques [24]. Emphasizing carbon reduction strategies from project inception creates an environment conducive to achieving systemic reductions, offering significant opportunities for substantial reductions throughout the life cycle of the project. This chapter emphasizes the importance of transitioning to sustainable practices in material production, construction techniques, and overall project planning. Overall, this study provides a foundation for developing innovative design concepts and guidelines to create low-carbon building materials' specifications, contributing to sustainability in the architecture, construction, and engineering (ACE) industry.

1 Introduction

Due to the increased concern for sustainability and climate change, environmental aspects have now become important in the planning, design, and construction of buildings and infrastructures. To answer and quantify the environmental impacts of construction projects, a method based on Life Cycle Assessment (LCA) of environmental data from raw material extraction, production, construction, operation and maintenance, and disposal, is frequently applied [1]. To meet the need to document environmental impacts for a product or service, standardized environmental declarations have been developed, the so-called Environmental Product Declaration (EPD), based on this LCA method.

Concrete is the world's most widely used building material and is dominant in infrastructure projects. On a worldwide basis, the production of cement and concrete accounts for about 5–8% of the total greenhouse gas emissions (i.e., CO_2 emissions), in which about 90% of the emissions come from the production of ordinary Portland

cement (OPC). However, by replacing some of the cement with supplementary cementitious materials (SCMs), like fly ash, silica fume, and slag, the emissions can be reduced. It is considered that the SCMs do not emit CO_2, since they are waste products from other materials production.

Important concrete infrastructures, like bridges, dams, harbors, etc., are designed with a working life (service life) of 100 years or more. In determining the service life of steel-reinforced concrete structures exposed to marine environments or de-icing salts, the ability of the concrete to resist the ingress of chloride ions is crucial. From long-term field studies of concrete exposed to the marine environment, it has been observed a more rapid reduction in the ionic diffusivity through concrete with time for concretes containing fly ash or slag [2–4] compared to plain OPC concrete. This reduced diffusion rate is beneficial in delaying the onset of chloride-induced corrosion, and thus enhancing the service life of the structures. The chloride ingress in concrete may be modelled through Fick's second law of diffusion. In this model, a reduction of diffusion rate with time is included in a parameter describing the observed time dependency of the diffusion coefficient.

This paper deals with the application of low-carbon concretes in concrete infrastructures exposed to chloride-induced corrosion. The main objective is to highlight the importance of including durability (or service life) properties of relevant low-carbon concretes in the assessment of greenhouse gas emissions from concrete infrastructures. Section 2 presents calculations of CO2 emissions from road culvert solutions limited to the production and construction process stage. In Sect. 3, Fick's second law of diffusion is applied to study the effect of various concrete binders on chloride ingress and the service life of concrete structures exposed to the marine environment.

2 Greenhouse Gas Emissions from Road Culvert Solutions

2.1 Background

Assessments of greenhouse gas emissions have been carried out for two alternative road culvert solutions, a concrete box culvert and a steel pipe culvert, respectively. The culvert is a part of a road construction project in Norway and allows pedestrians and light traffic to pass under the roadway. As a part of road infrastructure, the culvert was designed for a service of 100 years.

The concrete box culvert was a cast-in-place construction, whereas the steel pipe culvert was made of corrugated steel elements transported to the construction site. The mass quantities for materials were based on the proposed design of the two culvert solutions.

The calculations of greenhouse gas emissions (Global Warming Potentials) were performed for the production stage, phases A1-A3, and the transport of the products to the construction site, phase A4, as defined in [1]. The Global Warming Potential (GWP) is given as amount of kg CO_2 equivalents (kg CO_2-eq). The calculations of

GWP related to the transport of the products to the construction site are based on generic GWP data from known databases in the software package One Click LCA [5].

2.2 Data for GWP Calculations

Concrete culvert solution A concrete strength class C45 (characteristic compressive strength of 45 MPa at 28 days) was required for the concrete culvert solution. No further measures were set for corrosion protection beyond the requirements given for concrete cover to the reinforcement for achieving a service life of 100 years.

The concrete volume of the box culvert was estimated to be 524 m^3, which included the needed transition plate for the overlying road. The amount of steel reinforcement was set to 180 kg/m^3 of concrete. Two types of low-emission concretes (low-carbon concretes) were included in the study, a low-carbon concrete B with a GWP of 270 kg CO_2-eq/m^3 and a low-carbon concrete A with a GWP of 220 kg CO_2-eq/m^3, given in accordance with the Norwegian Concrete Association Publication No 37 [6]. This publication defines low-carbon concrete as structural concrete produced in accordance with the rules in NS-EN 206 [7] where measures have been taken to limit greenhouse gas emissions. The GWP from the reinforcement was based on an EPD for a relevant steel reinforcement product for concrete.

In the calculations of GWP from the transport of materials to the construction site, phase A4, the transport distance was set to 10 km for the ready-mixed concrete and 30 km for the reinforcement.

Steel culvert solution To achieve a design service life of 100 years of the steel culvert, double-sided hot-dip galvanizing and epoxy painting on the outer parts were used. The mass of the corrugated steel elements is estimated to be 33.5 tons. The GWP for the production stage (phases A1-A3) was based on a product-specific EPD for galvanized corrugated steel plates.

The steel culvert elements were produced in Poland and transported to the construction site; a distance estimated to about 1300 km.

2.3 Results and Discussion

The results from the calculated greenhouse gas emissions are presented in Fig. 1 for both culvert solutions. The total GWPs (phases A1-A4) from the concrete culvert solution with low-carbon concrete B is estimated to be 176 tons CO_2-eq. Using low-carbon concrete A, the total CO_2 emissions are reduced to 149 tons. The total GWP from the steel culvert solution is only 76.5 tons.

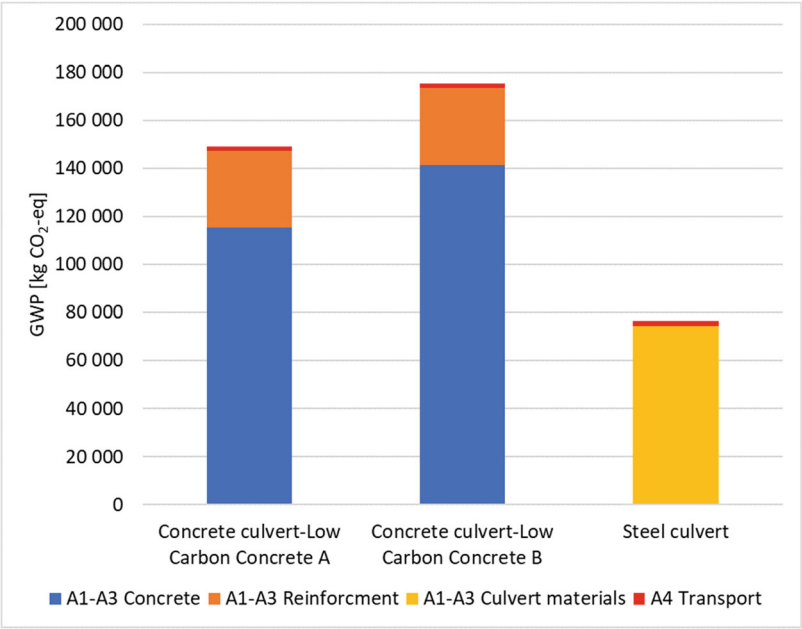

Fig. 1 Calculated Global Warming Potential (GWP) for the concrete and the steel culvert solutions. Results are presented for the construction stage (A1-A3), and transport (A4)

As can be seen, the production stage (A1-A3) is dominating in terms of CO_2 emissions, and the emissions from the transport of the products to the construction site are only 1–3% of the total GWP for the various solutions. The steel culvert has by far the lowest carbon footprint with the emissions of about 50% of the emissions from the low-carbon A culvert. To further reduce the emissions from the culvert with low-carbon concrete A, the quantity of concrete must be reduced by optimization of the structural design.

For the construction project in question, the steel culvert solution was chosen and built as shown in Fig. 2.

3 Impact of Concrete Binders on Chloride Ingress and Service Life

3.1 General

In the construction case presented in Sect. 2, only the greenhouse gas emissions (GWP) related to product and construction process stages (A1-A4) were included in the Life Cycle Assessment (LCA) of the culvert solutions. As the specified design service life is assumed obtained through the provisions given in the codes and

Fig. 2 Steel culvert chosen for a Norwegian road project. (Photo G. Markeset)

standards for the design of concrete structures and the associated materials standards, the GWP linked to the use stage (phases B1-B7) of the LCA is rarely included. However, the provisions for durability and service life within codes and standards are typically based on experiences from old and outdated concrete qualities and types where the focus has been more on strength than on greenhouse gas emissions. In the LCA of concrete infrastructure, the emission related to service life is an important factor, especially for new low-emission concretes with different types and amounts of SCMs.

In the design of concrete structures exposed to chloride-induced corrosion, the end of service life is often defined at the time when the chloride concentration at the surface of the reinforcement has exceeded a critical level resulting in depassivation and corrosion initiation. The critical chloride concentration, or chloride threshold level (C_{crit}) for corrosion initiations, becomes thus a key parameter in the prediction of the design service life. During the "corrosion-free service life" there should be no need for repairs and durability-enhancing measures.

3.2 Modelling of Chloride Ingress in Concrete

The chloride ingress in concrete can be modelled by Fick's second law of diffusion:

$$C(x,t) = C_i + (C_0 - C_i)\ \text{erfc}\left(\frac{x}{2\sqrt{D_a(t)\cdot t}}\right) \tag{1}$$

where $C(x, t)$ = chloride concentration at depth x at time t, C_0 = chloride concentration at the exposed concrete surface, C_i = initial chloride content in the concrete, erfc = error function complement, and $D_a(t)$ = apparent (average) chloride diffusion coefficient at time t.

In Eq. (1) the chloride concentration at the concrete surface C_0 is assumed constant. Values of apparent diffusion coefficient $D_a(t)$ represent an integrated value over the period of exposure. The diffusivity decreases with time caused by the long-term evolution of the micro-structure of the concrete and pore blocking of the exposed concrete surface layer. A commonly used empirical expression for the time-dependent diffusion coefficient in Fick's second law is:

$$D_a(t) = D_0 \left(\frac{t_0}{t}\right)^{\alpha} \tag{2}$$

where D_0 = apparent chloride diffusion coefficient at the age t_0, and α = ageing exponent.

Several investigations have been conducted worldwide to stipulate the aging exponent α, and many different values have been found in the literature. Most of the values are based on data from marine concrete structures with different concrete compositions and under varying exposure conditions. However, similar systematic investigations for de-icing salt exposure are lacking.

A systematic long-term field investigation suitable for determine reliable data for this aging effect for relevant concrete recipes, with and without SCMs, is presented in [3, 8]. These studies included concrete recipes with CEM I and fly ash contents varying from zero to 35% by weight of cement, and one series of ternary blend concrete with 4% silica fume (SF) and 20% fly ash (FA). The water binder ratio was in the order of 0.40–0.45 for all the concretes. The concrete samples were exposed to seawater in the tidal zone over a period of 9 years, and chloride profiles were measured at different time intervals. Table 1 presents the parameter values for D_0 at 28 days, α and C_0, determined for the concretes with CEM I, 20% FA (FA20), 20% FA and 4% SF (FA20SF4), and 35% FA (FA30), respectively.

Referring to Table 1, the aging exponent α varies from 0.19 for plain CEM I concrete to 0.52 for the FA35 concrete. However, the FA35 concrete has the highest

Table 1 Parameters (means values) determined on concrete samples exposed to seawater in the tidal zone/8/

Type of binder	Aging exponent α	Calculated apparent diffusion coefficient D_0 at 28 days [m^2/s]	Surface chloride concentration C_0 [% of concrete weight]
CEM I	0.19	$7.9\ 10^{-12}$	0.61
CEM I with 20% FA (FA20)	0.40	$8.7\ 10^{-12}$	0.95
CEM I with 20% FA and 4% SF (FA20SF4)	0.46	$4.1\ 10^{-12}$	0.87
CEM I with 35% FA (FA35)	0.52	$9.7\ 10^{-12}$	0.85

apparent diffusion coefficient at 28 days. The chloride content at the concrete surface obtained after 9 years of exposure was lower for the CEM I concrete compared to the concretes with SCMs.

3.3 *Chloride Ingress and Service Life for Concretes with Different Binders*

Fick's second law (see Eqs. (1) and (2)) is applied to simulate the chloride ingress in the four concretes based on the parameters given in Table 1. Figure 3 shows the calculated chloride profiles, i.e. the relation between chloride concentration and penetration depth, for the different concretes after 50 years of exposure. Comparing the CEM I concrete and the concretes with 20% and 35% FA, respectively, the reduction in diffusivity through concrete with time, modelled through the aging parameter, has a clear effect on the chloride ingress after 50 years of exposure. However, by including 4% silica fume a much lower early-age diffusion coefficient was achieved compared to the FA concretes as illustrated by the FA20SF4 concrete in Table 1, and thus a lower chloride penetration over time. Furthermore, despite the lower chloride concentration at the concrete surface of the CEM I concrete, the chlorides have penetrated much deeper into the concrete compared to the concretes containing SCMs.

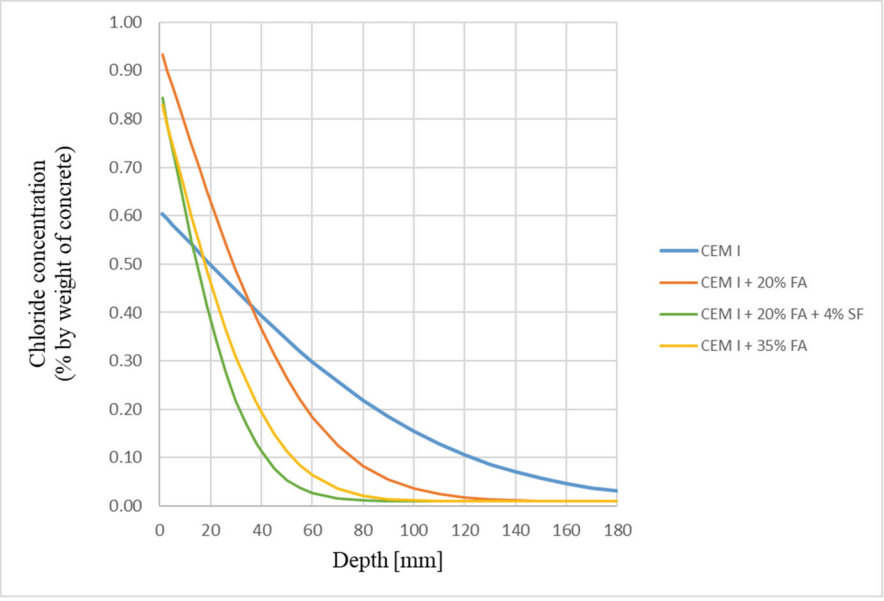

Fig. 3 Predicted chloride ingress profiles for the different concretes after 50 years of exposure

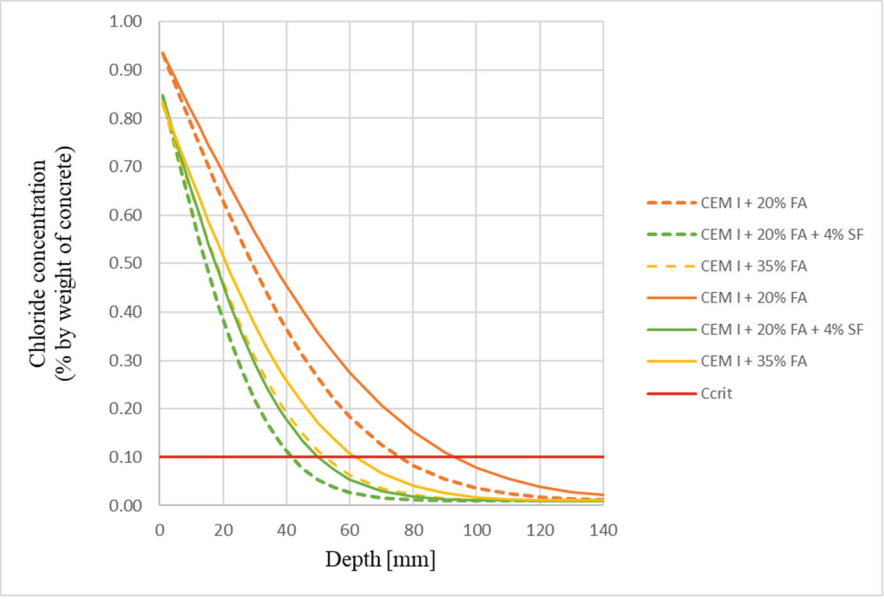

Fig. 4 Chloride profiles predicted for SCM concretes after 50 years (dotted lines) and 100 years (solid lines) of exposure. The horizontal red line is assumed $C_{crit} = 0.1$

Plain OPC concrete is not a suitable concrete for reinforced concrete structures exposed to chloride-induced corrosion (exposure classes XS2, XS3, XD2, XD3), both due to high CO_2 emissions (high cement content) and low chloride resistance (short service life). This is accounted for in NS-EN-1992 National Annex [9] through the requirement that the concrete binder must contain a minimum of 6% silica fume or a minimum of 14% in total of fly ash, silica fume, and slag.

Calculation of the achieved service life for different concrete compositions may be estimated by a probabilistic service life procedure, as presented in e.g [13, 16]. In this paper, a deterministic approach has been chosen to study the effect of different concrete binders on achieved service life. In Fig. 4 the chloride profiles predicted after 50 and 100 years of exposure are presented for the SCM concretes FA20, FA35, and FA20SF4, respectively. As can be observed, the chloride ingress profile of the FA35 concrete after 50 years of exposure coincides with the chloride profile of the FA20SF4 concrete after 100 years, and further, the concrete with only 20% FA will achieve the shortest service life of the studied concretes. The critical chloride concentration C_{crit} needed to initiate corrosion on the surface of the reinforcement is not known for the different SCM concretes. The normal value considered in numerous standards is a C_{crit} of 0.4% by weight of cement (or about 0.07% by weight of concrete). However, there is a huge scatter in reported values of C_{crit} [10–12]. Based on experience from probabilistic service life calculations a reasonable deterministic value of *C*crit would be 0.1 by % of concrete weight. Using this C_{crit}-value, the needed concrete cover to the reinforcement for achieving a "corrosion-free" service

life of 100 years varied from about 50 mm for the FA20SF4 concrete to 95 mm for the FA20 concrete.

As illustrated in Fig. 4, the required cover thickness for the FA20 concrete is about twice the cover needed for the FA20SF4 concrete, which also results in higher CO_2 emissions. Moreover, the service life of a reinforced concrete structure can be twice as long by using FA20SF4 concrete instead of FA35 concrete. If the use stage in the life cycle assessment is neglected, the FA35 concrete will emit less CO_2 than the FA20SF4 concrete. In structural design, the compressive strength of the concrete is an important parameter. For the SCM concretes, the compressive strength at 28 days will be lowest for the FA35 concrete due to high FA content, and highest for the FA20SF4 caused by the addition of 4% SF.

The parameters D_0, $C_{0,}$ and α applied in the simulations (see Table 1) are based on mean values, i.e. the uncertainties in the model parameters are not included. Further, the predicted service lives are very sensitive to the model parameters α and C_{crit} [3, 13]. The C_{crit} for the different concretes is not known and may depend on the type and amount of SCMs as a reduction of pH in the concrete may reduce the C_{crit}. Further, the apparent diffusion coefficient $D_a(t)$ decreases with exposure time and is found to reach an asymptotic value after 10–20 years of exposure depending on exposure condition and type of binders [2, 3, 8, 14, 15].

4 Discussion and Conclusions

To reduce CO_2 emission from concrete structures, different strategies can be used, e.g. by substituting Portland cement with supplementary cementitious materials (SCMs) and by optimizing the design to reduce concrete volume. In some cases, the optimal low-emission solution may be to apply other materials and structural solutions, as discussed in Sect. 2. Based on the calculations of greenhouse gas emissions (GWPs) from the two culvert solutions, the main source of the emissions comes from the production of the products (ready-mixed concrete, reinforcement, and steel elements). Despite using a low-carbon concrete with a low GWP emission (220 kg CO_2-eq/m^3) in the concrete culvert solution, the amount of concrete was far too high to compete with the carbon footprint of the steel culvert solution.

In the development of different low-emission concretes, the focus has mainly been on the reduction of carbon footprint by using SCMs. However, the resistance against chloride ingress may vary considerably among the different types of SCM concretes, as discussed in Sect. 3. Using Fick's second law of diffusion, the calculated service life for a reinforced concrete structure exposed to seawater in the tidal was found to be twice as long by using concrete with 20% fly ash and 4% silica fume than by using concrete with 35% fly ash. The parameter values used in the calculations are determined from concrete samples exposed to the marine environment in Norwegian coastal areas. For other marine environments or de-icing salt exposures relevant parameter values should be found by performing systematic long-term field studies.

The chloride ingress calculations, and thus the predicted service lives, are very sensitive to the model parameters α (aging exponent) and C_{crit} (critical chloride concentration). The C_{crit} may depend on the type and amount of SCMs, and thus, further investigations are recommended. Care should also be taken by using α-values obtained from short-term exposure tests to extrapolate the chloride ingress to 100 years of exposure and more, as too high α-value will overestimate the service life.

For concrete infrastructures like bridges, the safety and service life requirements may limit the application of very low-emission concretes due to low early strength and reduced durability performance. The study presented in Sect. 3 demonstrates the importance of including durability-related parameters (diffusion rate, service life, cover thickness, etc.) in the assessment of CO_2 emissions from reinforced concrete infrastructures. The GWP from concrete is typically given per volume unit. However, a more appropriate unit should be to include service life and strength parameters in the GWP calculations, and instead present the CO_2 emissions as GWP of the required concrete volume per unit of compressive strength and service life (or other durability-related parameters).

1 Introduction

South Africa is facing a waste issue in the form of limited landfill airspace availability, with major metropolitan areas like the cities of Cape Town and Johannesburg expected to reach landfill capacity by the next decade. The diversion of construction and demolition waste (CDW) from these landfill sites has high potential not only in terms of slowing the rate that landfills will reach capacity, but also in terms of potential economic gains both in the formal and informal economic sectors [1].

CDW is one of the largest contributors to waste in South Africa by mass and volume. Through the National Waste Information Baseline Report, the South African Department of Environmental Affairs (DEA) [2] reported that 4.7 million tonnes of CDW were produced annually in South Africa as of 2011. This was estimated to be 20% of total general waste produced by mass and, of this value, 16%

was reported to be recovered for reuse or recycling. Annual CDW production as of 2017 was reported by the DEA [1] in the State of Waste Report to have decreased to 4.5 million tonnes. If these values are both taken to be true, the higher rate of CDW production in 2011 may be related to infrastructure development encouraged by the FIFA World Cup which took place in South Africa in 2010. Nineteen per cent of the 4.5 million tonnes of CDW was reported as being recovered for reuse, recycling, or use as backfill material [1]. These values, however, may be an underestimation of CDW production. Values extrapolated using national gross domestic product (GDP), GDP contribution of the Western Cape province, and waste generation statistics from the Western Cape range between 8.7 and 10.8 million tonnes in 2017 [3, 4]. Discrepancies in these values may be due to inaccurate reporting in the formal waste management sector as well as the omission of informal waste management and illegal dumping practices in both the National Waste Information Baseline Report and the State of Waste Report.

While the overall proportion of CDW relative to total waste generated in the Western Cape is consistent with the national value of approximately 20%, between 30% and 40% of the 1.7 million tonnes of CDW produced in the province in 2017 is estimated to have been diverted from landfills to be reused or recycled [4]. The percentage of waste diverted increased to between 61% and 69% in the years 2018 to 2021 [5]. Over the period from 2018 to 2021, between 22% and 29% of total waste in the Western Cape was diverted from landfill. Forty-four per cent of this waste, totalling 1.3 million tonnes, was comprised of CDW [5].

The discrepancy between the recovery rates for CDW observed nationally and in the Western Cape suggests that recovery rates and waste management practices in other provinces are far below that of the Western Cape. This paper presents a review of various factors linked to the existence and enforcement of legislation at a national, provincial, and municipal level with a view to evaluate why the Western Cape is showing better performance and how other provinces can improve performance.

2 Role of Government in Waste Management

Based on the constitutional right of all South Africans to an environment that is not harmful to health and well-being and to have the environment protected, the DEA of the South African national government has developed the National Environmental Waste Act which is supported by the National Waste Management Strategy. Key principles governing this strategy include a waste hierarchy prioritising reduction, reuse, and recycling of waste materials over disposal, and extended producer responsibility where producers of waste are responsible for planning and financing waste management [6]. This, in turn, is linked to financial incentives and penalties throughout the product lifecycle as illustrated in Fig. 1. Incentives include subsidies linked to product recycling and reuse [7]. Penalties include [7]:

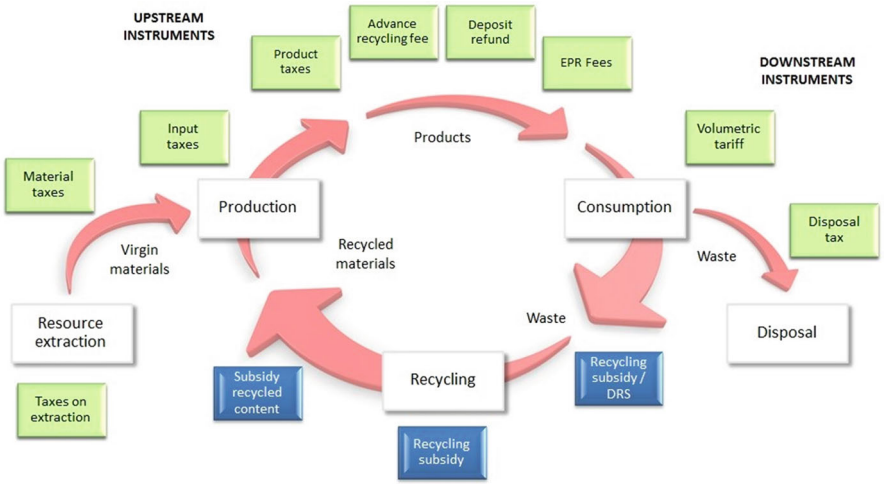

Fig. 1 Financial incentives throughout the lifecycle of a product, according to the South African Department of Environmental Affairs [7]

- Taxes on extraction and materials to minimise resource extraction and encourage either a reduction of materials needed or the use of secondary resources instead of virgin material resources.
- Integrated fees paid upon purchase to cover recycling at the end of the product lifecycle in the form of advanced recycling fees.
- A deposit refund system where the customer gets a rebate when the product is returned, recycled, or disposed of in an environmentally friendly way.
- Extended producer responsibility (EPR) fees where producers pay fees corresponding to the quantity of product being consumed to cover downstream waste management costs.
- A volumetric tariff corresponding to consumption with the goal of reducing consumption.
- A disposal tax to discourage waste disposal to landfill.

The National Waste Management Act mandates that all provinces develop, submit, and implement waste management plans in line with their development goals and waste management needs. Information to be included is the types and quantities of waste, strategies on how waste will be minimised, plans promoting reuse and recycling of waste, and potential methods of disposal that are environmentally friendly and less reliant on landfill usage [6]. Based on the relevant provincial waste management plan, municipalities must then develop, submit, and implement waste management plans and pass by-laws on waste removal, storage, and disposal services. Municipal governments are then responsible for the compliance to and enforcement of the by-laws.

3 Waste Management at the Local Level

Because municipal governments, guided by the relevant waste management plans and by-laws, are responsible for monitoring waste management of local industries and businesses on behalf of the provincial and national governments, the waste management plans and by-laws of municipal governments were compared to evaluate if this was causing the discrepancy in CDW recovery rates observed.

South Africa has a total of 257 municipalities, 8 of which are metropolitan municipalities. Metropolitan municipalities represent 80.4% of public sector revenue and are the centre of rapid and consistent infrastructure development [1]. Consequently, this is where a majority of CDW is generated. Furthermore, the positive link between population size, income, GDP, and waste generation can be leveraged. Therefore, only the four most populous metropolitan municipalities, namely, the City of Cape Town Metropolitan Municipality in the Western Cape, the City of Johannesburg Metropolitan Municipality in Gauteng, eThekwini Metropolitan Municipality in Kwa-Zulu Natal, and Ekurhuleni Metropolitan Municipality in Gauteng, were chosen. Provinces and metropolitan municipalities are shown in Fig. 2.

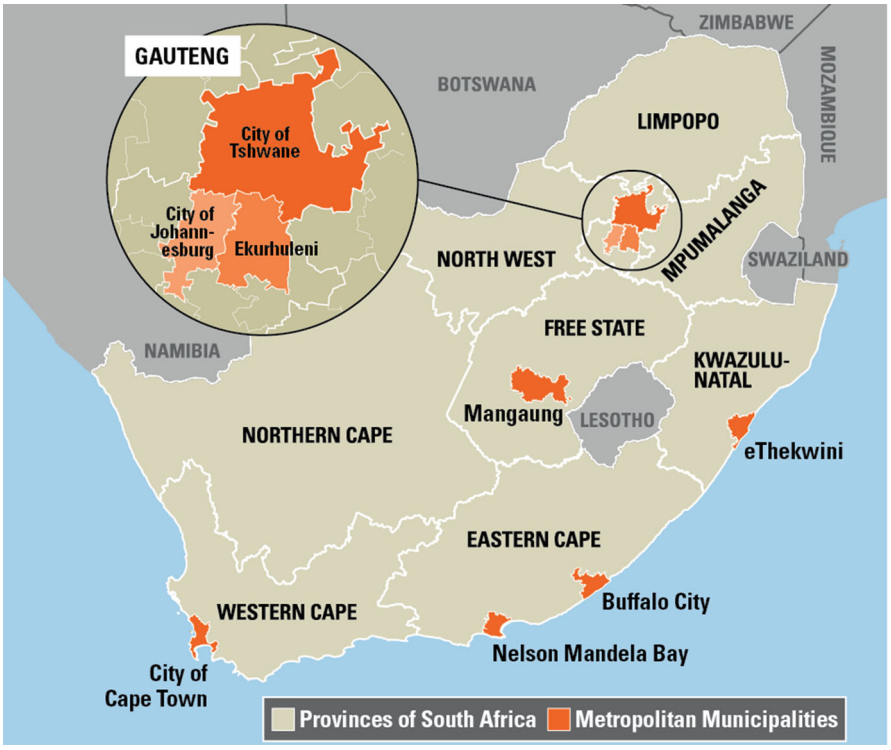

Fig. 2 Map of South Africa showing provinces and metropolitan municipalities [8]

Waste management plans are included in the national waste management strategy as a tool to assist provinces and municipalities in planning their goals with respect to waste management as well as how these goals will be achieved and monitored. However, fewer than 50% of municipalities and provinces have waste management plans in place [7].

Of the four municipalities considered, only eThekwini Metropolitan Municipality is located in a province that does not have a provincial waste management plan. All four have municipal waste management plans and associated by-laws. Although the waste management plans refer to the specific context and development goals of each municipality, all four sets of by-laws require those generating CDW, termed building waste, to develop a project-specific waste management plan which is to be submitted and approved by the local waste management officer before any waste can be generated [9–12]. In addition to the requirements of a waste management plan detailed in Sect. 2, these must include [9–12]:

- an impact assessment of the proposed works on the local environment,
- a projection of resources that will be consumed and may result in waste,
- a list of the services that will be used to store, collect, transport, and dispose of waste generated, with confirmation if an external contractor is being used,
- a plan on how recyclable and non-recyclable waste sources will be defined and separated, and,
- targets for minimisation of resources consumed, minimisation of waste produced, and optimisation of opportunities to reuse, recycle, and recover waste.

The fact that the by-laws governing the behaviour of those who produce and manage CDW in these three municipalities are the same, suggests that the differences in statistics reporting waste management behaviour are due to the enforcement and penalties related to these by-laws rather than the by-laws themselves.

In addition to the completion and submission of a waste management plan, those who generate building waste in the City of Cape Town municipality must complete a standardised form. The form asks for all information included in the waste management plan and also includes information about the site, the name and contact details of the owner, the scope and origin of the building work (partial demolition, full demolition, new building, and alterations to existing building). This allows the application process to be streamlined.

The city of Cape Town has also provided additional centralised CDW recycling facilities that can be used as an alternative to traditional landfills which are located outside of the city borders. The use of these facilities reduces the transport costs associated with dumping CDW and there is no associated dumping fee when sending materials to a recycling facility. In contrast, from 2019, Cape Town landfills have started to charge R20 (approx. €1) per tonne of uncontaminated mineral waste from CDW (including concrete, mortar, masonry components, sand, and stone) [4]. Prior to this, all CDW was accepted for free on the basis that it would be used as cover material in landfill. As shown in Fig. 3, the total volume of mineral CDW received was reduced from approximately 1.24 million tonnes in 2016/17 to 0.41 million tonnes in 2018/19 [4]. The resulting proportion of unused mineral CDW has,

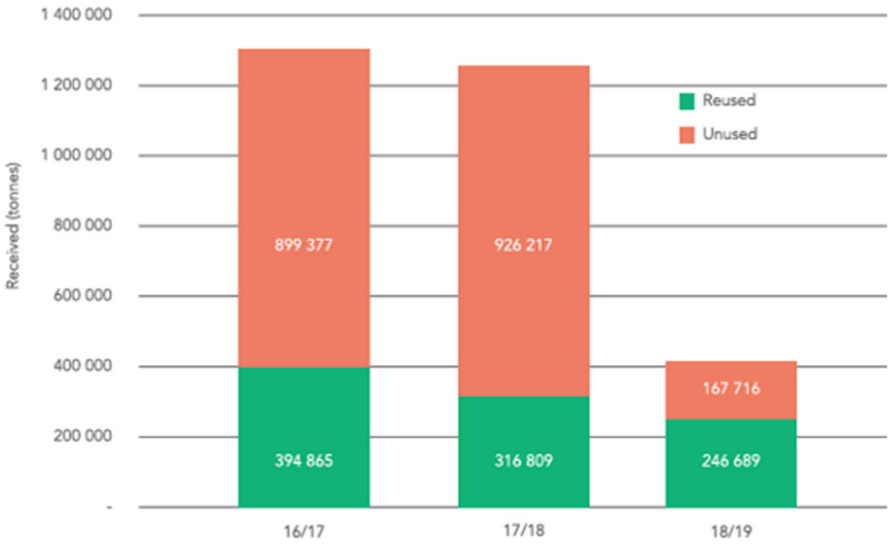

Fig. 3 Mineral fraction of CDW received at landfill sites in the City of Cape Town Municipality from 2016–2017 to 2018–2019 [4]

therefore, been reduced as has excess CDW in landfill not needed as cover material. This demonstrates that in this case the financial penalties detailed in Fig. 1 act in support of the legislation when it comes to changing consumer behaviour.

The mineral waste that is received at landfills and recycling facilities are sorted, cleaned, and processed to be used as bricks and blocks where discrete units can be separated out or as crushed recycled aggregate. The latter is then used as backfill material, landscaping material, aggregate in the sub-base and base of road construction, or aggregates in the production of concrete bricks and blocks and other concrete products in precast yards. Several government-funded projects and private enterprises, both formal and informal, exist in the vicinities of where this waste is being sent and are using it for resale value (e.g. scrap metal and intact clay bricks) or as input materials in the production of new products (e.g. the production of bricks and blocks using recycled aggregate). The presence of these enterprises not only promotes local economic growth and development, but also provides a use for the material that may have been otherwise treated as waste.

The other three municipalities all classify all CDW as zero-rated waste based on the premise that it can be used as landfill cover. The waste management plans and by-laws of all four of the municipalities encourage the recovery of waste material, but don't prohibit sending CDW to landfill. So long as the waste management plan is approved by local government, CDW produced can be dumped. If there is no additional factor encouraging the producers of waste to use alternative disposal methods, taking CDW to landfill may be chosen as the most cost and time efficient

option. As in Cape Town before 2019, when tariffs on disposal were introduced, the existence of legislation alone without the support of financial penalties and incentives may not be sufficient to encourage a change in consumer behaviour.

4 Recommendations

While there is a robust legislative framework to guide waste management in South Africa, there is a lack of enforcement of legislation and the relevant by-laws, support to encourage compliance, and consequences where there is non-compliance [13]. Furthermore, a lack of oversight and support from local government to those producing waste may limit the prioritisation of reducing, reusing, and recycling waste materials over disposal. Where guidelines are not promoted or enforced and cost-effective and efficient alternatives to disposal not provided, disposal will continue to be the default. As mentioned above, the city of Cape Town Municipality has streamlined the administrative tasks associated with CDW management and provided funds to enterprises using CDW to resell or produce new products. This has encouraged those producing waste to participate in the waste management system and provides an alternative to disposal for waste produced.

An additional use for this waste materials may be found through improved coordination of different government sectors. As outlined in the 2023 Market Study of the Circular (& Waste) Economy of South Africa [14] report commissioned by the Dutch government to identify potential economic opportunities in the South African waste management sector, CDW produced from government infrastructure can be used in new public infrastructure projects such as low-cost housing and roads.

However, due to a lack of funds and underperformance in service delivery, local government may require private sector participation to further increase waste recovery and improve waste management efficiency. This may take the form of public-private partnerships where, in a collaboration between parties from the private sector and government, an institution from the private sector performs a service usually performed by government or uses government-owned assets to perform a service [13]. In such partnerships, the private institution assumes most of the operational, technical, and financial risk. It is believed that through this model, the chances of corruption are reduced, the public has access to better and more economical services, and the provision of business opportunities stimulates the economy. Examples of public-private partnerships in the South African waste sector as shown in the city of Cape Town may include facilities to collect, characterise, process, and stockpile CDW for recycling or facilities using products from CDW for resale or to produce new products. Businesses created may be able to channel any profits generated into improved mechanisation of operations as well as training of employees.

It is estimated that 60,000 jobs were created in the South African waste sector as of 2016 [13]. These jobs are often directed towards unskilled, informal labour and are beneficial in the South African context where there is a large unemployed population with a lack of vocational training. Jobs take the form of waste picking, recovery, and recycling [13]. Informal waste pickers are estimated to have saved South African municipalities between R309 and R749 million (approx. between €15.5 and €37.5 million) [15]. They currently operate at little to no cost to municipalities. Training these workers and equipping them with skills to manage the waste value chain may result in improved space maximisation and management in landfills and waste management sites, ensure environmental compliance, and allow waste streams to be more closely monitored. This may require improved integration of the formal and informal waste management sectors. Integration may include increased regulation and monitoring in the form of registration and personal protective equipment requirements, increased support in assisting waste stream separation through mechanisation or provision of buy-back facilities, the establishment of businesses to employ these workers and pay them a regular wage, or in the full absorption of the informal sector by the formal sector [15]. Implementation of any of these measures would require consideration of the context and needs of the local population.

5 Conclusion

The efficient and appropriate management of CDW is key in overcoming the issue of South African landfill scarcity and environmental protection from waste. Findings suggest that robust legislation alone may not be sufficient in encouraging consumers to minimise the waste produced, optimise recovery, reuse and recycling opportunities, and avoid material disposal. As is shown in the case of the City of Cape Town Metropolitan Municipality, changes to waste producer and material consumer behaviour may have to be encouraged by improving the ease with which environmentally friendly behaviours like recycling waste or using this waste as a secondary resource can be enacted as well as implementing financial penalties and incentives which may negatively or positively impact potential profits.

1 Introduction

As the environmental impact of modern society grows, the construction industry is actively seeking environmentally friendly materials to reshape construction methods, maintenance processes, and waste management [1–3]. Recycling emerges as a fundamental strategy, particularly in utilizing industrial wastes, providing a promising avenue for sustainable construction practices [4, 5]. Moreover, the overconsumption of natural resources is another factor the construction sector needs to address. With the building industry responsible for approximately 30% of total natural resource depletion [6], the recycling of end-of-service materials such as

wood and rubber could play a critical role in reducing the carbon footprint of the construction sector.

Bio-sourced products emerge as an alternative in construction, offering a versatile and sustainable array of benefits. Not only do these products regulate sound and heat effectively, creating a conducive indoor environment, but they also play a crucial role in carbon sequestration, contributing to environmental sustainability. Furthermore, wood-based materials exhibit excellent energy-dissipating properties, enhancing safety and resilience in various applications. Moreover, their lightweight nature and adaptability for modular construction provide flexibility and efficiency in building processes [7–9].

Within a similar framework, exploring alternative uses for end-of-service material, such as scrap tires, can produce innovative solutions for sustainable construction practices. Scrap tires, designated as hazardous waste, create havens for pests like rats, snakes, and mosquitoes and pose a significant fire risk, potentially releasing harmful substances such as carbon dioxide and dioxins into the environment. In response to these environmental challenges, recycling scrap tires into masonry units emerges as an environmentally friendly solution, offering a dual advantage. By repurposing this waste material, it is possible to simultaneously eliminate shelters for pests and reduce the risk of fires that could result in the release of hazardous substances. Furthermore, integrating recycled tires into masonry units enhances their physical and mechanical properties. Rubberized concrete, a byproduct of recycled tires, exhibits a lower density and higher energy absorption capacity compared to traditional concrete, making it a valuable construction material. In addition to these structural benefits, rubberized concrete also offers advantages in acoustic and thermal properties, exhibiting a higher noise reduction coefficient and lower heat transfer properties [10–13].

By using this by-product material with sustainable alternatives, such as geopolymer, the overall sustainability of these materials can be further improved. Such a combination facilitates rapid strength development and enhances durability while providing increased protection against fire and weathering. This study focused on the innovative reuse of end-of-service wood and crumb rubber to develop environmentally friendly materials that can be used in the production of masonry units. As such, the viability of producing wood geopolymer composites (WGC) with the required workability and strength was explored. The study also explored the integration of crumb rubber to create wood–rubber–geopolymer composites (WRGC).
